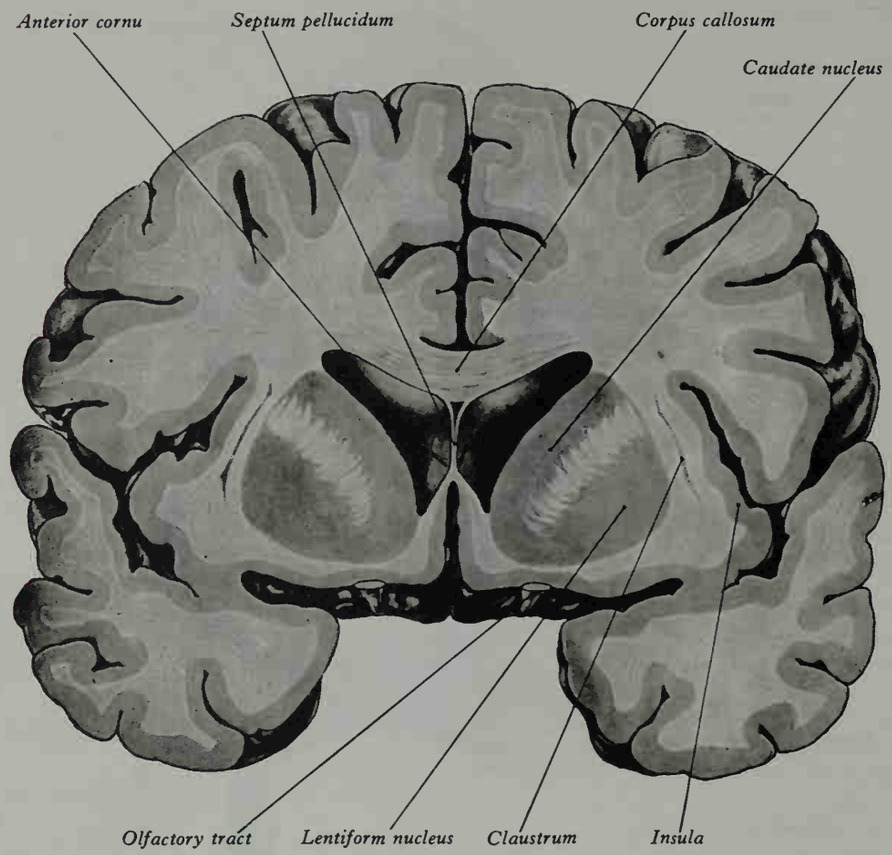
7.153 The central area of the ventral part of the oblique coronal section of the brain shown in 7.95, photographed at higher magnification to show some structural features in greater detail; compare with 7.98, 156 for appropriate labelling. Note in particular: (1) the anterior, medial and lateral parts of the dorsal thalamus, separated by the internal medullary laminae; (2) the relation of the caudate nucleus to the anterior and inferior cornua of the lateral ventricle; (3) the lentiform nucleus, divided into an external putamen and an internal globus pallidus; the latter again divided into internal and external parts; (4) the internal capsule, external capsule, claustrum, extreme capsule and insular cortex; (5) the sectioned profiles of the subthalamic and red nuclei, and the substantia nigra; (6) the hippocampus projecting into the floor of the inferior cornu of the lateral ventricle. Other structural features on this section are discussed at many points throughout the text. Compare also with 7.152. (Dissection by Dr. E. L. Rees, Dept. of Anatomy, Guy's Hospital Medical School.)

Where the two layers of pia mater described above are fused they constitute the *tela choroidea of the third ventricle*, as usually defined, although the choroid plexuses of the lateral ventricles are in fact extensions of it. Viewed from above it is a triangular fold, with a rounded apex at the level of the interventricular foramina, often indented by the anterior column of the fornix (7.159). Its lateral edges are irregular, due to the contained vascular fringes of the choroid plexuses of the lateral ventricles. At the two posterior or basal angles of the tela choroidea these vascular fringes curve onwards into the inferior cornua of the lateral ventricles, while the wide central part of the base of the tela marks the limit of fusion of the pial layers, which depart from each other here as already detailed. When the tela choroidea has been removed a transverse slit is left between the splenium and the junction of the roof of the third ventricle with the tectum: this is the *transverse fissure*, but it is, of course, not a cerebral fissure in the true sense or usage of the term, for it is not due to a folding of the cerebral cortex. It merely marks the posterior limit of the *extra-cerebral space* enclosed by the posterior growth of the corpus callosum above the third ventricle. In the space, enclosed between two layers of pia mater are the choroid plexuses of the third ventricle (p. 981).

The microscopic structure of a choroid plexus is essentially as follows. The irregular fringes visible to the naked eye are covered with large numbers of microscopic *villous processes*, each containing afferent and efferent vessels, an intervening capillary plexus, a small amount of supporting connective tissue, and nerve fibres. The villi show varying degrees of complexity (7.160), and sections demonstrate the large surface area created in this way. This has been estimated to be at least 200 cm^2 (Voetmann 1949), and this does not allow for the *microvilli* which electron microscopy shows on the ventricular aspect of the ependymal cells (Maxwell and Pease 1956). The ependymal microvilli are not as regular in size and distribution as in some other sites, such as the small intestine (p. 1347), being more akin to those seen in the epithelium of the proximal part of the renal tubule. As in the latter, the basal aspects of the ependymal cells present, to a lesser extent, a series of invaginations (Pappas and Tennyson 1962). (Scott *et al.* 1974 have reported a preliminary scanning electron microscopic study of the surface features of human fetal and infant choroid plexus; their observations largely confirm the above remarks.) These appearances, coupled with an absence of secretory granules, an unspecialized Golgi apparatus, and other features, suggest a role concerned with water transport rather than secretion. However, physiological studies (Davson 1970) provide considerable evidence that the cerebrospinal fluid, largely produced by the choroid plexuses, cannot be regarded as a mere filtrate. Ultrastructural studies have also shown that some ependymal cells possess *cilia*, that tight junctions exist between them, and that a distinct *basement membrane* separates them from the adjacent capillaries (Wislocki and Ladman 1958). The latter are sometimes of the fenestrated type, and experiments (Brightman and Reese 1969) in which the protein peroxidase was used as a tracer, showed that, while the capillary endothelium was readily permeable to the tracer, its passage was blocked by the tight junctions between the choroidal ependymal cells. These findings are probably of importance in relation to the concept of a *blood-brain barrier* which is further discussed on pp. 1052, 837.

The *stroma* of the choroidal villi is derived from the pia mater of the tela choroidea. It consists of pial fibroblasts and few, if any, collagen fibres. The cells are much flattened and do not form complete sheets between the ependyma and the capillary endothelium. Nerve fibres appear to be absent from the actual villi, but in the larger stems from which these branch the amount of connective tissue is greater and myelinated and non-myelinated nerve fibres and small nerve bundles have been identified (Clark 1934; Cooper 1958). The functional significance of these fibres is still uncertain, but the non-myelinated fibres are considered to be vasomotor postganglionic sympathetic elements; others are thought to be derived from the vagus and glossopharyngeal nerves. Comparatively few studies of the nerves of the

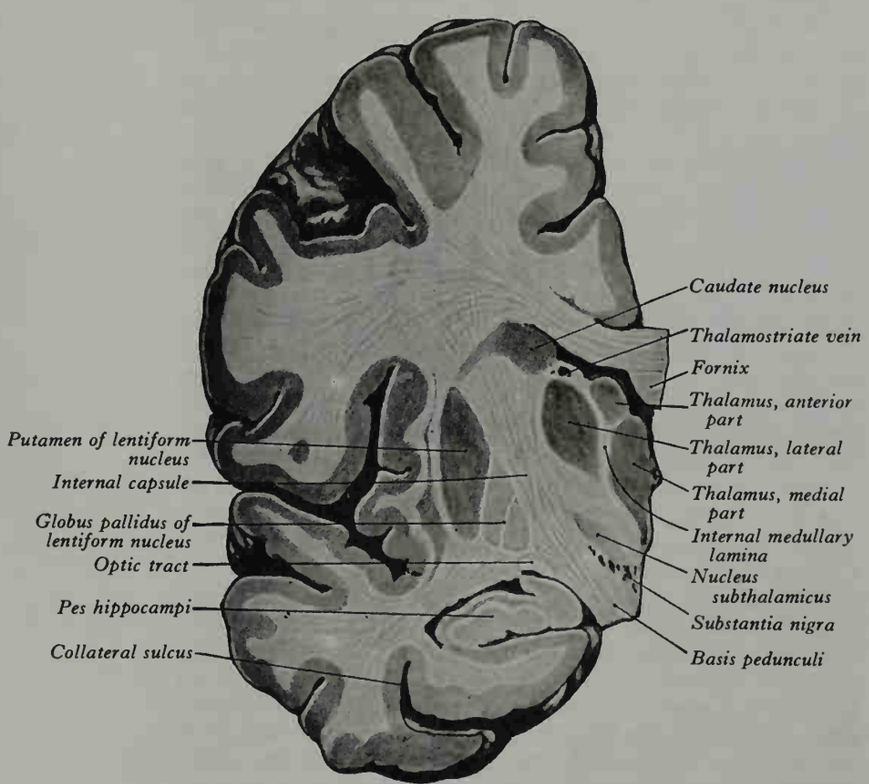
7.154 Diagram of the main components of the internal capsule. Descending motor fibres are shown in yellow, corticofugal fibres to the thalamus and pons, etc. in red, and ascending fibres in blue. (From Strong and Elwyn's *Human Neuroanatomy*—see Bibliography for details). However, see also in text references concerning alternative views about the position of the corticospinal fibres.



choroid plexuses have been reported and much uncertainty of their distribution and role persists. However, histochemical studies (Lindvall *et al.* 1977) have revealed the occurrence of cholinergic nerve fibres in association with the vessels and epithelium of all the choroid plexuses in a variety of mammals, including a primate (baboon).

The *blood supply* of the choroid plexuses in the tela choroidea is derived from the anterior choroidal branch of the internal carotid, and the choroidal branches of the posterior cerebral artery (pp. 691, 698), the former being usually a single vessel, the latter three to five in number (Millen and Woollam 1953). The two sets of arteries anastomose to some extent. The capillaries drain into a rich venous plexus, which is served by a single choroidal vein leaving the tela choroidea. This commences in the vicinity of the basal angle of the tela, at the junction of the parts of the choroid plexus in the body and the inferior cornu of the lateral ventricle. This region also corresponds to the frontier between the territories of the anterior and posterior choroidal arteries, and at this point also a solitary so-called 'glomus' (p. 632) is situated. This structure is near the free edge of the choroid plexus, and many of the tributaries of the choroidal vein converge towards it. Apart from the occurrence of this body nothing appears to have been established regarding its significance in the plexus.

Cerebral Dimensions



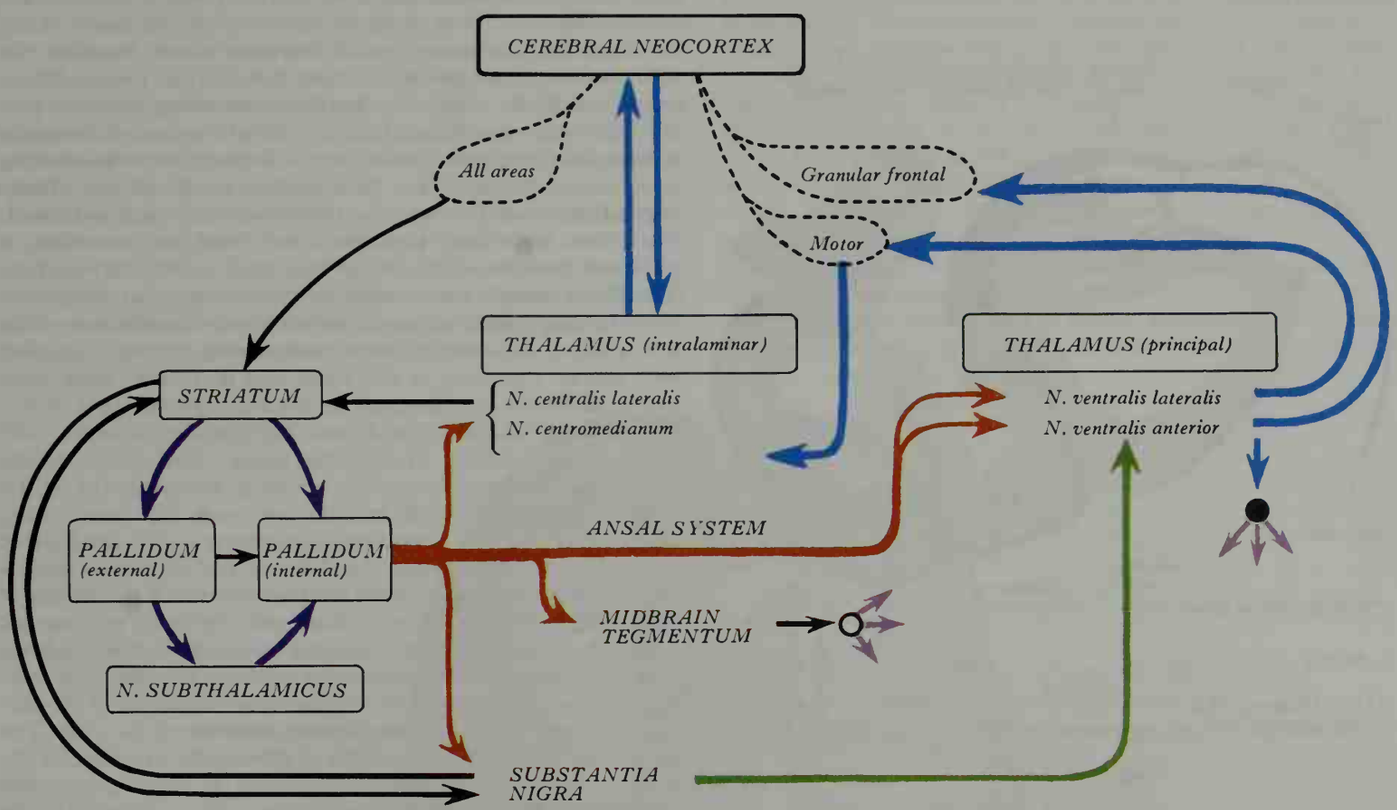
The human brain has been weighed and measured by many observers; and it has been compared in its volume, weight, relationship to total body weight, and in the proportionate size of its main divisions with the brains of many other vertebrates. Even without actual quantification, such comparisons permit some interesting generalizations regarding the relation between development of brain size and various abilities in mankind and other animals. But even metrical data, where they are available in reliable quantity, are merely estimates of the bulk of nervous tissue, which largely disregard degrees of organization or even the proportions of particular neuronal elements, such as nerve cells, nerve fibres, neuroglia and vascular elements; and such considerations must obviously be taken into account if valid comparisons are to be made. Clearly, therefore, no more than crude deductions are to be expected from data of this kind. Furthermore, available measurements are usually dependent upon small series of observations in any particular species, even sometimes upon a single example. Hence little allowance for individual variation can have been made, whether due to sex, age, or nutritional state, or indeed any other factors which may influence brain size or its relation to body size and weight; and it is particularly this ratio which is the focus of most attention. Even in respect to the human, for whom much more adequate series of observations have been recorded, the effects of such factors are often overlooked.

An 'average' human male adult's brain is said to weigh about 1,450 gm. and that of his female counterpart about 100 gm. less, but such figures are not useful without a corresponding range, which is of the order of 1,240 to 1,680 in males and 1,130 to 1,510 in females. Proportionately males and females differ rather less in brain weight than total body weight. Even the ranges quoted would exclude numbers of famous people whose brain weights lay well outside such extremes, and in both directions. (Consult Blinkov and Glezer 1968, for examples and much other data.) Different ranges for various races have been stated, but the differences between their means are not significant in general, when the much greater variation in body weight is taken into consideration. Chrzanowska *et al.* (1973, 1975), in a study of 1,670 human brains (896 male and 774 female, ranging from 20 to 89 years in age), concluded that the average difference between the sexes is 130–150 gm. They also stated that brain weight is positively correlated with height, and they recorded progressive diminution in brain weight, in both sexes, from 30 to 40 years onwards. They have computed a loss in weight of one-ninth in the brains of both sexes by the 90th year.

7.155A Posterior aspect of a coronal section through the anterior cornua of the lateral ventricles.

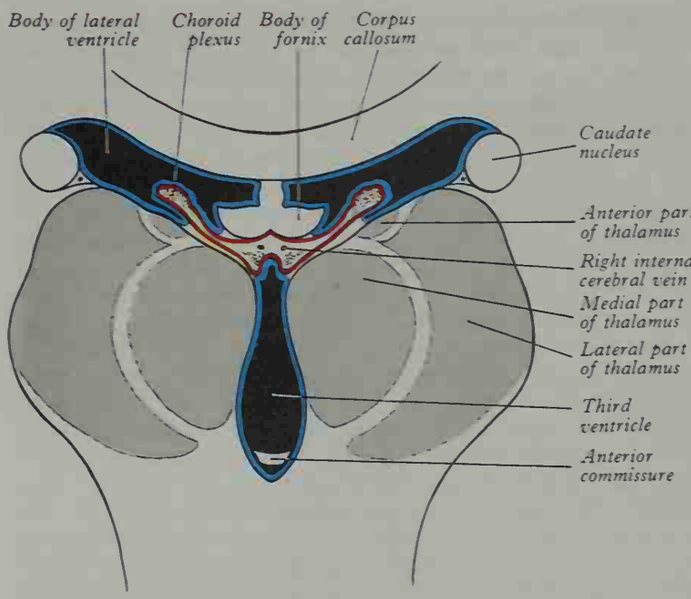
Prior to maturity, of course, the human brain varies markedly in weight and in ratio to total body weight (Purpura and Schadé 1964), showing throughout its growth, however, the same relatively outstanding development which characterizes the adult. Unlike some other mammals, such as rodents, in which the maximum growth rate may be pre- or post-natal, the cerebral growth spurt in mankind and primates in general is peri-natal—in late fetal development and the first year of extrauterine life. During this first year the brain at least doubles in weight (Dogson 1962), and it reaches about 90 per cent of its final weight by the sixth year. Most of this increase is due to factors such as myelination rather than any augmentation in the number of nerve cells, and for this reason alone any comparison of the growing human brain, on the basis of weight, with the brains of adults or of other species, is pointless where correlation with ability is the criterion.

7.155B Anterior aspect of a coronal section through the right cerebral hemisphere.



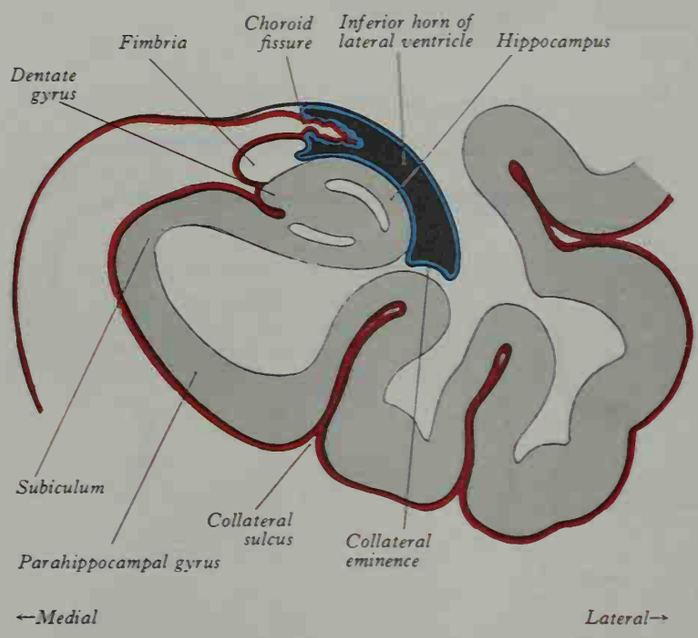
The human brain is obviously large, both absolutely and relatively; but it is surpassed in both respects by those of certain other mammals. Dolphins, elephants (4,000–5,000 gm.) and whales (6,800 gm. has been recorded in the blue whale, *Balaenoptera musculus*) have heavier brains than man, although this is offset by brain:body weight ratios of about 1:600 in elephants and of about 1:850 in large whales. However, in dolphins the ratio is approximately 1:40, which is somewhat 'better' than the human average of about 1:50. In some small mammals, such as mice, the ratio may be as low as 1:35, while in smaller primates ratios as low as 1:12 have been estimated (squirrel monkey). Amongst the primates man occupies an almost average position in brain: body weight ratio, the larger apes and monkeys falling much below him in this regard. In absolute size of brain, of course, he much surpasses any other primate; a male gorilla (Schultze 1969) may have a cranial capacity of 412–752 cm^3, and while this is only a rough indication of actual brain weight, it is well below the human range (say, 1,200–1,500 cm^3). The largest gorilloid brain recorded weighed 750 gm. (Holloway 1968), which is distinctly less than the usual human range. Nevertheless, extremely small brain weights have been recorded in microcephalic idiots; but what is more significant is that brain weights in dwarfs which were *below* the average upper limit for gorillas have nevertheless been recorded in humans possessing at least elementary speech; and the symbolic abstractions of language are widely regarded as correlated with the large absolute size of the human cerebrum. This view has, however, been questioned (Lenneberg 1964); and while a certain, as yet indefinable minimal size of brain must be associated with the

extraordinary potentialities of mankind in cerebration, it is clear that the kind of data so far mentioned cast little illumination on this problem.



As has already been said above, measurements of brain size and brain-to-body weight ratio afford no indication of organization within the brain; nor do they take into account the density of packing or total numbers of nerve cells in any particular brain. While it has been said that this density does not vary greatly in mammalian brains when calculated for the whole organ, estimates of this kind are few and subject to much error. Figures for samples taken from the cerebral cortex are perhaps open to the same strictures, but it is of interest to note here that a cubic millimetre of cortex has been estimated to contain as many as 142,000 cells in the mouse, 21,500 in the macaque, and merely 10,500 in man. However, the area of the human cerebral cortex (p. 1005) is at least twelve times greater than that of the macaque, which may nevertheless have a brain-to-body weight ratio similar to man's.

Another mode of approach to the problems of comparison of mammalian and especially primate brains (Tilney and Riley 1928) has been to estimate the weights of the main divisions of the brain, such as cerebrum, cerebellum, midbrain, medulla oblongata, olfactory bulb, neocortex, paleocortex, archicortex, corpus striatum, and other features, and to express some of these quantities as indices. (As an example of a more recent such study consult Stephan *et al.* 1970.) Large numbers of species of insectivores and primates have been compared in this manner, and although in many instances only one sample from each species has been measured, highly interesting comparisons are possible. While it is, of course, easy to appreciate, without any metrical data, that in the human brain the olfactory structures are small, absolutely and relatively, that the cerebrum-pons-cerebellum complex is markedly developed, or that the cerebral cortex is very extensive in the human brain, quantitative assessment of such statements is much more valuable. In comparing man and the gorilla, for example, the ratio by weight of their medullae oblongatae is approximately 9·6:7, despite the fact that the gorilla weighs at least twice as much as the man. The ratios for the mesencephalon, cerebellum and diencephalon are roughly 2:1, but the human telencephalon is three times as heavy as the gorilloid. The olfactory bulb of the gorilla is almost thrice the size of the human, while the latter's hippocampus is nearly two and a half times as heavy as the gorilla's. Incidentally the ratio of olfactory bulb to hippocampus in the gorilla is hence about 1:15 and in man 1:90, an interesting commentary on the status of the hippocampus as part of the 'rhinencephalon' (*see* p. 990). Legait *et al.* (1973) have made a volumetric comparison of the hypothalamus and hypophysis relative to total brain volume in a large series of mammals (principally rodents). They observed a constant brain/hypothalamic ratio, but some variation between the comparative volumes of hypothalamus and hypophysis, particularly for the anterior lobe of the latter (adenohypophysis).



Space does not permit further exploration of such data, and it must be said that though considerations of this kind may have marked significance in evolutionary comparisons between man and other mammals, particularly sub-human primates, they do not provide any clear definition in morphological terms of what it is that is responsible in man's brain for the enormous complexity of his behaviour. Perhaps it is rather in this, and his consequently ever more complex culture, that the essence of humanness can best be defined. It is noteworthy that in assessing the human paleontological record the accent has gradually passed from comparison of cranial capacities to that of culture. The Australopithecinae, with brains little if at all larger than those of gorillas, may leave us in doubt; but in *Homo habilis*, with—it is true—a considerably larger but still very modest cranial capacity, doubts evaporate as to his humanity; and perhaps most of all because of his ability, as revealed in surviving artefacts. In more recent ancestors also, and again not merely because of increasing *hominoid* brain size (in which *Homo neanderthalensis* even surpassed us, yet is now extinct), but even more because of the

7.156 A scheme of the principal connexions of the basal nuclei. At the points indicated the dorsal thalamic nucleus ventralis anterior projects on to several subcortical regions including the thalamic nucleus ventralis lateralis. The midbrain tegmentum probably establishes polysynaptic relationships with the spinal cord grey matter and the thalamic intralaminar nuclei. Colour has been used to assist visualization of the individual pathways. See text for further comment. (Based on data summarized by Professor K. E. Webster (1975) of the Department of Anatomy, King's College, University of London; by kind permission of the author.)

increasing evidence of their *human* behaviour are we convinced of their close relationship to ourselves. Their abilities, which from such simple beginnings have led to the great achievement and communication of practical and abstract creation in our own era, are no more likely than our own to be explicable in terms of gross cerebral mensuration. (For important discussions of the significance of brain size consult Tobias 1970, 1971; Jerison 1970; Van Valen 1974.)

Blood Vessels of the Brain

The arterial supply of the brain (pp. 686, 695) is derived from the **internal carotid** and **vertebral arteries** which lie in the subarachnoid space (p. 1049). The vertebral and basilar arteries give branches to the spinal cord, brainstem and cerebellum, the basilar artery terminating at the upper border of the pons by dividing into two posterior cerebral arteries. The internal carotid artery terminates by dividing into **anterior** and **middle cerebral arteries**. The anterior cerebral arteries are interconnected by the **anterior communicating artery**. Just before terminating, the internal carotid artery communicates through the **posterior communicating artery** with the **posterior cerebral artery**, thus completing a vascular circle, the **circulus arteriosus**, around the interpeduncular fossa (**6**.61). For details of collateral circulation following blockage of the main feeders of the circle, *see* Fields *et al.* (1965), and Gillilan (1974). From the circulus arteriosus, or vessels close to it, **central branches** are given off to supply the interior of the cerebral hemisphere and the thalamus. These vessels form six principal groups: (1) an *anteromedial group*, derived from the anterior cerebral and anterior communicating arteries (*see* p. 690); (2) a *posteromedial group*, from the posterior cerebral and posterior communicating arteries; (3 and 4) right and left *anterolateral groups*, from the middle cerebral arteries; (5 and 6) right and left *posterolateral groups*, from the posterior cerebral arteries after they have wound round the cerebral peduncles. (For details consult Kaplan and Ford 1966.) Lang and Brunher (1978) have described a recurrent central ramus arising from the anterior cerebral artery beyond the origin of its anteromedial group of central rami and running back to join these. It was often observed to be double. They name this vessel *arteria recurrens anterior*.

The entire blood supply of the **cerebral cortex** is derived from the **cortical branches** of the anterior, middle and posterior cerebral arteries. They reach the cortex in the pia mater. They divide in its substance, give off branches which penetrate the brain cortex perpendicularly and are divisible into long and short rami (Von Bonin 1950). The **long** or **medullary arteries** pass through the grey matter and penetrate the subjacent white matter to a depth of 3 or 4 cm (Lewis 1957) without intercommunicating and thus constitute many independent small systems. **Deep medullary vessels** extending from the central branches towards the cortex have been described, but these are identified as recurrent branches of the long or medullary vessels (Lewis 1957). The **short arteries** are confined to the cortex, where they form with the long vessels a compact network in the middle zone of the grey matter, the outer and inner zones being sparingly supplied with blood. Lazorthes *et al.* (1968) and de Reuck (1972) have drawn attention to differences in the angio-architecture in iso- and allo-cortical areas, the former being more elaborate, with arterioles terminating in different strata. The vessels of the cortical system are not so strictly 'terminal' as those in the central system (Sunderland 1938) but they approach this type closely, for, although neighbouring vessels anastomose with one another on the surface of the brain, they become end arteries as soon as they pierce its substance. Even the anastomoses on the surface of the brain, however, are in general only between microscopic branches of the cerebral arteries, and there is little clear evidence that they can provide the means of a vicarious circulation in cases of occlusion of larger vessels. Owing to the cellularity of the grey matter, its blood supply is much richer than that of the white. The *lateral surface* of the hemisphere is principally supplied by the *middle cerebral artery*; the area adjacent to the superomedial border as far back as the parieto-occipital sulcus is supplied by the *anterior cerebral artery*, and the occipital lobe and most of the inferior temporal gyrus (excluding the temporal pole) is supplied by the *posterior cerebral artery* (**6**.59, 60). The *medial* and *inferior surfaces* of the cerebral hemisphere are supplied by the *anterior* and *posterior* cerebral arteries. The area supplied by the anterior cerebral artery extends almost to the parieto-occipital sulcus and includes the medial part of the orbital surface. (For a highly detailed study of the distribution of the anterior cerebral artery in 53 hemispheres and 300 angiograms consult Farnarier *et al.* 1977.) The remainder of this surface and the temporal pole are supplied by the middle cerebral artery. The rest of the medial and inferior surface is supplied by the posterior cerebral artery (**6**.59, 60). The junctional zone near the occipital pole between the territories of the middle and posterior cerebral arteries corresponds to the part of the striate cortex concerned with the macula. The phenomenon known clinically as '*sparing of the macula*' is considered to be due to the collateral circulation of blood from branches of the middle cerebral artery into those of the posterior, when the latter vessel is blocked. The middle cerebral

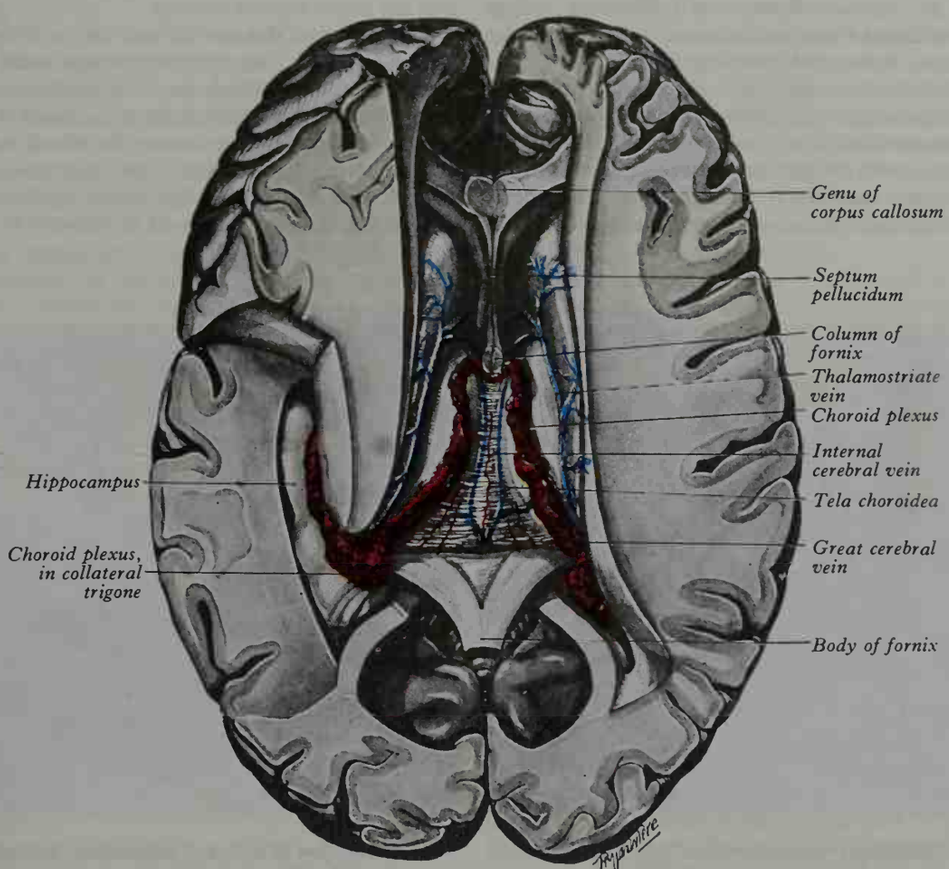
artery may in fact itself supply the macular area (Smith and Richardson 1966).

Most of the *corpus striatum* and *internal capsule* is supplied by the medial and lateral striate rami of the central branches of the middle cerebral artery, the remainder being supplied by the central branches of the anterior cerebral artery. One ramus of the middle cerebral is Charcot's 'artery of cerebral haemorrhage' (p. 691).

The *choroid plexuses* of the *third* and *lateral ventricles* are supplied by branches of the internal carotid and posterior cerebral arteries.

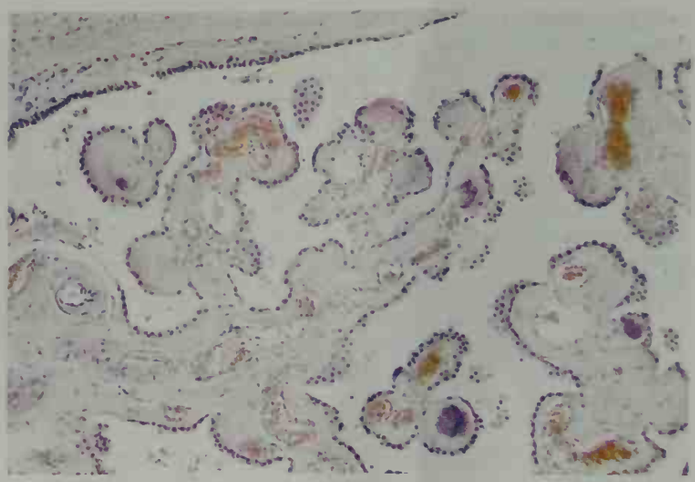
The finer details of the vessels of some parts of the diencephalic region have been well explored, particularly in relation to the hypophysis cerebri and its related hypothalamic nuclei (*see* p. 966 and Haymaker *et al.* 1969). Detailed studies of the vascularization of the lamina terminalis (Duvernoy *et al.* 1969) and of the posterior wall of the third ventricle (Plets 1969) have been reported. The arterial supply to the lamina is derived from the anterior cerebral arteries and their communicating vessel, and these are described as forming a superficial capillary plexus in the pia mater which drains into a second, more deeply situated plexus of sinusoidal capillaries, characterized by loops or vortices, these draining in their turn into the veins of the hypothalamus. The physiological significance of these arrangements is unknown. The main artery to the posterior parts of the third ventricle is the medial branch of the posterior choroidal artery, and this supplies the posterior commissure, habenular region, the pineal gland, and medial parts of the thalamus, including the pulvinar. The *thalamus* is supplied chiefly by branches of the posterior communicating, posterior cerebral and basilar arteries. The pattern of branches from these main feeders, and the varying details of the angioarchitecture in the different nuclei of the thalamus, have been described *in extenso* in the human brain, together with a full critique of the literature by Plets *et al.* (1970) and by Percheron (1977). The latter has denied the often described thalamic supply from the anterior choroidal artery; he derives almost the entire thalamic supply from branches of the posterior cerebral and basilar arteries (p. 696).

The *midbrain* is supplied by the posterior cerebral, superior cerebellar and basilar arteries. The crura cerebri are supplied by vessels entering on the medial and lateral sides. The medial vessels pass to the inner side of the crus and also supply the upper and inner part of the tegmentum, including the nucleus of the oculomotor nerve. The lateral vessels supply the lateral part of the crus and the tegmentum. The colliculi are supplied by three vessels on each side from the posterior cerebral and superior cerebellar arteries. There is an additional supply to the crura cerebri and the colliculi and their peduncles from the postero-lateral group of central arteries from the posterior cerebral artery.



The *pons* is supplied by the basilar and the anterior inferior and superior cerebellar arteries. Direct branches from the basilar artery enter along the basilar sulcus. Branches also enter along the trigeminal, abducent, facial and vestibulocochlear nerves and nervus intermedius. There is also a supply from the pial plexus.

The *medulla oblongata* is supplied by the vertebral, anterior and posterior spinal, posterior inferior cerebellar and basilar arteries. Some arteries enter along the anterior median fissure and the posterior median sulcus. Other vessels enter along the rootlets of the last four cranial nerves and intermediately to supply the central substance. In addition there is a supply from the same sources through a pial plexus.



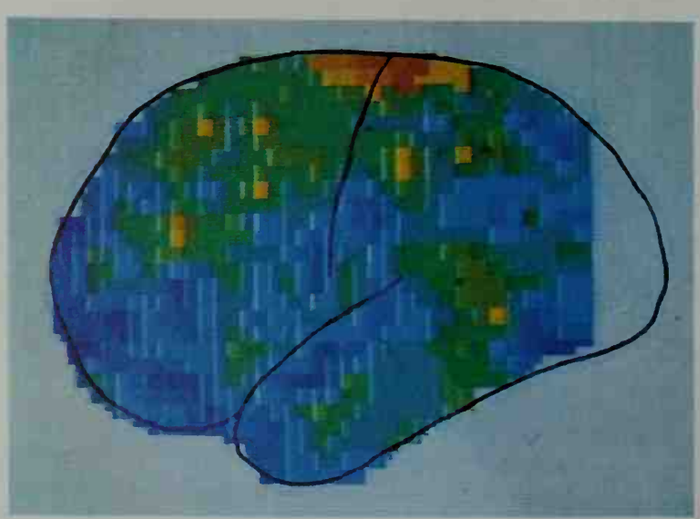
The *cerebellum* is supplied from the three pairs of cerebellar arteries, and the latter, like the cerebral arteries, form superficial anastomoses. Their internal distribution has not been extensively studied, but the possibility of anastomoses of their deeper, medullary branches, as distinct from cortical branches, has been reported (Gomes 1969). The anatomy and development of the cerebellar arteries have been reviewed by Gillilan (1974). According to Kielbasinski (1976) the vermis is supplied by one or both of the inferior cerebellar arteries.

The *choroid plexus* of the *fourth ventricle* is supplied by the posterior inferior cerebellar arteries.

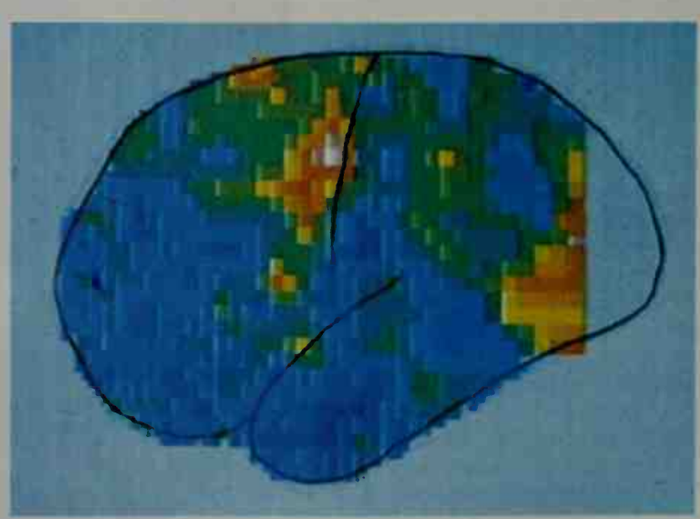
The blood supplies of the optic chiasma, tract and radiation are of marked clinical interest. The chiasma is supplied in part by the anterior cerebral arteries, but its median zone depends upon rami from the internal carotids which reach it by way of the stalk of the

7.159 The tela choroidea of the third ventricle and the choroid plexus of the lateral ventricle.

7.160 A section of part of the choroid plexus of the lateral ventricle, stained with haematoxylin and eosin. Note the ependyma lining the ventricular wall above, and covering the loose connective tissue cores of the processes of the plexus, which contain numerous small blood vessels, including many capillaries. A calcareous deposit (dark blue) is present in one process. Owing to the complexity of the ramification of the processes, several appear as disconnected islands of tissue.



hypophysis cerebri. The anterior choroidal and posterior communicating arteries supply the optic tract, and the radiation receives blood through deep branches of the middle and posterior cerebral vessels. For further details consult Abbie (1938); Bergland and Ray (1969).



Cerebral Blood Flow and Functional Localization

That the level of functional activity, metabolism, and volume flow of blood in unit time through most tissues fluctuate in close correspondence has long been known in general physiology. In relation to nervous tissues also, although the mechanisms of selective control of blood flow through particular regions was unknown, as early as 1937, Schmidt and Hendrix using thermocouples demonstrated a marked increase in flow through the feline visual cortex, compared with surrounding regions, during localized retinal illumination. Subsequent years provided many confirmatory experiments in the brains of experimental animals using similar methods, but not only confined to the visual pathway. In recent years, with the advent of a wide and increasing range of appropriate radio-isotopes and scanning cameras there has been a dramatic upsurge of interest in cerebral blood-flow studies. Much of the initial stimulus stemmed from a new technique, non-invasive in character, potentially able to localize with considerable accuracy intracranial pathological states that modified the blood-flow pattern significantly, for example, neoplasms, post-traumatic loci, intracranial abscess, cerebral infarction and so forth (*see* Maisey 1978). In large measure, these objectives determined the particular radionuclide and methodology chosen. Some groups, however, soon realized the possible power of the technique in monitoring fluctuating levels of blood flow (and therefore of functional activity) of different regions of, for example, the normal cerebral cortex during a wide range of activities (*see* Lassen *et al.* 1978). Briefly, an isotope of the inert gas xenon (xenon 133) dissolved in sterile saline is injected into a carotid artery and the subject's head is subsequently scanned during the arrival and 'washout' of the isotope by means of a gamma-ray camera; the latter carries 254 scintillation detectors each collimated to scan about 1 cm^2 of the surface of the cerebral cortex. The results from this grid of detectors is processed in a digital computer and then displayed on a colour television screen. The colour of each *pixel*, or picture, denotes a particular range of blood flow through the subjacent cortex (the mean flow rate is green), down to 20 per cent below mean are shades of blue, up to 20 per cent above mean are through orange to shades of red. Illustration 7.161 shows two examples of the technique in use. Already some hundreds of apparently normal cerebral hemispheres have been scanned during a wide range of activities from the 'resting' state, through uncomplicated voluntary movements, sensory stimulation of various modalities, to complex activities such as reading aloud and problem-solving. Broadly, the 'functional areas' mapped by traditional means have been confirmed. Clearly, however, in the forthcoming years there will occur increases in resolution of the technique, both spatial and temporal, and this offers a most exciting prospect for future researches into the localization of cerebral functions.

The venous drainage of the brain (pp. 743–749) can be divided into that serving the cerebral hemispheres and that serving the brainstem and cerebellum. The veins are thin-walled, devoid of valves and the majority cross the subarachnoid space to join the dural venous sinuses.

The veins of the cerebrum can be divided into external and internal groups. The external cerebral veins are grouped in three sets, the superior which drain forwards into the superior sagittal sinus, the inferior which drain principally into the transverse and cavernous sinuses and the middle which are further subdivided into superficial and deep. The *superficial middle cerebral vein* drains the majority of the lateral surface of the hemisphere, follows the lateral sulcus and terminates in the cavernous sinus.

7.161 A & B Patterns of presumed relative levels of neuronal activity in different regions of the cerebral cortex as revealed by measurement of regional blood-flow. A shows the pattern which accompanies movement of the contralateral foot, and B shows a pattern which accompanies activity of the eyes engaged in a pursuit movement. The colour scales indicate the percentage flow rate above or below the mean (dark green). (Radioactive xenon scan pictures kindly supplied by Doctors N. A. Lassen, D. H. Ingvar, and E. Skinhoj, Bispebjerg Hospital, Copenhagen. See text.)

The *deep middle cerebral vein* drains the region of the insula and unites with the *anterior cerebral* and *striate veins* to form a *basal vein*. The areas drained by the anterior cerebral and striate veins correspond approximately with those supplied by the anterior cerebral artery and the central branches entering the anterior perforated substance. The striate veins have been described in detail by Rosa and Borzone (1973). The basal veins pass backwards alongside the interpeduncular fossa and midbrain, receive tributaries from this vicinity and join the *great cerebral vein*.

The two **internal cerebral veins** are formed near the interventricular foramen by the union of the *thalamostriate* and *choroidal veins* draining the choroid plexuses of the third and lateral ventricles. They travel backwards parallel to one another between the layers of the tela choroidea of the third ventricle and unite to form the great cerebral vein, which enters the straight sinus.

The veins of the *midbrain* join the basal or great cerebral veins.

The veins of the *pons* drain either into the basal vein, cerebellar veins, the petrosal sinuses, transverse sinus or the venous plexus of the foramen ovale.

The veins of the *medulla oblongata* drain into the veins of the spinal cord, the adjacent dural venous sinuses or along the last four cranial nerves by radicular veins to the inferior petrosal sinus or superior bulb of the jugular vein. For a detailed systematic account of the superficial veins of the brainstem consult Tournade *et al.* (1972) and Duvernoy (1975).

The **veins of the cerebellum** drain mainly into the adjacent sinuses or, from the superior surface, to the great cerebral vein.

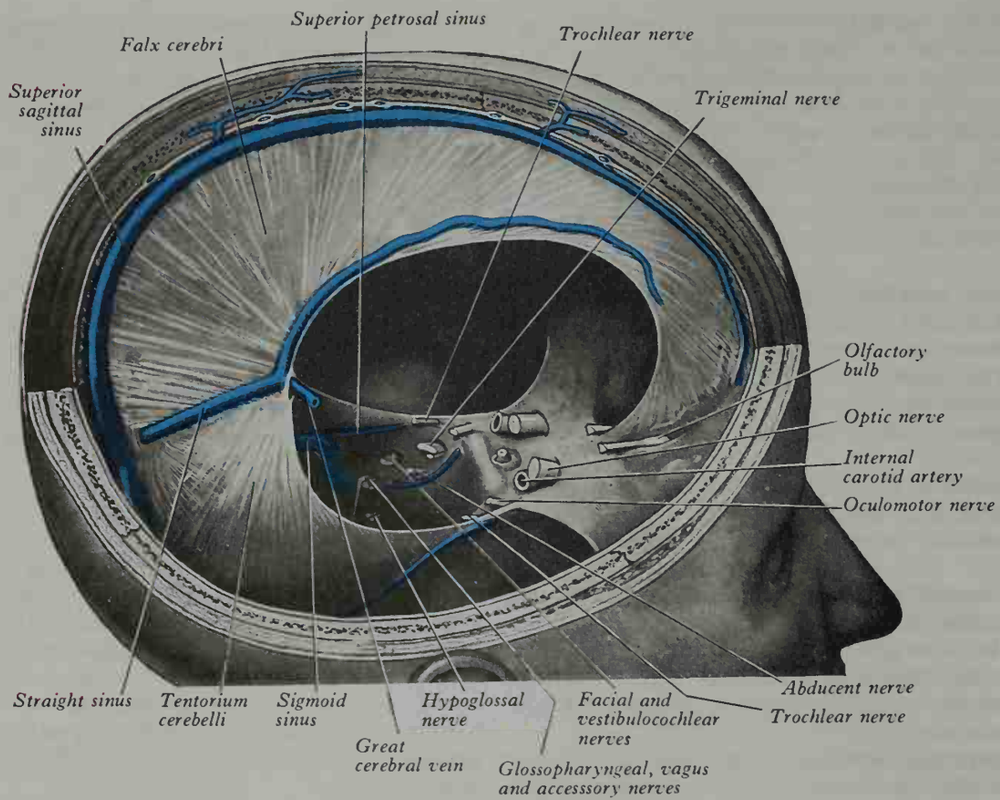
Although the *innervation* of the intercranial arteries, including those supplying the brain, remains something of a physiological mystery, there is no doubt that a considerable supply of postganglionic sympathetic fibres is distributed along the arterial trees of the internal carotid and vertebral arteries, and that myelinated fibres accompany these in lesser numbers. A parasympathetic supply is supported by more dubious evidence. For a review of the literature of this topic, consult Nelson and Rennels (1970), and Purves (1972).

There are no lymphatics in the central nervous system. The subarachnoid space is prolonged along the olfactory nerves, thus providing a route between this space and the tissue spaces in the mucoperiosteum of the nasal cavities. The so-called perivascular spaces around brain vessels have been a subject of much controversy (p. 1052). Electron microscope appearances confirm the extension of pial elements into the brain around vessels in various mammals such as the rat (Samarasinghe 1965), and cat (Jones 1970). In the latter study the arachnoid 'space' around the small arterioles entering the cortex of the cerebrum was seen to contain electron-dense material, consisting of collagen bundles, pial cells, and cells resembling macrophages, possibly derived from the leptomeninges. These elements do not, apparently, form a complete sheath to the vessels, large areas being seen in which the basement membranes of the brain and vessel are opposed. The 'space' does not extend around capillaries, where the two basement membranes fuse. These observations also entail that the perivascular spaces are not continuous with whatever space exists around neurons.

The Meninges

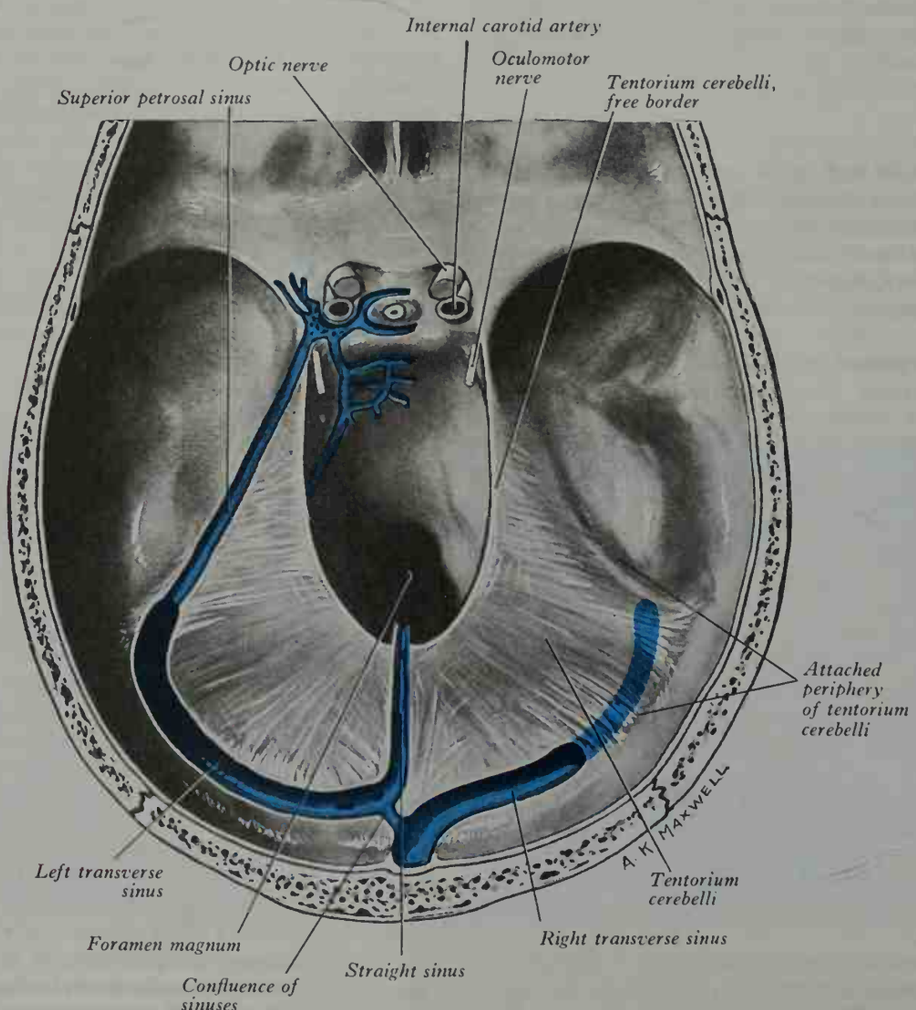
The brain and the spinal cord are enveloped by three membranes (meninges), named from without inwards: the dura mater, the arachnoid and the pia mater.

THE DURA MATER



The dura mater is a thick and dense inelastic membrane. The portion of it which encloses the brain (*cerebral dura mater*) differs in several particulars from that which surrounds the spinal cord (*spinal dura mater*), and therefore it is necessary to describe them separately; the two parts, however, form one complete membrane, and are continuous with each other at the foramen magnum.

The cerebral dura mater lines the interior of the skull, and serves the twofold purpose of an internal periosteum to the bones, and a supportive membrane for the brain. It is said to be composed of two layers, an *inner* or *meningeal* and an *outer* or *endosteal*; but these are closely united, except along certain lines where they separate to enclose the venous sinuses which drain the blood from the brain (p. 743). The dura mater adheres to the inner surfaces of the cranial bones, and sends blood vessels and fibrous processes into them, the adhesion being most marked at the sutures, at the base of the skull, and around the foramen magnum. The blood vessels and fibrous processes are torn across when the dura mater is detached from the bones, and consequently the outer surface of the membrane presents a rough and fibrillated appearance; the inner surface is smooth. The endosteal layer of the dura mater is continuous through the sutures and the foramina of the skull with the pericranium, and through the superior orbital fissure with the periosteal lining of the orbital cavity. The meningeal layer provides tubular sheaths for the cranial nerves as the latter pass through the foramina at the base of the skull. Outside the skull these sheaths fuse with the epineurium of the nerves, and the sheath of the optic nerve is continuous with the sclera of the eyeball.



The meningeal layer of the cerebral dura mater is reduplicated inwards as four processes or septa which partially divide the cranial cavity into a series of freely communicating spaces for the lodgement of the subdivisions of the brain.

(1) *The falx cerebri* (7.161), so named from its sickle-like form, is a strong, arched process of dura mater which descends vertically in the longitudinal fissure between the cerebral hemispheres. It is narrow in front, where it is fixed to the crista galli of the ethmoid bone, and broad behind, where it blends in the median plane with the upper surface of the tentorium cerebelli; the narrow, anterior part is thin, and is frequently perforated by numerous apertures. The upper margin of the falx cerebri is convex, and attached to the inner surface of the skull on each side of the median plane, as far back as the internal occipital protuberance; the superior sagittal sinus (p. 744) runs along this margin. Its lower margin is free and concave, and contains the inferior sagittal sinus. The straight sinus runs along its attachment to the tentorium cerebelli.

(2) *The tentorium cerebelli* (7.161, 162) is a crescentic, arched lamina of dura mater which covers the cerebellum, and supports the occipital lobes of the cerebrum. Its concave, anterior border is free, and between it and the dorsum sellae of the sphenoid bone there is a large oval opening, the *tentorial incisure*, which is occupied by the midbrain and the anterior part of the superior surface of the vermis of the cerebellum. Its convex outer margin is attached (*a*) posteriorly, to the lips of the transverse sulci of the occipital bone and the postero-inferior angles of the parietal bones, where it contains the transverse sinuses; (*b*) laterally, to the superior borders of the petrous parts of the temporal bones, where it encloses the superior petrosal sinuses. Near the apex of the petrous part of the temporal bone, the lower layer of the tentorium is pouched forwards and laterally, beneath the superior petrosal sinus, to form a recess between the endosteal and meningeal layers of dura mater of the middle cranial fossa. This recess is called the *trigeminal cave* and envelops the roots of the trigeminal nerve and the posterior part of its sensory ganglion; it is a little more extensive below than above the ganglion. The evaginated meningeal layer terminates by fusing with the anterior part of the ganglion. At the apex of the petrous part of the temporal bone the free border and attached periphery of the tentorium cross each other (7.162); the anterior limits of the free border are fixed to the anterior clinoid processes of the sphenoid bone, whilst those of the attached periphery end on the posterior clinoid processes of

7.162A The cerebral dura mater and its reflexions, exposed by the removal of a part of the right half of the skull and brain.

 7.162B The superior aspect of the tentorium cerebelli.

that bone. As already described the straight sinus runs in the line of attachment of the posterior part of the inferior border of the falx cerebri to the tentorium cerebelli.

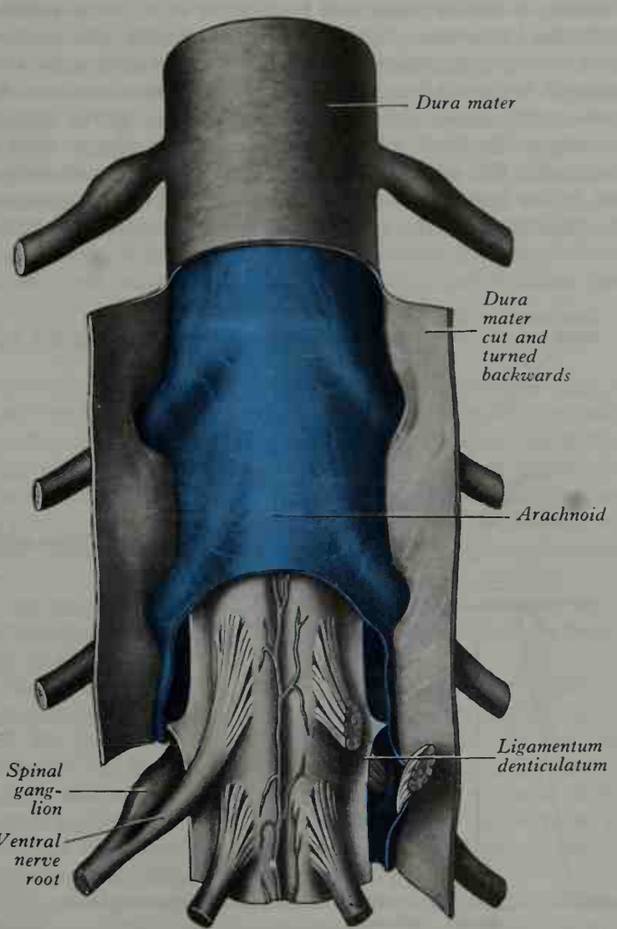
For details of the comparative anatomy and phylogeny of the tentorium cerebelli *see* Klintworth (1968).

(3) *The falx cerebelli* is a small, sickle-shaped process of dura mater which is situated below the tentorium cerebelli, and projects forwards into the posterior cerebellar notch. Its base, directed upwards, is attached to the posterior part of the inferior surface of the tentorium cerebelli, in the median plane; its posterior margin contains the occipital sinus, and is fixed to the internal occipital crest; its apex frequently divides into two small folds, which are lost on the sides of the foramen magnum. Hasan and Das found the falx cerebelli double in 76 of 100 cadavers (*see* p. 746).

(4) *The diaphragma sellae* (7.162) is a small, circular, horizontal fold of dura mater, which forms a roof for the sella turcica and almost completely covers the hypophysis; a small opening in its centre transmits the infundibulum.

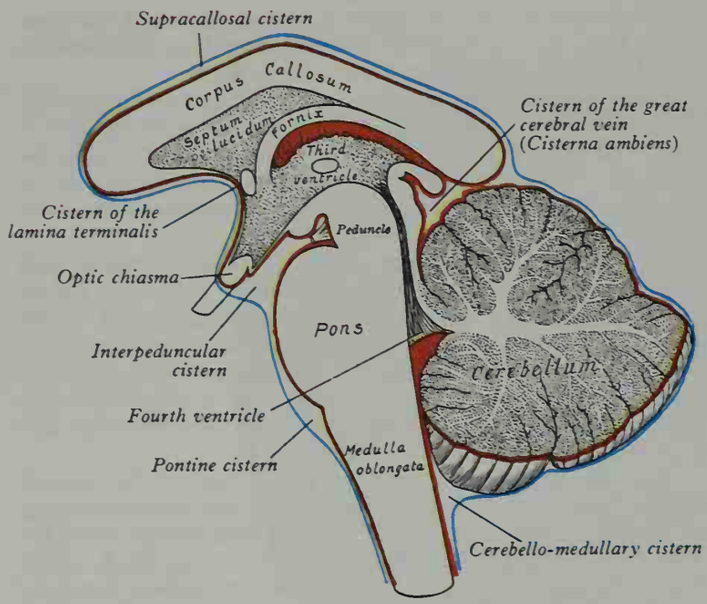
The arrangement of the dura mater in the central part of the middle cranial fossa requires further description. As the free rim of the tentorium cerebelli is traced forwards, it converges on the attached periphery, and crosses it near the apex of the petrous part of the temporal bone. It is then continued forwards as a clearly visible ridge on the dura mater as far as the anterior clinoid process, to which it is attached. This ridge marks the junction of the roof and lateral wall of the cavernous sinus (7.161).

The attached periphery of the tentorium cerebelli follows the superior border of the petrous part of the temporal bone and, after being crossed by the free border, continues forwards to the posterior clinoid process as a somewhat rounded and indefinite ridge on the dura mater.



An angular interval exists between the anterior parts of the attached periphery and free border (7.162), and in this interval the dura mater forms part of the roof of the cavernous sinus. Here it is pierced in front by the oculomotor and behind by the trochlear nerves. These two nerves remain in close contact with the dura mater after piercing it and are carried forwards and downwards into the lateral wall of the cavernous sinus (6.127).

From the anteromedial portion of the lateral part of the middle cranial fossa the dura mater ascends, forming the lateral wall of the cavernous sinus. When it reaches the ridge produced by the forward continuation of the free border of the tentorium cerebelli, it is carried medially, forming the roof of the cavernous sinus, and is here pierced by the internal carotid artery (7.162).



Medially, the roof of the cavernous sinus is continuous with the upper surface of the diaphragma sellae. At, or just below, the opening in the diaphragma for the infundibulum of the hypophysis, the dura mater, arachnoid and pia mater blend with one another and with the capsule of the hypophysis (p. 1438), so that within the sella turcica it is impossible to differentiate the individual membranes or to recognize the subdural and subarachnoid spaces (6.127).

Apart from its function as the periosteum of the internal surfaces of the cranial bones, the dura mater may act as a steadying influence, through the agency of the tentorium and falx, upon the movement of the brain within the cranial cavity, but this is merely a speculation. A number of venous sinuses are enclosed within its thickness and certain of these are in actual edges of the dural partitions. The junction of the great cerebral vein with the straight sinus in the tentorium cerebelli is a particularly critical point in the venous drainage of the brain. If the relation between these two venous channels is much altered for anything more than short periods of time, as may occur when 'space-occupying' lesions above the tentorium cause a descent of the brainstem relative to the tentorium, obstruction of the great cerebral vein may ensue, with the sequelae of back-pressure, oedema of the choroid plexuses and over-production of cerebrospinal fluid.

The structure of the dura mater is basically fibrous, white collagen fibres predominating with an admixture of elastic fibres. The collagen fibres are densely arranged in laminae, in which the fibres are often arranged in a parallel manner, with wide angles between these groupings in adjacent laminae, producing a latticed appearance particularly easy to see in the tentorium cerebelli. The cerebral dura mater is often described as consisting of two layers, an *endosteal* layer acting as the periosteum of the cranial bones to which it is attached, and a *meningeal* or cerebral layer internal to this. This description owes more, perhaps, to the separation where venous sinuses occur and to the splitting of the cerebral dura mater at the foramen magnum and optic canals than to any marked histological differences. The smaller branches of the meningeal vessels are, of course, largely in the endosteal region, since they are, despite their name, primarily periosteal in distribution. Fibroblasts occur throughout the dura mater, but osteoblasts are naturally confined to the endosteal level. The elastic fibres separate the laminae of collagen fibres, which are also and more extensively separated by lacunar spaces considered by some to be continuous with the subdural space (*vide infra*). These spaces are mainly confined to the inner part of the dura mater. In sum, therefore, there are a number of features which distinguish the external from the internal levels of the dura, but there is no discontinuity or any other kind of boundary upon which a clear distinction of a bilaminar nature could be based. At all foramina in the cranium the endosteal element is continuous through them with the external periosteum. At the sutures, before their fusion, the endosteal element is continuous with the sutural membrane, and the dura mater is more strongly attached at these locations. Elsewhere it is more easily detached from the cranial bones. The meningeal element is continuous through the appropriate foramina with the dural sheaths of the spinal cord and the optic nerves. At other foramina it is said to be 'pierced' by the nerve or vessel passing through them, but it is perhaps more accurately described as becoming continuous with perineurium or adventitial sheaths. Though in close apposition to the arachnoid mater internal to it, the dura mater is very easily separated from the former, as exemplified by the occurrence of subdural haemorrhages between them. Although contrary views have been recorded, there is little doubt that a layer of flattened 'mesothelial' cells is a constant feature of the internal aspect of the dura mater and that small amounts of fluid, though as a mere capillary film,

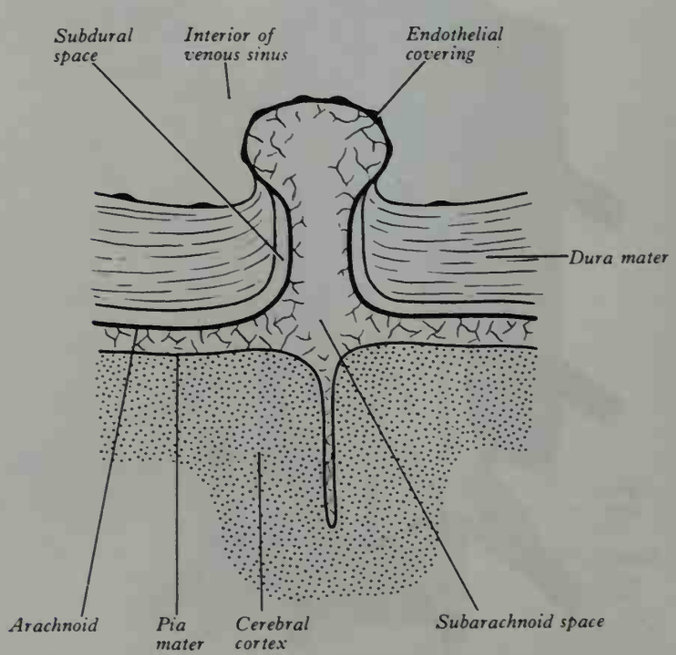
7.163 A part of the spinal cord exposed from the ventral aspect, showing its meningeal coverings.

7.164 A diagram showing the positions of the principal subarachnoid cisterns. *Red:* pia mater. *Blue:* arachnoid mater.

usually exist as a zone of potential separation between arachnoid and dura. Rascol and Izard (1974) have confirmed by electron microscopy the existence of epithelial cells in this region, regarding them as 'neurothelium'. They describe them as arranged in several irregular layers, with abundant intercellular spaces, devoid of collagen fibres. The cells display tonofilaments and desmosomes, but these observers consider that the epithelium is fragile and easily torn apart to produce a 'subdural space'. (The structure of the subjacent arachnoid is described on p. 1051.)

The arteries of the cerebral dura mater are very numerous. Those in the anterior fossa of the skull are the anterior meningeal branches of the anterior and posterior ethmoidal and internal carotid arteries, and a branch from the middle meningeal artery. Those in the middle fossa are the middle and accessory meningeal branches of the maxillary artery; a branch from the ascending pharyngeal artery, which enters the skull through the foramen lacerum; branches from the internal carotid artery, and a recurrent branch from the lacrimal artery. Those in the posterior fossa are meningeal branches from the occipital artery, one entering the skull through the jugular foramen, and another through the mastoid foramen; the posterior meningeal branches of the vertebral artery; occasional meningeal branches from the ascending pharyngeal artery, entering the skull through the jugular foramen and hypoglossal canal. The meningeal arteries are chiefly distributed to bone, in contrast to those of the spinal dura mater, and are therefore inappropriately named. Only very fine branches are distributed to the dura itself within the cranium.

The *veins* returning the blood from the cranial dura mater are described on pp. 745–749.



The nerves of the cerebral dura mater have been the subject of a number of investigations over a long period (von Luschka 1850, 1860; Arnold 1851; Hovelacque 1927; Siwe 1931; Penfield and McNaughton 1940; Kimmel 1961*a* and *b*). The best recognized dural innervation arises from the *trigeminal nerve*, including its ganglion and three principal divisions or their branches, from the upper three *cervical nerves*, and from the *cervical sympathetic* trunk. Other less well-established meningeal branches have been described as arising from the vagus and hypoglossal nerves, and also possibly from the facial and glossopharyngeal nerves (but *vide infra*).

In the *anterior cranial fossa* the meningeal nerves are twigs from the anterior and posterior ethmoidal nerves, and anterior filaments from the meningeal branches of the maxillary (*nervus meningeus medius*) and mandibular (*nervus spinosus*) divisions of the trigeminal. The principal area of distribution of the latter two nerves is, however, to the dura of the *middle cranial fossa*, which also receives filaments directly from the trigeminal ganglion. The *tentorium cerebelli* receives on each side the recurrent *tentorial nerve*, a branch of the ophthalmic division of the trigeminal. The dura mater of the *posterior cranial fossa* is innervated by ascending meningeal branches from the upper cervical nerves which enter the cranium through the anterior part of the foramen magnum (second and third cervical), and through the hypoglossal canal and jugular foramen (first and second cervical nerves). A number of separate filaments enter by each of these routes. Whilst *direct* meningeal branches from the vagus and hypoglossal, and possibly other cranial nerves, cannot be excluded, strong evidence has been accumulated (Kimmel 1961*a* and *b*) showing that nerves so described are in most cases recurrent filaments from the cervical nerves, which, for a short distance, run within the connective tissue sheath of the cranial nerve concerned.

All the foregoing meningeal nerves contain a postganglionic sympathetic component, either derived directly from the superior cervical sympathetic ganglion, or by receiving a communication from one of its perivascular sympathetic nerve extensions into the cranium. These are probably vasomotor fibres, and experiments have been quoted to show that they exert a vasoconstrictor action on pial vessels. Current physiological teaching, however, accords little importance to autonomic control of intracranial arteries in general (but *see* cerebral blood flow—p. 1044).

Various types of sensory nerve ending, including simple end-bulbs, and Meissner's and Pacinian corpuscles, have been described in the dura mater in various mammals, but little recent information is available concerning man. Thus, the functional role of the sensory and autonomic supply to the dura mater remains uncertain.

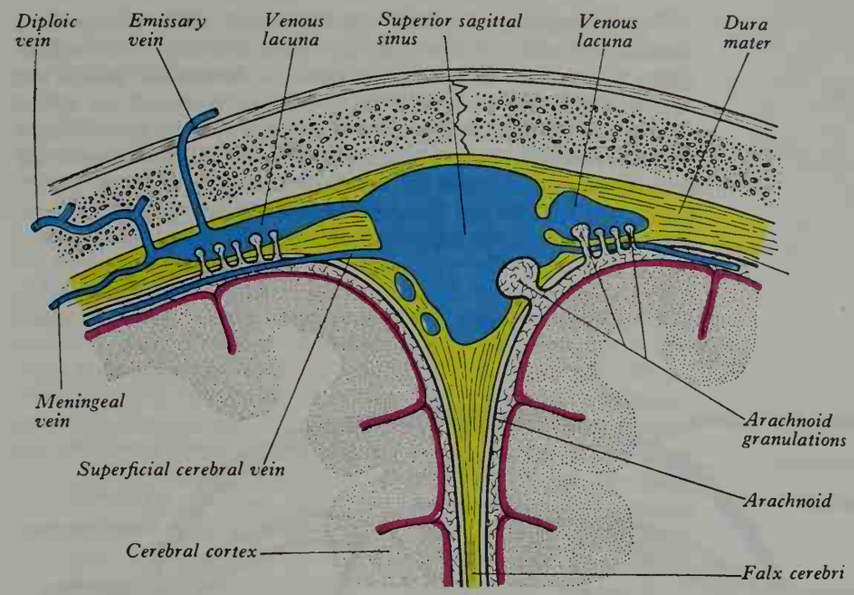
The spinal dura mater (7.163, 167) forms a loose sheath around the spinal cord, and represents only the inner, or meningeal, layer of the cerebral dura mater; the outer, or endosteal, layer being represented by the periosteum lining the vertebral canal, which is separated from the spinal dura mater by an interval, termed the *extradural space*. The spinal dura mater is attached to the circumference of the foramen magnum, and to the posterior surfaces of the bodies of the second and third cervical vertebrae; it is also connected by fibrous slips to the posterior longitudinal ligament of the vertebrae, especially near the lower end of the vertebral canal. The subdural cavity ends at the lower border of the second sacral vertebra; below this level the dura mater closely invests the filum terminale of the spinal cord and descends to the back of the coccyx, where it blends with the periosteum. The dura mater has tubular prolongations along the roots of the spinal nerves and the spinal nerves themselves as they pass through the intervertebral foramina (7.167). These

7.165 A diagram to show the structure of a small arachnoid granulation. (After W. E. Le G. Clark.)

prolongations are short in the upper part of the vertebral column, but gradually become longer below, owing to the increasing obliquity of the nerve roots (7.37). The dural sheaths of the spinal nerves fuse with their connective tissue sheaths in or slightly beyond the intervertebral foramina. This continuity may act as a slight check on movements of the nerves when tensed by bodily movement. In the cervical region, where the nerves are short and vertebral movement greatest in range, the nerve sheaths are bound strongly to the periosteum covering the adjacent transverse processes (Sunderland 1974).

The extradural space lies between the spinal dura mater and the periosteum and ligaments within the vertebral canal; it contains a quantity of loose fat and areolar tissue and a plexus of veins. The loose fat and areolar tissue of the space, which is known to clinicians as the *epidural space*, extends laterally for a short distance through the intervertebral foramina along the spinal nerves. Dyes or other fluids injected into the sacral hiatus under pressure can spread upwards to the base of the skull in the extradural space, and local anaesthetics injected in the neighbourhood of one spinal nerve immediately outside the intervertebral foramen may spread either upwards or downwards to affect the nerves of adjoining segments, or may spread to the opposite side. In each instance the spread occurs through the extradural space. (For the nerve supply of the spinal dura mater, *see* p. 1089.)

The subdural space is a potential space between the dura mater and the arachnoid mater. It contains a film of serous fluid which moistens the surfaces of the opposed membranes. It does not appear to communicate with the subarachnoid space, but is continued for a short distance on the cranial and spinal nerves, and is in free communication with the lymph spaces of the nerves. Around the optic nerve it is continued as far as the back of the eyeball. The significance of the subdural space in terms of function remains a matter of argument rather than demonstration. Possible connexions with venous channels on the one hand and with hypothetical lymph spaces in the substance of the dura mater on the other have been claimed and disclaimed. (*See* Hoffmann and Thiel 1956, for a discussion of these views.) The evidence of electron microscope observations is against the occurrence of any specialized cells of epithelial type in the dura mater, apart from its arachnoid surface, all the dural fibroblasts being of similar appearance. The dural lacunae may in fact be artefacts; certainly the evidence available refutes the passage of significant amounts of a lymphatic fluid from the dura into the subdural or subarachnoid spaces (Kaplan and Ford 1966). In the case of the spinal dura mater, however, there is undoubtedly a lymphatic drainage in regard to the extradural adipose tissue, and this may also include the dura itself (Millen and Woollam 1962).



THE ARACHNOID MATER

The arachnoid is a delicate membrane enveloping the brain and spinal cord and lying between the pia mater internally and the dura mater externally. It is separated from the dura mater by the *subdural space*, but here and there this space is traversed by isolated connective tissue trabeculae which are most numerous on the posterior surface of the spinal cord. It is separated from the pia mater by the *subarachnoid space*, which is filled with cerebrospinal fluid.

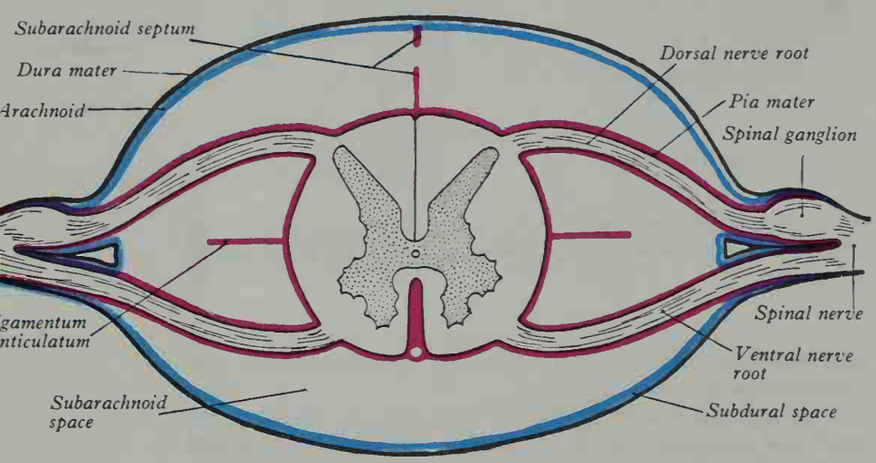
The arachnoid surrounds the cranial and spinal nerves, and encloses them in loose sheaths as far as their points of exit from the skull and vertebral canal.

The *cerebral part of the arachnoid* invests the brain loosely, and does not dip into the sulci between the gyri, nor into the fissures, with the exception of the longitudinal fissure. On the upper surface of the brain it is thin and transparent; at the base it is thicker, and slightly opaque towards the central part, where it extends between the two temporal lobes in front of the pons, so as to leave a considerable interval between it and the pia mater. It cannot be identified in the hypophysial fossa.

The *spinal part of the arachnoid* (7.163, 167) is a thin, delicate tubular membrane loosely investing the spinal cord. Above, it is continuous with the cerebral arachnoid; below, it widens out, invests the cauda equina, and ends at the level of the lower border of the second sacral vertebra. (For the structure of the pia-arachnoid *see* p. 1051.)

7.166 A coronal section through the vertex of the skull to show the arrangement of the veins and the meninges of the brain and arachnoid granulations.

The subarachnoid space is the interval between the arachnoid and pia mater. It contains the cerebrospinal fluid and the larger blood vessels of the brain, and is traversed by a network of delicate connective tissue trabeculae, which connect the arachnoid to the pia mater. The pia mater and the arachnoid are in close contact on the summits of the cerebral gyri; but where the arachnoid bridges the sulci, angular spaces are left, in which the subarachnoid trabecular tissue is found. At certain parts of the base of the brain, the arachnoid is separated from the pia mater by wide intervals, which communicate freely with each other and are named *subarachnoid cisterns*; in these the subarachnoid tissue is scanty and may be absent.



The Subarachnoid Cisterns (7.164).

The *cerebello-medullary cistern* (*cisterna magna*) (7.164) is formed by the arachnoid bridging the interval between the medulla oblongata and the inferior surface of the cerebellum and is triangular on sagittal section; it is continuous below with the subarachnoid space of the spinal cord. The *pontine cistern* (7.164) is an extensive space on the ventral surface of the pons. It contains the basilar artery, and is continuous below with the subarachnoid space of the spinal cord, behind with the cerebello-medullary cistern, and rostral to the pons with the interpeduncular cistern. As the arachnoid extends across between the two temporal lobes, it is separated from the cerebral peduncles and the structures in the interpeduncular fossa by the *interpeduncular cistern*, which contains the circulus arteriosus. Anteriorly the interpeduncular cistern is continued rostral to the optic chiasma and is prolonged over the surface of the corpus callosum; here the arachnoid stretches between the cerebral hemispheres immediately below the free border of the falx cerebri, and this leaves a space in which the anterior cerebral arteries are contained. The *cistern of the lateral fossa* contains the middle cerebral artery, and is formed in front of each temporal lobe by the arachnoid bridging the lateral sulcus. The *cistern of the great cerebral vein* (*cisterna ambiens*, or *superior cistern*) occupies the interval between the splenium of the corpus callosum and the superior surface of the cerebellum; it contains the great cerebral vein and the pineal gland. It is a widely used neurosurgical landmark.

Other less prominent cisternae have been described; these include the *prechiasmatic* and *postchiasmatic cisterns* related to the optic chiasma, the *cistern of the lamina terminalis*, and the *supracallosal cistern*, all of which, in the above account, were included as extensions of the interpeduncular cistern, and which contain the anterior cerebral arteries.

The subarachnoid space communicates with the general ventricular cavity of the brain by three openings: the *median aperture* (p. 932) is in the median plane in the inferior part of the roof of the fourth ventricle; the two *lateral apertures* are at the extremities of the lateral recesses of that ventricle (p. 932), behind the upper roots of the glossopharyngeal nerves. There is no direct communication between the subdural and subarachnoid spaces. Communications exist between the tissue spaces in the nasal mucous membrane and the subarachnoid space through channels which are present along the course of the olfactory nerves.

The spinal part of the subarachnoid space is a relatively wide interval, and is largest at the lower part of the vertebral canal,

7.167 A transverse section through the spinal cord and its membranes. *Black:* dura mater. *Blue:* arachnoid mater. *Red:* pia mater.

where the arachnoid encloses the roots which form the cauda equina. Above, it is continuous with the cranial subarachnoid space; below, it ends at the level of the lower border of the second sacral vertebra. It is partially divided by two septa, termed, respectively, the subarachnoid septum and the ligamentum denticulatum. Both are described later (p. 1051).

The arachnoid granulations (7.165, 166) are small fleshy-looking elevations, usually collected in clusters, which are present in the vicinity of the superior sagittal, transverse, and some other sinuses. When the sagittal sinus and the venous lacunae on each side of it are opened, granulations will be found protruding into their interior (7.166). On close inspection they may be seen at the age of eighteen months, and at the age of three they are disseminated over a considerable area; they increase in number and size as age advances. They cause absorption of the bone, and so produce the pits or depressions on the inner aspect of the skull cap. Arachnoid granulations are macroscopic enlargements, or distensions, of minute projections of the arachnoid mater, termed *arachnoid villi*, which are normally present in great numbers in young subjects.

The growth and structure of the arachnoid villi and granulations have been studied in much detail (Le Gros Clark 1920). Histologically each villus appears as a diverticulum of the subarachnoid space, penetrating into the interstices of the dura mater, and covered by a layer of flattened cells containing large oval nuclei and lightly staining protoplasm. In the subarachnoid space there is a reticulum of fine fibrous tissue, the density of which is as a rule greater at the periphery than at the centre of the granulation; in advanced age it frequently contains calcareous nodules.

At the summit of the villus the mesothelial cells proliferate and form a cap which penetrates the surrounding dura mater, and fuses with the endothelial lining of one of the intradural venous sinuses (7.165); in doing so it pulls out a little stalk of arachnoid containing a diverticulum of the subarachnoid space. Except at the point of fusion with the endothelial lining of the sinus, the villus is surrounded by the subdural space and the dura mater; the latter, covered on its cerebral surface by a layer of mesothelium, is invaginated into the venous sinus by the protrusion of the granulation.

Fluid injected into the subarachnoid space passes into these granulations and villi, and it has been found experimentally that fluid passes by osmosis from the arachnoid villi into the venous sinuses of the dura mater.

The *cerebrospinal fluid* (Davson 1970) is a clear, slightly alkaline fluid, with a specific gravity of about 1007. It contains in solution inorganic salts similar to those in the blood plasma, and also traces of protein and glucose. The cerebrospinal fluid is secreted into the ventricles of the brain by the choroid plexuses and into the subarachnoid space by the plexuses sited in the lateral recesses of the fourth ventricle (p. 932). From the ventricles it passes through the median aperture and the foramina of the lateral recesses of the fourth ventricle and so gains the subarachnoid space in the cerebello-medullary cistern and the pontine cistern. Within the cranium the cerebrospinal fluid flows upwards through the gap in the tentorium cerebelli and then forwards and laterally over the inferior surface of the cerebrum. Finally it ascends the superolateral aspect of each hemisphere to reach the arachnoid villi associated with the superior sagittal sinus, and so is able to pass back again into the bloodstream. It is generally held that within the vertebral canal there is no active flow, but that the process of diffusion and alterations of posture serve to maintain the character of the fluid constant throughout the whole extent of the subarachnoid space. Experimental work (Howarth and Cooper 1949) suggests that the spinal cerebrospinal fluid may drain back locally into the venous system, through the vertebral venous plexuses, the intervertebral veins and the posterior intercostal and upper lumbar veins into the azygos and hemiazygos veins. The cerebrospinal fluid supports the brain and spinal cord, and it maintains a uniform pressure upon them. It has been stated that a brain weighing 1,500 gm. in air, weighs no more than 50 gm. in cerebrospinal fluid, and through the latter, the total weight of the system is evenly distributed to the meningeal parieties, and their mechanical supports. Our knowledge of the circulation of the cerebrospinal fluid and of the arachnoid villi was, to a large extent, built up on the work of Weed (1920, 1938). Electron microscope studies suggest that there is an open communication between the subarachnoid space and the lumen of the superior sagittal sinus by means of fine tubules, lined by an endothelium, traversing the core of arachnoid granulations in the sheep. A valvular action is hypothecated for these tubules, but this form of drainage, if confirmed, does not exclude filtration (Jayatilaka 1965).

Applied Anatomy. Diseases of the central nervous system and its membranes are often reflected in alterations of the cells which are normally found in the cerebrospinal fluid or in alterations in the concentration of its chemical constituents. Interference with the circulation of the fluid is indicated by variations in the pressure within the meninges. The determination of these alterations and variations is often of service in diagnosis.

Specimens of the cerebrospinal fluid may be obtained by the operation of *lumbar puncture*, which is performed through the interval between the laminae or spines of the third and fourth (or fourth and fifth) lumbar vertebrae. A fine trocar and cannula is inserted at the point of intersection of the intertubercular plane with the posterior median line and is passed obliquely upwards and forwards above the upper border of the spine of the fourth lumbar vertebra. It is carried through, or parallel to, the supraspinous and interspinous ligaments into the vertebral canal. The dura mater and the arachnoid are punctured and the instrument is introduced into the subarachnoid space below the lower end of the spinal cord (7.34). When the trocar is withdrawn, the cerebrospinal fluid escapes through the cannula at the rate of one drop per second, under normal conditions, but when the fluid is under increased pressure it escapes in an almost continuous stream. It should also be noted that the introduction of a large needle, such as a trocar, between the vertebral laminae is rather difficult except at lumbar levels. Moreover, the introduction of its point, accurately enough to withdraw fluid, into the narrow subarachnoid space surrounding the spinal cord would be extremely difficult, apart from the danger to the cord itself.

THE PIA MATER

The pia mater closely invests the brain and spinal cord; it is a vascular membrane, consisting of a plexus of minute blood vessels held together by an extremely fine areolar tissue. The *cerebral pia mater* invests the entire surface of the brain, dips between the cerebral gyri and between the cerebellar laminae, and is invaginated to form the tela choroidea of the third ventricle, and the choroid plexuses of the lateral and third ventricles (pp. 1028 and 981); as it passes over the roof of the fourth ventricle, it forms the tela choroidea and the choroid plexuses of this ventricle (p. 932). Upon the surfaces of the hemispheres it gives off from its deep surface a multitude of sheaths around the minute vessels that run perpendicularly for some distance into the cerebral substance. On the cerebellum the membrane is more delicate; the vessels from its deep surface are shorter, and its relations to the cortex are not so intimate. Like the arachnoid, the pia mater cannot be identified in the hypophysial fossa.

The *spinal pia mater* (7.163, 167) is thicker, firmer, and less vascular than the cerebral pia mater, but like the latter it consists of an outer '*epi-pia*' containing the larger vessels, and internal to this a so-called '*pia-glia*' or '*pia-intima*' in direct contact with the nervous tissue (*vide infra*). Between the layers are cleft-like spaces which communicate with the subarachnoid space, and a number of blood vessels. The spinal pia mater covers the spinal cord, and is intimately adherent to it; in front it dips into the anterior median fissure and lines its walls, the two layers involved being connected by a loose open meshwork of fine fibrous strands (7.167). A longitudinal fibrous band, called the *linea splendens*, extends along the median plane anteriorly. The *ligamentum denticulatum* is situated on each side and the *subarachnoid septum* is present posteriorly (7.167). Below the conus medullaris the pia mater is continued as a longer slender filament, named the *filum terminale* (p. 865).

The pia mater forms sheaths for the cranial and spinal nerves; these sheaths are closely connected with the nerves, and blend with their common membranous investments.

The *ligamentum denticulum* (7.163, 167) is a narrow, fibrous sheet situated on each side of the spinal cord, between the ventral and the dorsal nerve roots. Its medial border is continuous with the pia mater at the side of the spinal cord. Its lateral border presents a series of triangular tooth-like processes, the points of which are fixed at intervals to the dura mater. These processes are twenty-one in number, on each side. The first process crosses behind the vertebral artery at the point where that vessel pierces the dura mater, and is separated by the artery from the ventral root of the first cervical nerve; it is attached to the dura mater immediately above the margin of the foramen magnum, a short distance behind the hypoglossal nerve, and the spinal part of the accessory nerve ascends on its posterior aspect (7.59). The last process is between the exits of the twelfth thoracic and first lumbar nerves, and consists of a narrow oblique band running downwards and laterally from the conus medullaris (7.163). Changes in the form and position of the denticulate ligament during spinal movements have been demonstrated by cineradiographic techniques (Epstein 1966).

The *subarachnoid septum* is an interrupted sheet of fibrous tissue, situated in the median plane. It connects the arachnoid to the pia mater opposite the posterior median sulcus (7.167). Incomplete and cribriform in the cervical region, it forms a more complete partition at thoracic levels.

The Microscopic Structure of the Leptomeninges

The finer structure of the arachnoid and pial meninges is more appropriately described in conjunction (Winckler 1960). They have a common phylogenetic history, develop embryologically in continuity, and preserve this intimate relationship in their final differentiation to such an extent that they are frequently regarded as a *pia-arachnoid* rather than two separable entities. They will, however, be described here successively, largely because it is still widely customary to employ separate names for them.

The structure of the arachnoid mater, like that of the pia, is essentially that of loose, irregular connective tissue. Both the leptomeninges, like the dura mater, or pachymeninx, are regarded as being of mesodermal origin, though there is some doubt with respect to the innermost region of the pia mater, which may be of ectodermal derivation (Millen and Woollam 1961). In the most primitive vertebrates all three meninges are represented by an undifferentiated *meninx primitiva*; but in tetrapods a distinction into the thick external dura mater and a more delicate internal leptomeninx is established, and in mammals and birds this reaches its most differentiated form. All three meninges develop in the mesenchyme surrounding the central nervous system, with the possible proviso mentioned above.

The *arachnoid mater* consists of collagen, elastin, and reticulin fibres, together with flattened cells usually regarded as mesothelial in type, although there is some disagreement as to this latter point. Both on its dural aspect and on its internal surface, where it forms the external boundary of the subarachnoid space, cells with long cytoplasmic processes and a paler cytoplasm than the fibrocytes of the dura mater are arranged in several layers, with an underlying basement membrane. Tight junctions between some of these cells are demonstrable by electron microscopy (Nelson *et al.* 1961), but collagen fibres are interspersed among them and elastic fibres may also appear between the layers of cells. The fibre elements of the arachnoid are of more gracile proportions than those of the dura mater. Fine strands or *trabeculae* of arachnoid tissue extend inwards across the *subarachnoid space*, and these also are usually considered to show a covering of 'mesothelial' cells, within which are collagen fibres and then reticulin fibres surrounding the numerous small vessels which pass through the trabeculae to reach the pia mater and central nervous system. The trabeculae vary much in size and distribution; most are fine strands and they are most numerous in the intracranial part of the subarachnoid space, but are largely absent where this is dilated to form cisternae (p. 1049) and are little evident in the spinal region of the space in man. Descriptions of the trabeculae are frequently illustrated from other mammals and this may convey a false or exaggerated impression of their development in mankind. The spaces between the trabeculae are usually extensive and are described as running together to form a single intercommunicating subarachnoid space; but in the human arrangement large stretches of the space are completely free from trabeculae.

Crossing the subarachnoid space the arachnoid trabeculae fuse with the pia mater, which is itself sometimes regarded as divisible into two layers (*vide infra*), the external being a vascularized connective tissue stratum, covered by a mesothelium bounding the subarachnoid space on its internal or cerebral aspect. Some observers regard this stratum of the pia mater as being arachnoid tissue, considering only the avascular layer of collagen and other fibres and their accompanying cells which are immediately adjacent to nervous tissue to represent the true pia. In this case the subarachnoid space is described as being *in* the arachnoid mater. Others prefer to think of the two leptomeninges as a conjoined pia-arachnoid membrane, as stated earlier.

The arachnoid mater is not itself much vascularized, and is often described as avascular; but it does act as a connective tissue support for large numbers of small vessels and their accompanying nerve supplies, traversing the trabeculae to reach the pia mater. Its mesothelial elements and basement membrane, and particularly the tight junctions between the cells, are a barrier to free diffusion of colloidal substances between the subarachnoid space, subdural space, the central nervous system and its non-capillary vessels in both their extra- and intra-cerebral sites. The return of the cerebrospinal fluid is thus largely, if not entirely limited to the arachnoid villi (p. 1048), where this permeability barrier is modified and also circumvented by a system of minute valvular canals. The barrier is also absent where the craniospinal nerves pass through fused sleeves of pia and arachnoid as they blend with the perineurium. At these locations cerebrospinal fluid can diffuse through the arachnoid tissue into neighbouring lymphatics.

The structure of the pia mater is also that of a loose connective tissue, containing collagen, elastin and reticulin fibres with flattened 'mesothelial' cells like those of the arachnoid. These cells are considered to be fibrocytic elements by some authorities, especially where they form several layers, associated

with reticulin fibres, next to the central nervous system. Here the most internal cells are directly apposed to a convoluted basement membrane, intervening between them and the subjacent end-feet of astrocytes. This relationship is so intimate that the most internal stratum of the pia, together with the basement membrane and the glial processes, is sometimes described as the '*pia-glia*'. It is also sometimes distinguished as the '*pia-intima*', and thus differentiated from the rest of the membrane, the '*epi-pia*', which is the pial element regarded as arachnoid by some, as mentioned above. Sleeves of both pia and arachnoid, with an intervening extension of the subarachnoid space, are carried into the central nervous system around the blood vessels entering or leaving it, forming the perivascular cuffs which have been the subject of so much past disagreement.

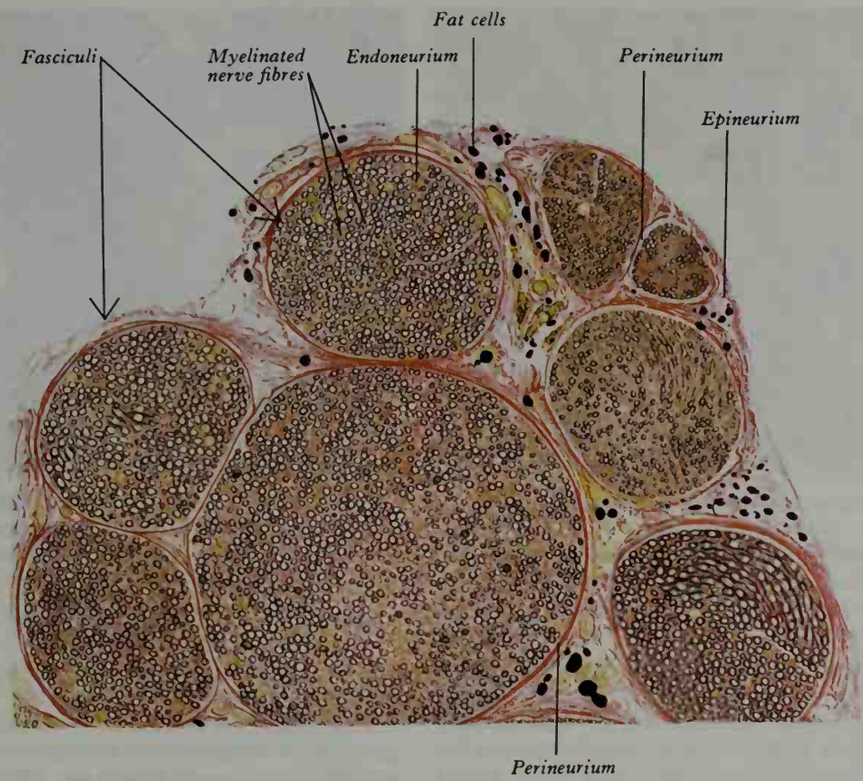
The pia mater contains large numbers of blood vessels and their accompanying nerve supplies. On the surface of the spinal cord the more external connective tissue layer of the pia, the epi-pia, is more developed than it is on the cerebral surface, where it is not easily identified. In this stratum the vessels are suspended by trabeculae of pial tissue which meet and blend with arachnoid trabeculae where these are present. Thus many pial vessels project from the surface as they ramify in their pia-arachnoid suspension, and are at least partially surrounded by extensions of the subarachnoid space. Where they turn into the central nervous system prolongations of the space and the two leptomeninges accompany each vessel as far as the commencement of its capillaries. Hence the latter are not separated from nervous tissue by the connective tissue or mesothelial elements which accompany the precapillary vessels; the 'pia-glial' barrier is absent. Current physiological views reject the concept of any significant interchange of fluid between the perivascular extensions of the subarachnoid space and nervous tissue or blood, nor is drainage circulation through them considered likely. It is suggested that these minute fluid-filled spaces merely act as a displaceable medium to accommodate the pulsatile variation in the calibre of the vessels which they surround.

The coverings of the central nervous capillaries are like those in the choroid plexuses (p. 1050) in the complete absence of ordinary connective elements from their surroundings. The neuronal level is separated from the blood only by the vascular endothelium, the end-feet of astrocytes and the basement membrane which they share. While the individual contribution of these structures to the human *blood-brain barrier* cannot yet be stated with certainty, abundant experimental evidence indicates that this is the major and probably the exclusive site of entry of fluid and solutes into the central nervous tissue, the arachnoid villi providing the main exit for cerebrospinal fluid, and the drainage of fluid from the nervous tissue being partly back into the prevenous ends of the capillaries and perhaps through ependyma into the ventricular system. Experiments in the mouse, using horseradish peroxidase as an electron-dense tracer have, however, shed some light on the problem of the blood-brain barrier (Brightman *et al.* 1970). In most of the central nervous situations examined, complete circumferential tight junctions, between adjacent capillary endothelial cells, totally prevent the passage of the tracer. Similar junctions exist between the modified ependymal cells which clothe the choroid plexus. To what extent such findings apply to other sites, animals and substances, remains speculative.

Apart from their functions in the production, circulation and reabsorption of the cerebrospinal fluid, the meninges also serve as a support to the central nervous system, especially in association with the buoyant effect of the fluid. Like connective tissues elsewhere they also provide routes of access and support for the vessels of the central nervous system, and they constitute at least a mechanical barrier against infection.

THE PERIPHERAL NERVOUS SYSTEM

The peripheral nervous system comprises the afferent, or centripetal, fibres which connect the sensory end organs to the central nervous system, and the efferent, or centrifugal, fibres which connect the central nervous system to the effector apparatus. It includes the twelve pairs of cranial nerves which arise from the brain, and the thirty-one pairs of spinal nerves which arise from the spinal cord. The sympathetic trunks with their various ganglia and branches belong to this system, but they will be dealt with in a separate section (pp. 1121–1138).



In the most primitive vertebrates the spinal cord gives rise to a series of ventral nerve roots, arising from the anterior grey column and motor in function, and a series of dorsal nerve roots, connected to the posterior grey column and sensory in function. The ventral and dorsal nerve roots do not unite, and they do not correspond in position. The ventral nerve root is segmental and is distributed to the myotome which corresponds to the neuromere from which it arises. The dorsal nerve root is intersegmental in position and runs in the intersegmental connective tissue to reach its cutaneous distribution. In the majority of fishes and in all higher forms the corresponding ventral and dorsal nerve roots which emerge from the spinal cord unite with one another to constitute the individual spinal nerves. The arrangement of the spinal nerves, therefore, follows a very primitive pattern and has not undergone much modification in the process of evolution.

The arrangement of the cranial nerves, on the other hand, has been very profoundly modified. The development and modification of the branchial system and the suppression of segments owing to the elaborate changes which occur in the region of the head have been largely responsible for this modification. In the brain, corresponding ventral and dorsal nerves *never* fuse, although adjoining ventral or dorsal nerves may and actually do unite. Owing to the complete disappearance of certain myotomes the corresponding ventral nerves become completely suppressed. Further, the dorsal nerves, originally sensory nerves supplying chiefly the skin of the head and the mucous membrane of the mouth and pharynx acquire motor fibres which they distribute to the musculature arising in the branchial region (p. 151). With the growth and modification of the brain and the consequent elaboration of the head region, the cutaneous areas of the head are transferred from one nerve to its neighbour, so that the functions of the individual dorsal nerves become altered.

The incorporation of some of the precervical segments in the head leads to the fusion of the corresponding ventral nerves, and the hypoglossal nerve so formed becomes added to the cranial series.

The cerebrospinal nerves, as we have seen in greater detail elsewhere (p. 838), consist of numerous nerve fibres collected into bundles, which are enclosed in connective tissue sheaths (7.168): a small bundle of fibres is called a *fasciculus*. Each fasciculus is surrounded by a connective tissue sheath, named the *perineurium*. Individual nerve fibres are ensheathed, held together and supported within the fasciculus by delicate connective tissue called the *endoneurium*; it is continuous with septa which pass inwards from the perineurium. The collagen fibres of the endoneurium tend to be longitudinally orientated and bundles are sometimes invaginated into the Schwann cells of non-myelinated nerve fibres (Gamble and Eames 1964). If small, the nerve may consist of only a single fasciculus; but if large, it consists of several fasciculi held together and invested by connective tissue; this investment is known as the *epineurium*. The cerebrospinal nerves consist both of myelinated and non-myelinated nerve fibres, the proportion of each varying with the functional roles of the nerve concerned.

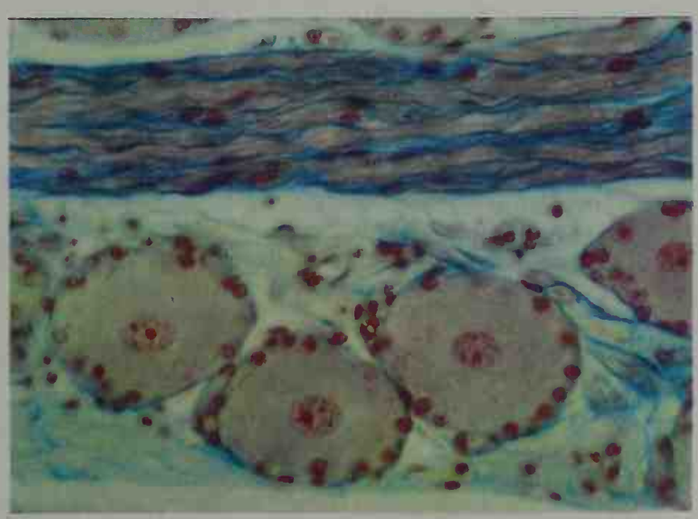
The blood vessels, supplying a nerve, end in a minute plexus of capillaries which pierce the perineurium, and run, for the most part, parallel with the fibres; they are connected together by short transverse vessels, forming narrow, oblong meshes, similar to the capillary system of muscle. Fine, non-myelinated, vasomotor nerve fibres accompany these vessels, and break up into fine fibrils which form a network around them. Myelinated fibres, termed

7.168 Transverse section of a peripheral nerve (cat.) Stained with osmic acid and van Gieson's technique. Note the nerve fasciculi, the epi-, peri- and endo-neurial connective tissue sheaths, and the regional variations in the calibre of the myelinated nerve fibres. Magnification about × 55.

nervi nervorum, run in the epineurium and terminate in oval or bulbous corpuscles (p. 855).

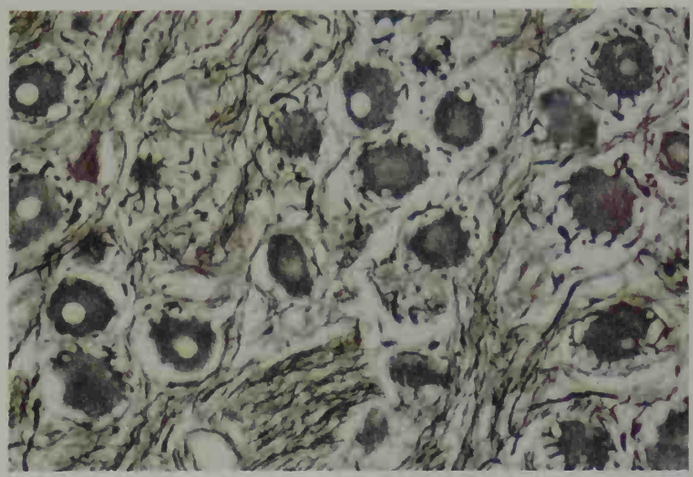
The cerebrospinal nerve fibres pursue an uninterrupted course from the centre to the periphery, but in separating a nerve into its component fasciculi, it is found that bundles of fibres from one fasciculus may join, at a very acute angle, another fasciculus proceeding in the same direction.

In their courses, nerves divide into branches, and these frequently communicate with branches of neighbouring nerves; such communications form what is called a *nerve plexus*. Such a plexus is formed by the ventral rami of the trunks of the nerves—as, for example, the cervical, brachial, lumbar and sacral plexuses—or by the terminal fasciculi, as in the plexuses formed at the periphery of the body. In the formation of a plexus, the component nerves divide, then join, and again subdivide in such a complex manner that the individual fasciculi become intricately interlaced. Hence, each branch leaving a plexus may contain filaments from more than one, and even all of the primary nerves entering the plexus. In the formation also of smaller plexuses at the periphery of the body there is a free interchange of fibres. In each case, however, the individual fibres remain separate and distinct.



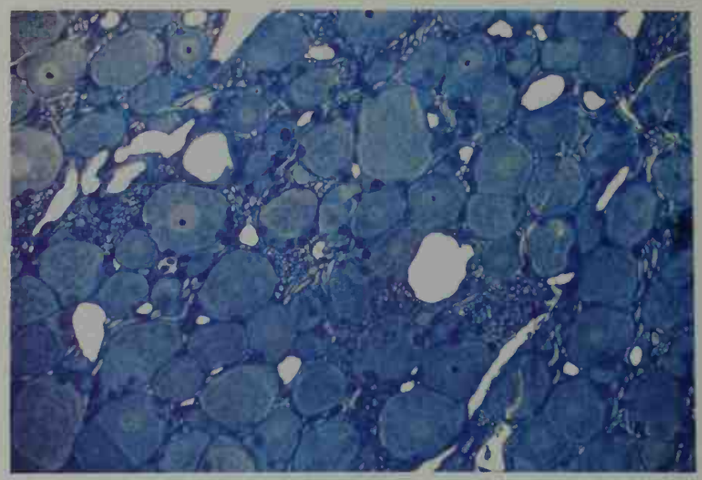
Through this interchange of fibres, every nerve leaving a plexus gains a more extensive connexion with the spinal cord than if it had proceeded direct to its distribution without joining other nerves.

The origin of a nerve is a phrase usually implying the locus of its emergence from or entry into the central nervous system. This site is sometimes called the *superficial origin*, the *deep origin* being the central group or groups of nerve cells from which the peripheral axons are derived, or to which they are proceeding. The superficial origin is in some cases single—that is to say, the whole nerve emerges from the central nervous system by a single root; in other instances the nerve arises by two or more roots. The *efferent nerve fibres* are the axons of nerve cells situated in the grey matter of the central nervous system. The *afferent nerve fibres* spring from nerve cells in the organs of special sense (e.g. the retina) or from nerve cells in the ganglia on the cerebrospinal nerves. Having entered the central nervous system they branch and send their ultimate twigs to terminate in synaptic association with nerve cells there.



The peripheral terminations of the sensory nerves are dealt with on pp. 849–857, and those of motor nerves on pp. 846–849.

Ganglia are aggregations of nerve cells found on some peripheral nerves. They are present in the dorsal roots of the spinal nerves and the sensory roots of the trigeminal, facial, glossopharyngeal, vagal and vestibulocochlear cranial nerves. They also occur in association with autonomic nerves (p. 1124). They vary considerably in form and size. Each ganglion is invested by a smooth, firm covering of fibrous connective tissue and associated flattened, fibrocyte-like cells, which is continuous with the perineurium of the nerves, and sends numerous processes into the interior of the ganglion.



Ganglia contain nerve cells and their nerve fibres, and fibres derived from cells elsewhere, which pass right through or

7.169 A typical field in a dorsal spinal nerve root ganglion. Note the characteristic juxtaposition of large ovoid nerve cell somata, and the fascicles of myelinated and non-myelinated nerve fibres. Note also the nuclei of the capsular (satellite) cells which surround each nerve cell. (Grübler's stain—material kindly provided by Dr. Lyn Gregson, Dept. of Anatomy, Guy's Hospital Medical School.)

7.170A Typical field in an autonomic ganglion (human ciliary ganglion), showing nerve cells evenly scattered among fascicles of nerve fibres. (Stained by Bielschowsky's silver and erythrosin technique in material kindly supplied by Dr. N. A. Locket, Institute of Ophthalmology, London.)

terminate within the ganglion. Their structure, which is treated briefly here, is considered in greater detail on p. 838. In the *spinal ganglia* the cells are large, unipolar, and occur in groups round the periphery; in the autonomic ganglia they are multipolar and are scattered more or less uniformly (7.169, 170). Each spinal ganglionic nerve cell has a nucleated capsule (p. 838), which is continuous with the Schwann cells of the nerve fibres connected with the cell. The larger nerve cells in the ganglia of the spinal nerves (7.169) are irregularly spherical in shape, and each gives off a single neurite ('dendro-axonal process') which runs towards the centre of the ganglion, and divides in a T-shaped manner; one limb (axon) of the crossbar enters the spinal cord, the other (dendrite) passes outwards to the periphery (but *vide infra*). Near its origin the dendro-axonal process is coiled forming a *glomerulus* (p. 829). The smaller cells, which are more numerous, and give rise to fine non-myelinated fibres in peripheral nerves and their roots, possess delicate initial dendro-axonal processes which do not form complicated glomeruli, and pass straight to their T-bifurcation.

Structurally the peripheral division of the process of a unipolar ganglion cell resembles an axon in every respect, but it functions as a greatly elongated dendrite. (It should be noted that the majority of neuroanatomists term all the elongated neurites in a peripheral nerve 'axons' whether they are afferent or efferent.) The somata of afferent neurons in primitive invertebrates, such as *Hydra*, are situated in the ectoderm, with superficial hair-like dendritic processes projecting from them. Such somata are located much deeper in all vertebrates, being close to the central nervous system. Their peripheral processes are presumably the much elongated homologue of the short 'dendrites' of the primitive nerve cells. The primary olfactory neurons retain this primitive position (p. 1143). In the sensory ganglia of the cranial nerves, the nerve cells are also unipolar, though in the ganglia of the vestibulocochlear nerve they remain bipolar in type.

THE CRANIAL NERVES

The craniocaudal sequence of cranial nerves is as follows:

1 Olfactory	5 Trigeminal	9 Glossopharyngeal
2 Optic	6 Abducent	10 Vagal
3 Oculomotor	7 Facial	11 Accessory
4 Trochlear	8 Vestibulocochlear	12 Hypoglossal

These nerves are continuous with the brain and traverse foramina in the base of the cranium. The **motor**, or **efferent**, parts of the cranial nerves arise within the brain from groups of nerve cells which constitute their *nuclei of origin*. They are connected with the cerebral cortex by the corticonuclear fibres; these arise from the cells of the motor areas of the cortex, descend chiefly in the genicular part of the internal capsule to the brainstem, where many, but not all cross the median plane and end by arborizing round the cells of the nuclei of origin of the motor cranial nerves. The **sensory**, or **afferent**, cranial nerves arise from nerve cells outside the brain; these nerve cells may be grouped to form ganglia on the trunks of the nerves, or may be situated in peripheral sensory organs such as the nose, eye and ear. The centrally directed processes of the cells run into the brain and there end by arborizing around nerve cells which are grouped to form their *nuclei of termination*. Fibres arise from the cells of these nuclei and usually after crossing to the opposite side, run up to connect the nuclei indirectly with the cerebral cortex. (Readers of the relevant parts of the 'Central Nervous System' will be aware that the foregoing remarks are a gross over-simplification.)

The fibres of most of the cranial nerves begin to acquire their myelin sheaths about the fourteenth week of intra-uterine life. The process is delayed until the twenty-second week in the cases of the sensory part of the trigeminal nerve and the cochlear division of the vestibulocochlear. In the case of the optic nerve myelination does not commence until the later stages of gestation.

The Olfactory Nerves

The olfactory nerves, serving the sense of smell (7.171), commence in the mucous membrane of the olfactory region of the nasal cavity; this region comprises the superior nasal concha and the opposed part of the nasal septum. The nerve fibres originate as the central, or deep, processes of the olfactory cells (7.118) of the nasal mucous membrane, and are collected into bundles which cross one another in various directions, thus giving the appearance of a plexiform network in the mucous membrane. They are then collected into about twenty branches, which traverse the cribriform plate of the ethmoid bone in lateral and medial groups, and end in the glomeruli of the olfactory bulb (7.118). Each branch has a tubular sheath of dura mater and pia-arachnoid, the former being continued into the periosteum of the nose, the latter into the delicate trabecular connective tissue perineurium (perineural sheaths) of the nerve bundles. The tissue spaces in these sheaths are continuous with those of the nasal mucous membrane and with the subarachnoid space above.

The olfactory nerves are non-myelinated and consist of bundles of fine axons enfolded within Schwann cells.

The olfactory nerves are unique in that their cells of origin develop in the ectoderm and retain this position throughout life in all vertebrates.

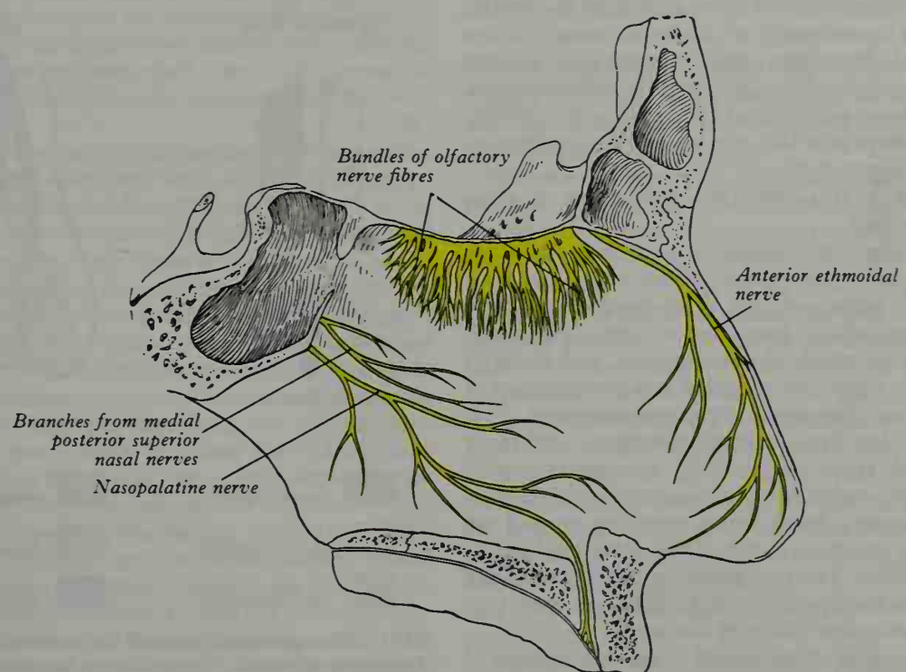
Applied Anatomy. In severe head injuries involving the anterior cranial fossa the olfactory bulb may become separated from the olfactory nerves, or the nerves may be torn, thus producing *anosmia*—loss of smell sensibility. Fractures in this situation may also involve the meninges and cerebrospinal fluid may escape into the nose. Such injuries also open up avenues for infection of the meninges from the nasal cavity. The extensions of the subarachnoid space around the bundles of olfactory nerve fibres have been regarded as a potential lymphatic drainage, and on this basis also certain meningeal infections are considered to spread along these nerves into the cranial cavity. The evidence for this is still equivocal.

Closely associated with the olfactory nerves is a pair of small nerves named the **nervi terminales** (Pearson 1941). These nerves were first seen in lower vertebrates, but their presence has been demonstrated in the human embryo and adult. They consist mainly of non-myelinated nerve fibres, and associated with them are small groups of bipolar and multipolar nerve cells. Each nerve runs along the medial side of the corresponding olfactory tract, and its branches traverse the cribriform plate of the ethmoid bone, and are distributed to the nasal mucous membrane. Centrally the nerve is connected to the brain close to the anterior perforated substance and septal areas; in some animals its fibres have been traced to the lamina terminalis, in others to the hypothalamic region. Its function is unknown; some are inclined to view it as a forward extension of the cephalic part of the sympathetic nervous system, which is distributed to the blood vessels and glands of the nasal cavity. In relation to its possible autonomic nature it is of interest that ganglion cells have been associated with the nerve by Pearson (1941) and others. The presence of such ganglia has been observed in the mouse by Grüneberg (1973), who does not, however, equate this with the ganglion cells scattered along the human terminal nerve. The connexions of the '*ganglion terminale*' are at present unknown. Bojsen-Møller (1975) considered the nerve to be entirely sensory. The **vomeronasal nerve**, with which the nervus terminalis has been frequently confused, is probably absent in adult man. (See also 994, 1114.)

The detailed architecture and central connexions of the olfactory bulb are described on pp. 991–995, and for the detailed structure of the olfactory mucosa *see* p. 1143.

The Optic Nerve

The optic nerve, mediating vision, is distributed to the eyeball. Most of its fibres are afferent and originate in the nerve cells of the ganglionic layer of the retina (p. 1172), but some are efferent, their source of origin being uncertain. Developmentally, the optic nerves and the retinae are parts of the brain (p. 176), and their fibres are provided with glial and not Schwann cell sheaths.



The fibres of the optic nerve form the innermost layer (*stratum opticum*) of the retina and are the axons of the cells in its ganglionic layer; they converge on the optic disc, and there pierce the outer layers of the retina, the choroid coat, and the lamina cribrosa of the sclera at the posterior part of the eyeball, about 3 or 4 mm to the nasal side of its centre. As the fibres traverse the lamina cribrosa they receive their myelin sheaths, and run in bundles which are collected to form the optic nerve.

The optic nerve, about 4 cm long, is directed backwards and medially through the posterior part of the orbital cavity. It then runs through the optic canal into the cranial cavity and joins the optic chiasma.

The intraorbital part of the nerve is about 25 mm long and has a slightly sinuous course, the length of the nerve being about 6 mm more than the distance between the optic canal and the eyeball. Posteriorly it is closely surrounded by the four recti, but anteriorly is separated from them by a quantity of fat, in which run the ciliary vessels and nerves. The ciliary ganglion lies between the nerve and the lateral rectus. The inferomedial surface of the nerve is pierced, at a distance of about 12 mm behind the eyeball, by the central artery and vein of the retina, which are then directed forwards in the centre of the nerve to the optic disc. In the optic canal, which is about 5 mm long, the nerve lies above and medial to the ophthalmic artery, and is separated medially from the sphenoidal and posterior ethmoidal sinuses by a thin lamina of bone; in front of the canal the nasociliary nerve and the ophthalmic artery run forwards and medially, crossing above the optic nerve, whilst the branch to the medial rectus from the inferior division of the oculomotor nerve passes below it (7.183).

The intracranial part of the optic nerve, about 10 mm long, runs backwards and medially from the optic canal to the optic chiasma. The posterior parts of the olfactory tract and gyrus rectus, and, near the chiasma, the anterior cerebral artery lie above it. The internal carotid artery is on its lateral side.

The optic nerve is enclosed in three sheaths, which are continuous with the membranes of the brain (7.258), and are prolonged as far as the back of the eyeball. The *outer sheath*,

7.171 The nerves of the septum of the nose. Right side.

derived from the dura mater, is thick and fibrous, and blends anteriorly with the sclera. The *intermediate sheath*, derived from the arachnoid mater, is thin and delicate. It is separated from the outer sheath by the subdural space, and from the inner sheath by the subarachnoid space. The *inner sheath*, derived from the pia mater, is vascular and closely invests the nerve. From its deep surface septa pass into the nerve and subdivide and reunite to enclose what appear, in transverse sections of the nerve, as polygonal areas, which are occupied by the bundles of nerve fibres. There are about 1,000 such fascicles. From the inner sheath also, an investment is carried on the central vessels of the retina as far as the optic disc.

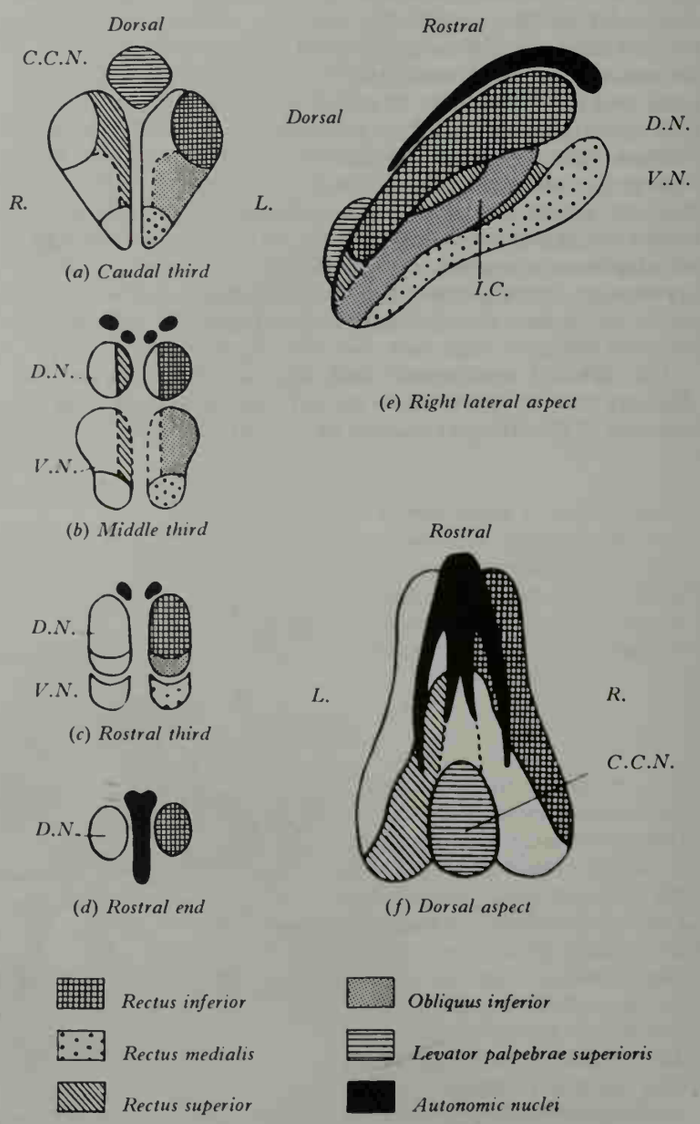
The ultrastructure of the meninges of the optic nerve resembles that of the meninges elsewhere (Anderson and Hoyt 1969), but the amount of collagen fibres in the pia and arachnoid is greater than in the general intracranial leptomeninges. Here, as elsewhere, the subarachnoid space is lined completely by epithelial cells of the pia-arachnoid which resemble flattened fibroblasts, forming multilaminar surface membranes of 'mesothelium' or 'meningothelium'.

Close to the eyeball the macular fibres (*papillo-macular bundle*) occupy the lateral part of the nerve, but, as they are traced backwards, they gradually come to lie medially; in front of the chiasma they are close to the medial margin. The fibres from the upper and lower portions of the retina lie above and below respectively; the fibres from the temporal quadrants lie laterally and those from the nasal quadrants medially.

The most recent counts of optic nerve fibres in man (Oppel 1963; Kupfer *et al.* 1967) give a figure of about 1,200,000 myelinated axons, about 92 per cent of which are small (about 1 μm in diameter), the rest varying from 2 to 10 μm. About 53 per cent cross in the chiasma. Most terminate in the lateral geniculate body, but fractions of uncertain size pass to the pretectal nucleus, superior colliculus, and certain hypothalamic nuclei (p. 973). A small proportion of the optic nerve fibres are efferent but of uncertain origin. Centrifugal nerve fibres passing to the retina have attracted much interest in birds, in which their occurrence is well established, being derived from the *isthmo-optic nucleus*, a group of nerve cells situated dorsolaterally at the junction of the mid- and hind-brains. (Consult Cowan and Clarke 1976 for details.)

The optic nerve is supplied by vessels from the plexus in the investing pia and by direct intraneural branches. The pial plexus receives branches from a superior hypophysial artery and the ophthalmic artery intracranially, from recurrent branches of the ophthalmic artery in the optic canal and from the posterior ciliary arteries and the extraneural part of the central retinal artery in the orbit. The intraneural branches to the nerve arise from the central artery, but their actual contribution to the blood supply of the nerve is probably small (Belmonte 1968; François and Neetens 1969). The rich blood supply of the optic papilla and the lamina cribrosa has recently been emphasized (Henkind and Levitsky 1969). The venous drainage is by the central vein of the retina (*see* p. 748, and Steele and Blunt 1956).

The optic chiasma (p. 974), and the **optic tract** (p. 975), have already been described.



Applied Anatomy. The optic nerve is peculiarly liable to neuritis or atrophy in certain affections of the central nervous system, and there are certain points in connexion with the anatomy of this nerve which may throw light upon such associations. (1) From its mode of development, and from its structure, the optic nerve must be regarded as a prolongation of the brain substance, rather than as an ordinary cranial nerve. (2) It receives sheaths from the three cerebral meninges, and these sheaths are separated from each other by spaces which communicate with the subdural and subarachnoid spaces respectively. The innermost sheath sends a process around the arteria centralis retinae into the interior of the nerve, and enters intimately into its structure. Thus inflammatory affections of the meninges or of the brain may readily extend along these spaces, or along the interstitial connective tissue in the nerve.

The *optic neuritis* or *papilloedema* that is often seen in cases of intracranial new growth with increased intracranial tension, is probably caused by increased pressure due to excess of fluid in the general subarachnoid space, since this is in direct communication with a prolongation of the space around the optic nerve as far as the lamina cribrosa (p. 1152).

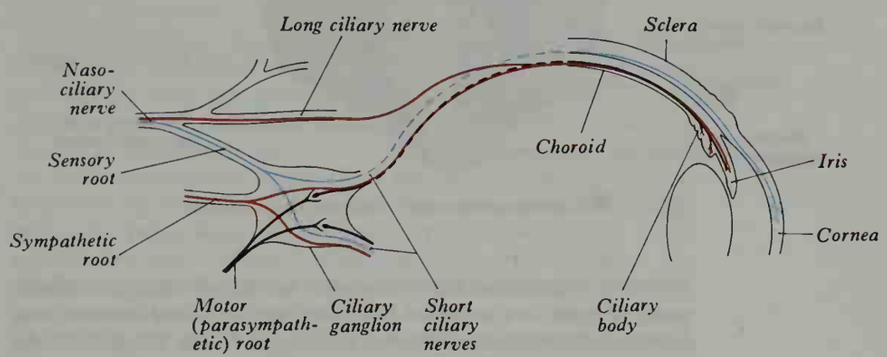
The Oculomotor Nerve

The oculomotor nerve (6.123, 124; 7.109, 120, 174, 184) supplies all the extraocular muscles, except the obliquus superior and rectus lateralis; it also supplies, through its connexion with the ciliary ganglion, the sphincter pupillae and the ciliaris, which are, of course, intraocular. It contains about 24,000 fibres.

The fibres of the oculomotor nerve arise from a *complex of nuclei* in the grey matter, ventral to the cranial part of the cerebral aqueduct, which extends cranially for a short distance into the floor of the third ventricle. From this the fibres pass forwards through the tegmentum, the red nucleus and the medial part of the substantia nigra, forming a series of curves with a lateral convexity, and emerge from the sulcus on the medial side of the cerebral peduncle (7.62, 64, 92). In its peripheral course the oculomotor nerve contains afferent nerve fibres whose cell bodies are in the trigeminal ganglion. (*See* Bortolami *et al.* 1977, and Manni *et al.* 1978, for recent observations and literature.) These afferents are considered to be proprioceptive. Small neurons, in variable numbers in different species, have been observed in the oculomotor nerve, and these are usually regarded as ectopic

7.172 The constituent parts of the nucleus of the oculomotor nerve in the monkey. (From R. Warwick 1953, by courtesy of the publishers of the *Journal of Comparative Neurology*: for significance of abbreviations consult Warwick 1950 and see text.)

proprioceptive neurons, perhaps displaced from the trigeminal ganglion (Tozer 1912; Bortolami *et al.* 1977).



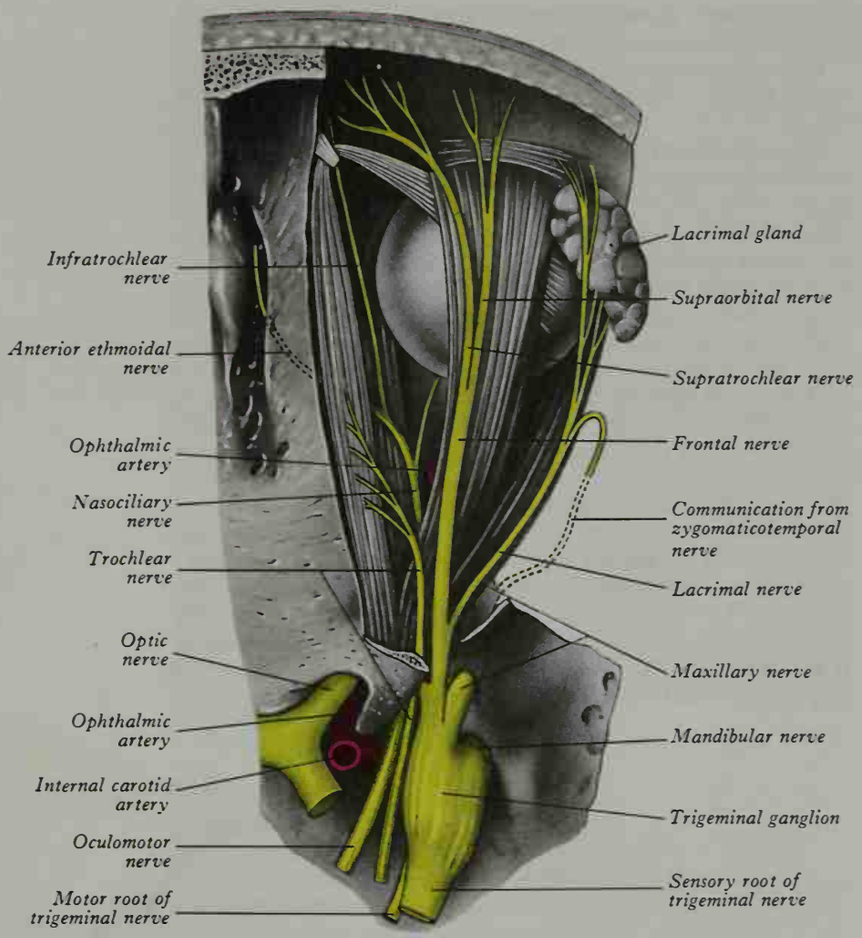
The nuclear complex from which the fibres of the oculomotor nerve are derived consists of a number of paired groups of large multipolar nerve cells, which can be identified in most mammals, together with paired masses of smaller multipolar nerve cells, which are not so easily identified, though well developed in primates and many other mammals, and which are the source of the parasympathetic outflow in the oculomotor nerves. On each side of the midline the large-celled oculomotor mass is topographically divided into **dorsolateral, intermediate** and **ventromedial nuclei** (7.172), which are extended in a columnar form approximately in the long axis of the midbrain (Crosby and Henderson 1948; Warwick 1950). These sub-nuclei become clearly identifiable in early fetal life in man (Pearson 1944). According to experimental evidence in monkeys they are the motor pools of the *rectus inferior, obliquus inferior* and *rectus medialis*, in that dorsoventral order (7.172). Dorsal to the right and left large-celled masses, and at a level corresponding to their caudal extremities, is a median nucleus, composed of similar large multipolar nerve cells, the **caudal central nucleus**, which in the same experimental study was observed to be the conjoined motor pool of the two *levators* of the upper eyelids (Warwick 1950, 1953). Dorsal to the right and left main oculomotor nuclei are the two **accessory** or **autonomic nuclei** (of Edinger and Westphal), composed of somewhat smaller multipolar nerve cells, whose axons travel out in the oculomotor to relay in the ciliary ganglion (Warwick 1954). These accessory nuclei are best developed at cranial oculomotor levels, where they fuse together and arch ventrally over the cranial end of the main oculomotor nuclei (7.172); in their more caudal, paired parts these autonomic columns frequently show a tendency to further splitting in man and other primates. Recent studies by Sugimoto *et al.* (1978), using the retrograde horseradish peroxidase technique suggest that many of the neurons of the oculomotor parasympathetic outflow may be sited near to but outside these autonomic nuclei.

Although a median group of larger motor nerve cells has been a standard feature of oculomotor topography for many decades, this 'central nucleus of Perlia' is a most variable entity in mammals, and indeed in the same species. The function of convergence was loosely ascribed to it at an early date on inadequate and fallacious evidence. Its degree of development in primates is not commensurate with its supposed function, nor is it possible to equate its size with binocular vision (Le Gros Clark 1926). Topographic observers have described it as frequently absent from the human midbrain (Tsuchida 1906; Crosby and Woodburne 1943). There are always a few scattered large motor cells in the midline raphe between the right and left oculomotor masses, but these never constitute a clear nuclear mass, like the caudal central nucleus; in any case, such nerve cells appear to innervate the superior rectus, and not the medial rectus (Warwick 1955).

Other views of the topographical arrangement of the motor pools of the extraocular muscles have been advanced (Brouwer 1918; Szentágothai 1942; Bender and Weinstein 1943), all of which suggest a craniocaudal pattern rather than the dorsoventral scheme described here; but in both forms of organization, which are very different in other ways, there is general agreement that the issuing oculomotor fibres, somatic and autonomic, are almost completely ipsilateral in their midbrain course. At the most some axons from the median raphe and the caudal central nucleus may cross into the opposite oculomotor nerve to innervate the rectus superior and the levator palpebrae superioris; but the extensive crossing of oculomotor axons which is a usual tenet of textbook accounts is not supported by any of the experimental studies quoted here, almost all of which were carried out in primates. The most recent study of oculomotor organization, carried out in the cat (Tarlov 1972, 1975), describes an array of longitudinal motor pools for individual muscles, but their arrangement differs from that observed in the monkey (Warwick 1955). Tarlov has also defined a projection (*see* p. 1074) to the oculomotor nucleus from the medial and superior vestibular nuclei, the terminals from both of which were found to provide a partially bilateral and overlapping distribution in certain oculomotor muscle 'pools'. This suggests excitatory and inhibitory roles, and certain physiological data tend to support this concept (High *et al.* 1971).

For a discussion of the claims of other nuclei in the vicinity of the oculomotor complex to be included with it, consult Warwick (1953).

Connexions of the oculomotor nucleus include fibres from: (1) the corticonuclear tracts of *both* sides; some fibres leave the tracts at the level of the oculomotor nucleus but some (aberrant pyramidal fibres) leave at a higher level and thereafter descend in the medial lemniscus; they end either directly on the cells of the nucleus or are linked to them via interneurons; (2) the medial longitudinal fasciculus by which it is connected to the nuclei of fourth, sixth and eighth cranial nerves (p. 939); (3) the tectobulbar tract, by which it is connected to the visual cortex through the medium of the superior colliculus; and (4) the pretectal nucleus of both sides for the light reflex. Horseradish peroxidase studies have indicated a projection from the oculomotor nucleus to the abducent (Graybiel and Hartwig 1974) and in the reverse direction (Maciewicz *et al.* 1975). Such internuclear reciprocal connexions are to be expected from the results of experimental stimulation of or damage to the medial longitudinal fasciculus, and from the clinicopathological data of internuclear ophthalmoplegia. These connexions are part of the 'mechanism' for the control of horizontal eye movements. (For a discussion consult Highstein 1977.) For much information on earlier work in this field consult Bender (1964), and for further comments *see* p. 1085.



7.173 A diagram showing the ciliary ganglion, with its roots and branches of distribution, *Magenta:* sympathetic fibres. *Heavy black:* parasympathetic fibres. *Blue:* sensory (cerebrospinal) fibres. Alternative pathways are given for the sympathetic fibres to the dilatator pupillae. A schematic sagittal section is shown of the upper lateral quadrant of the eyeball, but the retina has not been included.

Similar experiments (using horseradish peroxidase technique) suggest that many of the neurons in the autonomic nuclei of the oculomotor nerve (*vide supra*) project to the cerebellum and spinal cord (Sugimoto *et al.* 1978).

Course. On emerging from the brain, the nerve, invested by pia mater, lies in the subarachnoid space. It passes between the superior cerebellar and posterior cerebral arteries (8.196), and runs forward in the interpeduncular cistern on the lateral side of the posterior communicating artery. It then perforates the arachnoid and lies in the triangular interval between the free and attached borders of the tentorium cerebelli. Piercing the inner layer of the dura mater on the lateral side of the posterior clinoid process the nerve traverses the roof, and further forwards descends into the lateral wall of the cavernous sinus, where it lies above the trochlear nerve (6.127). In this situation it receives one or two filaments from the internal carotid plexus of the sympathetic, and communicates with the ophthalmic division of the trigeminal. It then divides into a superior and an inferior ramus, which enter the orbit through the superior orbital fissure, within the anulus tendineus communis to which are attached the four recti; here the nasociliary nerve is placed between the two rami (7.176, 269).

The *superior ramus*, the smaller, ascends on the lateral side of the optic nerve, and supplies the rectus superior and levator palpebrae superioris. The *inferior ramus* divides into three

7.174 The nerves of the right orbit, superior aspect.

branches. One passes below the optic nerve to the rectus medialis; another goes to the rectus inferior; the third and longest runs forwards between the rectus inferior and rectus lateralis, to the obliquus inferior. The branches enter the muscles on their ocular surfaces, with the exception of that to the obliquus inferior, which enters the posterior border of the muscle. From the nerve to the inferior oblique a short thick branch (sometimes represented by two or three separate branches) passes to the lower part of the ciliary ganglion and forms its *motor* or *parasympathetic root*. It consists of finely myelinated fibres, derived from the accessory oculomotor nucleus, which synapse about cells in the ganglion, whence postganglionic fibres pass in the short ciliary nerves to supply the sphincter pupillae and ciliaris (pp. 1159, 1161).

The ciliary ganglion (7.173, 176) is a small, flattened ganglion of a reddish-grey colour and the size of a large pin's head; it is situated near the apex of the orbit in some loose fat between the optic nerve and the rectus lateralis, lying usually on the lateral side of the ophthalmic artery. It is a peripheral ganglion of the parasympathetic system and its constituent cells are multipolar. These cells are not typical of autonomic ganglia in general, being much larger in dimensions; a very small number of nerve cells of typical autonomic type are also present (Warwick 1954).

Its *connexions* or *roots* (7.173) enter or leave it posteriorly, but only its parasympathetic function is basic; the sympathetic and sensory fibres merely pass through it, and are absent in some mammals. The *motor* or *parasympathetic root* is derived from the nerve to the inferior oblique and consists of preganglionic fibres which arise from the cells of the accessory (Edinger-Westphal) nucleus (7.109). These fibres are relayed in the ganglion and the postganglionic fibres travel in the short ciliary nerves to supply the sphincter pupillae and ciliaris. More than 95 per cent of these fibres supply the ciliaris, which is much the larger muscle in volume (Warwick 1954); hence this motor pathway is much more concerned with focusing of the eye than with the light reflex. The *sympathetic root* is a branch from the internal carotid plexus. It may pass direct to the ganglion or it may join the sensory root and reach the ganglion indirectly. It consists of postganglionic fibres from the superior cervical ganglion which traverse the ciliary ganglion without being interrupted, to emerge in the short ciliary nerves. They are distributed to the blood vessels of the eyeball and they may include the fibres which supply the dilatator pupillae when these fibres do not follow their usual course in the ophthalmic, nasociliary and long ciliary nerves. The *sensory root* is formed by a *ramus communicans* to the nasociliary nerve. It contains sensory fibres from the eyeball, which reach the ganglion in the short ciliary nerves and pass through it without being interrupted. It leaves the ganglion posteriorly and runs backwards to join the nasociliary nerve near the point where that nerve enters the orbit.

The *branches* of the ganglion are delicate filaments, eight to ten in number, which emerge from the front of the ganglion in two bundles, of which the lower is the larger. They are termed the *short ciliary nerves*. The postganglionic parasympathetic fibres in them are myelinated. In company with the ciliary arteries they run sinuously forwards, one set above the optic nerve, the other below. They subdivide into about fifteen to twenty branches, which pierce the sclera around the entrance of the optic nerve and pass forwards in delicate grooves on the inner surface of the sclera. They contain both motor and sensory fibres; the former are distributed to the sphincter pupillae and ciliaris, and to the choroidal and iridial blood vessels of the eyeball which provide a nutritive supply to many ocular tissues. The existence of proprioceptive fibres in the oculomotor nerve can no longer be doubted, in view of the occurrence of stretch endings in the extraocular muscles (p. 1085). How far such fibres travel in the oculomotor nerve, and where they terminate centrally are still unsettled problems (but *see* p. 1060). The blood supply of the ciliary ganglion has been investigated in man by Eliscova (1973); it is derived from small rami of the muscular, posterior ciliary and central retinal branches of the ophthalmic artery.

Applied Anatomy. Division of the oculomotor nerve leads, when complete, to (1) ptosis, or drooping of the upper eyelid, consequent on paralysis of the levator palpabrae superioris; (2) lateral strabismus (or squint), stemming from the unopposed action of the rectus lateralis and obliquus superior, which are not supplied by the oculomotor nerve and are therefore not paralysed; (3) dilatation of the pupil, because the sphincter pupillae is paralysed; (4) loss of accommodation, and of pupillary constriction on exposure to light, as the sphincter pupillae and the ciliaris are paralysed; (5) slight prominence of the eyeball, owing to most of its muscles being relaxed; and (6) diplopia, or double vision, the false image being higher than the true. Occasionally paralysis may affect only a part of the nerve—for example, there may be a dilated and fixed pupil, with ptosis, but no other signs. Irritation of the nerve causes spasm of one or other of the muscles supplied by it; thus, there may be medial strabismus from spasm of the medial rectus, accommodation for near objects only, from spasm of the ciliaris, or a contracted pupil owing to irritation of the sphincter pupillae.

The Trochlear Nerve

The trochlear nerve (7.174, 176), the most slender of the cranial nerves, supplies the superior oblique muscle of the eyeball. It contains about 3,400 fibres (Björkman and Wohlfart 1936), but in fetal life the number of fibres is greater, as in some other cranial nerves. According to Mustafa and Gamble (1979), however, the adult human nerve contains approximately 2,400 fibres, whereas fetal counts were 4,000 (at C.R. length 9·2 cm), 6,000 (at C.R. length 10 cm), and 3,200 (at C.R. length 24 cm). Many fibres therefore degenerate during fetal development, after an initial increase in numbers. As mentioned below, the orbital part of the trochlear nerve contains more fibres than its stem. This disparity in numbers is also observed in fetal trochlear nerves.

The trochlear nucleus is situated in the floor of the cerebral aqueduct, opposite the upper part of the inferior colliculus (7.62, 64, 91). This nucleus lies in line with the ventromedial part of the oculomotor nucleus, and occupies the position of the somatic efferent column. The medial longitudinal fasciculus is ventral to

the trochlear nucleus. The oculomotor and trochlear nuclei often overlap a little and can only be distinguished by the slightly smaller size of the trochlear nerve cells.

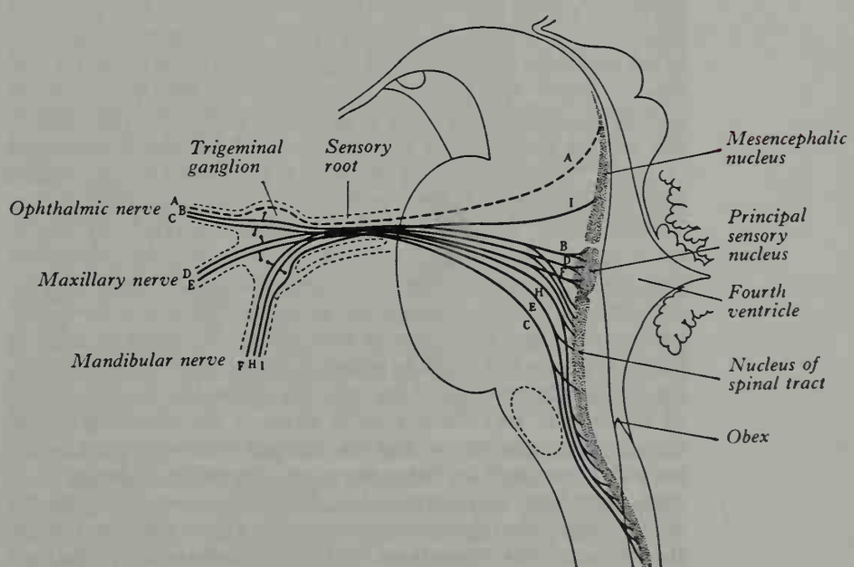
Connexions. The nucleus receives fibres from: (1) the corticonuclear tracts of *both* sides, probably in a manner similar to those of the oculomotor nerve nucleus (p. 1057); (2) the medial longitudinal fasciculus, by which it is connected with the nuclei of the third, sixth and eighth cranial nerves (p. 940); (3) from the tectobulbar tract, through which it receives impulses from the visual cortex through the medium of the superior colliculus (p. 941). (See also p. 1085.) Tarlov and Tarlov (1975) have studied the transmitter substances of the vestibulotrochlear projection in the cat, in which the tract is derived chiefly from the superior vestibular nucleus; they conclude that the transmitter is GABA (gamma-amino butyric acid) at the trochlear terminals of the projection, and they regard them as inhibitory.

Course. After leaving the nucleus the fibres of the trochlear nerve pursue a very unusual course (p. 937). They first run downwards and laterally through the tegmentum and then turn backwards round the central grey matter into the upper part of the anterior medullary velum. Here they decussate with the contralateral fibres, and, having crossed the median plane, emerge from the surface of the velum at the side of the frenulum veli, immediately below the inferior colliculus (**7**.90) It is the only cranial nerve that emerges from the brainstem on its dorsal aspect.

The nerve is directed laterally across the superior cerebellar peduncle, and then winds forwards round the cerebral peduncle immediately above the pons, and between the posterior cerebral and superior cerebellar arteries. It appears between the upper border of the pons and the temporal lobe, and pierces the inner stratum of the dura mater immediately below the free border of the tentorium cerebelli, a little behind the posterior clinoid process. It then passes forwards in the lateral wall of the cavernous sinus, below the oculomotor nerve and above the ophthalmic division of the trigeminal nerve (**6**.127). In this part of its course it is closely adherent to the tentorial branch of the ophthalmic nerve, which lies below it. Near the anterior end of the sinus it crosses the oculomotor nerve, and enters the orbit by the superior orbital fissure, above the orbital muscles, and medial to the frontal nerve (**7**.174). In the orbit it passes medially, above the origin of the levator palpebrae superioris, and finally enters the oribital surface of the obliquus superior (**7**.176).

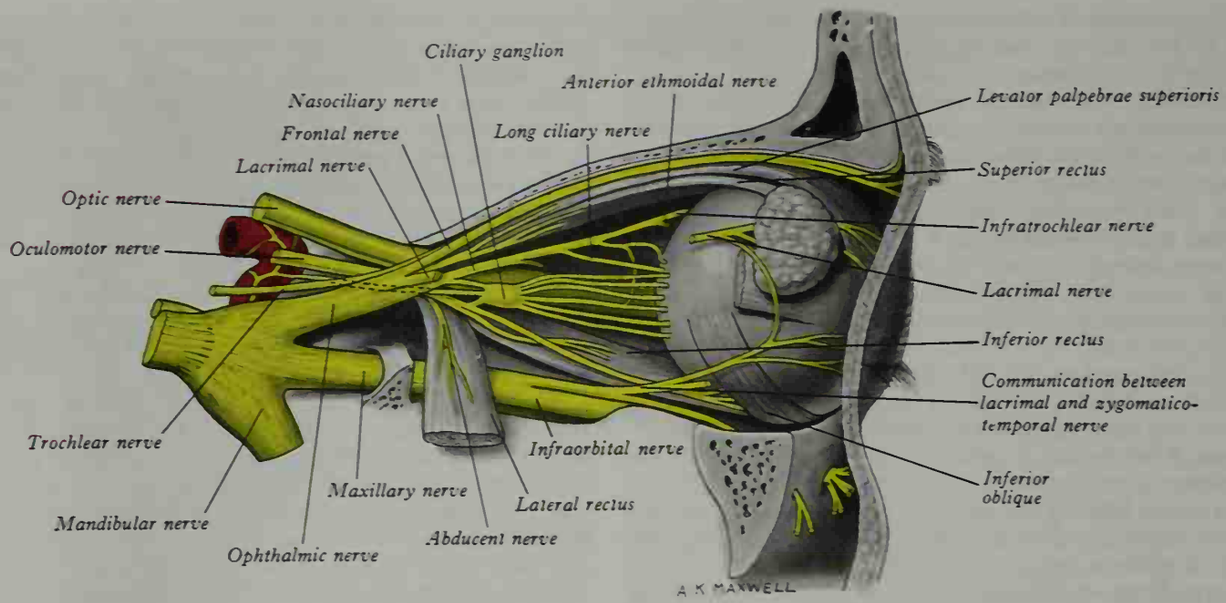
In the lateral wall of the cavernous sinus the trochlear nerve communicates with the ophthalmic division of the trigeminal nerve, and with the internal carotid plexus of the sympathetic. In the superior orbital fissure it occasionally gives off a branch to the lacrimal nerve. Although an exchange of fibres through communications in the cavernous sinus has been denied (Sunderland and Hughes 1946), subsequent evidence based on nerve fibre analysis in human material (Zaki 1960) suggests that a substantial component of fairly large nerve fibres, possibly proprioceptive in nature, are present in the trochlear nerve distal to the cavernous sinus. This part of the nerve contained 3,500 fibres, whereas proximal to the sinus the count was only about 2,400. Although it is sometimes assumed, as in the case of the oculomotor nerve, that proprioceptive fibres from the superior oblique muscle enter the brainstem via the trochlear nerve, the most recent study (Manni *et al.* 1970) suggests that these fibres leave the trochlear nerve peripherally and join the ophthalmic division of the trigeminal nerve.

Applied Anatomy. When the trochlear nerve is interrupted the superior oblique is paralysed so that the patient is unable to turn his eye downwards and laterally. Should the patient attempt to do this, the eye of the affected side is rotated medially, producing *diplopia* or double vision. Single vision exists in the whole of the field so long as the eyes look above the horizontal plane; diplopia occurs on looking downwards. To counteract this the patient holds his head forwards, and also inclines it to the sound side.



The Trigeminal Nerve

The trigeminal is the largest cranial nerve. It is the sensory nerve of the face, the greater part of the scalp, the teeth, the oral and the nasal cavities, and the motor nerve of the muscles of mastication and some others. It also contains proprioceptive nerve fibres from the masticatory and probably from the extraocular muscles. It divides into three branches, ophthalmic, maxillary and mandibular. Baumel (1974) has reviewed the functional significance of the widespread peripheral communications between the trigeminal and facial nerves. Despite the voluminous literature on the subject, uncertainties exist; but the preponderant view is that the trigeminal fibres which join from the facial are sensory and largely derived from the facial musculature.



The trigeminal nerve is continuous with the ventral surface of the pons, near its upper border, by a large sensory and a small motor root—the latter being placed medial and anterior to the former.

The fibres of the *sensory root* arise from the cells of the **trigeminal** (*semilunar*) **ganglion**. This ganglion (**7**.174, 177) occupies a recess (*trigeminal cave*) in the dura mater covering the trigeminal impression near the apex of the petrous part of the temporal bone (p. 311). It lies at a depth of 4·5–5 cm from the lateral aspect of the head, at the posterior extremity of the zygomatic arch. The ganglion is crescentic in shape, with its convexity directed anterolaterally; on its surface are visible a number of interlacing nerve fascicles. Medially it is in relation with the internal carotid artery and the posterior part of the cavernous sinus, inferiorly, with the motor root of the nerve, the greater (superficial) petrosal nerve, the apex of the petrous part of the temporal bone, and the foramen lacerum. It receives filaments from the internal carotid plexus of the sympathetic, and gives twigs to the tentorium cerebelli.

The branches of the unipolar cells of the trigeminal ganglion divide into peripheral and central branches. The former are grouped to form the *ophthalmic* and *maxillary* nerves, and the sensory part of the *mandibular* nerve. The central branches constitute the fibres of the sensory root of the nerve, which leaves the concave margin of the ganglion, runs backwards and medially below the superior petrosal sinus and the tentorium cerebelli, and enters the pons. Some fibres from proprioceptor endings in the masticatory and extraocular muscles may pass through the semilunar ganglion without connexion with nerve cell somata, but electrophysiological observations (Manni *et al.* 1970) strongly support the view that most, if not all, of the neurons innervating proprioceptors in the extraocular muscles have somata situated in the trigeminal ganglion (see also p. 1060).

7.175 The nuclei receiving the primary afferent fibres of the trigeminal nerve. A: proprioceptive fibres from ocular muscles. B: tactile and pressure fibres from ophthalmic areas. C: pain and temperature fibres from ophthalmic area. D: tactile and pressure fibres from maxillary area. E: pain and temperature fibres from maxillary area. F: tactile and pressure fibres from mandibular area. H: pain and temperature fibres from mandibular area. I: proprioceptive fibres from muscles of mastication. Proprioceptive fibres are believed to occur in all three divisions of the trigeminal nerve.

7.176 The nerves of the right orbit, and the ciliary ganglion. Lateral aspect.

On entering the pons the fibres of the sensory root course dorsomedially towards the **principal sensory nucleus** situated at that level (7.70). On approaching the nucleus about 50 per cent of the fibres divide into ascending and descending branches; the others ascend or descend without division. The descending fibres, which are predominantly finely myelinated or non-myelinated, form the **spinal tract of the trigeminal nerve** which descends into the upper cervical part of the spinal cord. As the tract descends terminals and collaterals are given off to synapse with the cells of the **spinal nucleus of the trigeminal nerve** (7.60–63, 66, 68, 175). The nucleus consists of small- and medium-sized cells and is continuous below with the substantia gelatinosa. The tract embraces the nucleus on its dorsolateral aspect. In the lower part of the medulla oblongata it is superficial and lies under the tuberculum cinereum. The fibres which synapse in the nucleus are concerned predominantly (but not exclusively) with painful and thermal sensibility. It has been demonstrated experimentally that (1) the fibres of the ophthalmic nerve are placed ventrally in the tract and descend to the lower limit of the first cervical segment of the spinal cord; (2) the fibres of the maxillary nerve lie in the central part of the tract and do not extend below the medulla oblongata; (3) the fibres of the mandibular nerve are placed in the dorsal part of the tract and do not extend much below the middle of the medulla oblongata (7.175). This experimental evidence is confirmed by the clinical results after section of the spinal tract (Smyth 1939; Brodal 1947; Falconer 1949) in cases of severe trigeminal neuralgia. Section of the tract 4 mm below the level of the obex renders the ophthalmic and maxillary areas analgesic but tactile sensibility, apart from the abolition of 'tickle', is much less affected. When it is desired to include the mandibular area as well, the section must be made at the level of the obex itself. In addition, as a result of this operation, the mucous membrane of the tonsillar sinus, the posterior third of the tongue and the adjoining parts of the pharyngeal wall (glossopharyngeal nerve) and the cutaneous area supplied by the auricular branch of the vagus nerve are also rendered analgesic; it may, therefore, be inferred that the fibres concerned join the spinal tract of the trigeminal nerve and end in its nucleus. During the course of these operations the laminated character of the tract has also been confirmed. A small group of sensory cells, associated with the glossopharyngeal nerve, but related to the spinal trigeminal tract, has been described (Bossy 1968). As well as the trigeminal, vagal and glossopharyngeal afferents to the spinal nucleus, others reach it from the sensory root of the facial nerve, the dorsal roots of the upper cervical nerves, and descending fibres from the sensorimotor regions of the cerebral cortex (see also p. 1086).

It is appropriate to divide the spinal trigeminal nucleus into three levels—*nucleus oralis* (the most rostral part, adjoining the principal sensory nucleus), *nucleus interpolaris* and *nucleus caudalis* (the most caudal part, continuous with the dorsal grey column)—because they differ in structure and to some extent in connexions. The nucleus caudalis closely resembles the neuronal pattern of the dorsal grey column, while the nuclei interpolaris and oralis are devoid of neurons 'equivalent' to the substantia gelatinosa. All levels receive afferents from the whole of the trigeminal sensory field; but all C fibres are believed to end in the caudal nucleus, and its neurons alone respond to noxious stimuli; moreover, its projection is to the contralateral ventroposterior nucleus of the thalamus, as is that of the nucleus oralis. On the other hand, the nucleus interpolaris projects to the anterior lobe of the cerebellum.

Some of the ascending trigeminal fibres, many of which are heavily myelinated, synapse around the small cells of the principal sensory nucleus which lies lateral to the motor nucleus and intervenes between the latter and the middle cerebellar peduncle: it is continuous below with the nucleus of the spinal tract (7.62, 175). It is considered to be concerned mainly with tactile sensibility.

Other ascending fibres enter the **mesencephalic nucleus**. This nucleus is composed of a column of *unipolar* cells. It is believed that their peripheral branches convey proprioceptive impulses from the muscles of mastication and it is also alleged (Corbin and Harrison 1940; Pearson 1949) that proprioceptive impulses travel to the mesencephalic nucleus from the teeth and from the facial and ocular muscles (7.62, 91, 155). The neurons of the mesencephalic nucleus are unique in being the only primary sensory neurons whose cell bodies are within the central nervous system (Johnston 1909). If, however, the primary proprioceptive neurons of the extraocular muscles are in fact situated in their motor nerves or the trigeminal ganglion (*see* pp. 1058, 1085), some at least of the mesencephalic trigeminal neurons may be 'secondary' in status. Small multipolar cells, possibly interneurons, occur near the unipolar neurons.

Connexions. The majority of the fibres which arise in the sensory nuclei of the trigeminal nerve cross the median plane and ascend in the trigeminal lemniscus (p. 938) to the nucleus ventralis posterior medialis of the thalamus (p. 958), from which fibres are relayed to the cortex of the postcentral gyrus (areas 3, 1 and 2, p. 1016). Some, however, ascend to the thalamus on the ipsilateral side. It is probable that collateral branches of both primary and secondary afferent trigeminal neurons reach many other central regions such as the cranial nerve nuclei, the reticular formation, cerebellum, tectum, subthalamus, hypothalamus, etc.,

but such details have not been established in the human brain. (Consult Humphrey 1969; Webster 1977; see also p. 1085.)

The nerve fibres which ascend to the nerve cells of the mesencephalic nucleus may afford collaterals to the motor trigeminal nucleus and the cerebellum. They are, of course, morphologically dendrites; the true axons of the mesencephalic neurons possibly descend in part to the principal trigeminal sensory nucleus, but little is known of them. Physiological evidence suggests that the mesencephalic nucleus is modulated during masticatory reflex activity by connexions with the vagus nerve, but anatomical confirmation is lacking (Manni *et al.* 1977).

The motor nucleus of the trigeminal nerve gives rise to the fibres of the motor root. It is ovoid in shape with typical large multipolar cells interspersed with smaller multipolar cells. It lies in the upper part of the pons on the medial side of the principal sensory nucleus, which is separated from it by the fibres of the trigeminal nerve. It occupies the position of the branchial (special visceral) efferent column (7.62, 64, 70). Detailed analysis has shown that the motor nucleus of the trigeminal consists of a number of relative discrete sub-nuclei, the axons of which innervate individual muscles (Szentágothai 1949).

Connexions. The motor nucleus receives fibres from the corticonuclear tracts of *both* sides; these fibres leave the tracts at the level of the nucleus or at a higher level in the pons (aberrant pyramidal fibres) and descend in the medial lemniscus. They may end on the cells of the nucleus or are linked to them by interneurons. The motor nucleus receives fibres from the sensory nuclei of the trigeminal nerve, and, as stated above, possibly some from the mesencephalic nucleus, forming monosynaptic reflex arcs for the proprioceptive control of the muscles of mastication. It also receives fibres from the reticular formation, red nucleus and the tectum, from the medial longitudinal fasciculus and possibly fibres from the locus ceruleus, by which salivary secretion and mastication are correlated.

THE OPHTHALMIC NERVE

The ophthalmic nerve (7.174, 179, 182), the superior division of the trigeminal nerve, is wholly sensory. It supplies branches to the eyeball, the lacrimal gland and the conjunctiva, to a part of the mucous membrane of the nasal cavity, and to the skin of the nose, eyelids, forehead and scalp. It is the smallest division of the trigeminal nerve, and arises from the anteromedial part of the trigeminal ganglion as a flattened band, about 2·5 cm long, which passes forwards in the cavernous sinus close to its lateral wall and below the oculomotor and trochlear nerves (6.127); just before entering the orbit through the superior orbital fissure, it divides into three branches, viz. *lacrimal*, *frontal* and *nasociliary*.

The ophthalmic nerve is joined by filaments from the internal carotid plexus of the sympathetic, and communicates with the oculomotor, trochlear and abducent nerves, a route by which the proprioceptive fibres of these nerves may pass into the trigeminal. It supplies a recurrent meningeal branch (*tentorial nerve*), which crosses below and adheres to the trochlear nerve, and is distributed to the tentorium cerebelli (p. 1045).

The lacrimal nerve (7.174) is the smallest of the main branches of the ophthalmic nerve. It sometimes receives a filament from the trochlear nerve, but possibly this filament consists of fibres which have previously passed from the ophthalmic to the trochlear nerve. The lacrimal nerve enters the orbit through the lateral part of the superior orbital fissure (7.177), runs along the upper border of the rectus lateralis with the lacrimal artery, and receives a twig from the zygomaticotemporal branch of the maxillary nerve, often said to contain secretomotor fibres for the lacrimal gland (*see*, however, p. 1123). It enters the lacrimal gland and gives off several filaments to the gland and the conjunctiva. Finally it pierces the orbital septum, and ends in the skin of the upper eyelid, joining with filaments of the facial nerve.

The lacrimal nerve is occasionally absent, and its place is then taken by the zygomaticotemporal branch of the maxillary nerve. Sometimes the latter branch is absent and is replaced by a branch of the lacrimal nerve.

The frontal nerve (7.174, 176) is the largest branch of the ophthalmic division. It enters the orbit through the superior orbital fissure (7.174) above the muscles, and runs forwards between the levator palpebrae superioris and the periosteum. About midway between the apex and base of the orbit it divides into a small supratrochlear and a large supraorbital branch.

The *supratrochlear nerve* runs medially and forwards, passes above the trochlea of the obliquus superior, and gives off a descending filament to join the infratrochlear branch of the nasociliary nerve. The nerve then emerges from the orbit between the trochlea and the supraorbital foramen, curves upwards on the forehead close to the bone in company with the supratrochlear branch of the ophthalmic artery, and sends filaments to the conjunctiva and skin of the upper eyelid; it then ascends under cover of the corrugator and the frontal belly of the occipitofrontalis and divides into branches which pierce these muscles and supply the skin of the lower part of the forehead close to the median plane.

The *supraorbital nerve* runs forwards between the levator palpebrae superioris and the roof of the orbit, passes through the supraorbital notch or foramen, and gives off palpebral filaments to the upper eyelid and conjunctiva. It then ascends upon the forehead with the supraorbital artery, and divides into a smaller medial and a larger lateral branch, which supply the skin of the scalp, reaching nearly as far back as the lambdoid suture. These two branches are at first situated deep to the frontal belly of the occipitofrontalis; the medial branch perforates this muscle, the lateral branch pierces the epicranial aponeurosis. The undivided nerve and both branches supply small twigs to the mucous membrane of the frontal sinus and to the pericranium; some reach the sinus through foramina in the floor of the supraorbital notch.

The nasociliary nerve (7.174, 176) is intermediate in size between the frontal and lacrimal nerves, and is more deeply placed. It enters the orbit through the medial part of the superior orbital fissure within the common tendinous ring, which gives origin to the recti muscles of the eyeball, and here it is situated between the two rami of the oculomotor nerve (7.176). It crosses the optic nerve with the ophthalmic artery, and runs obliquely below the rectus superior and obliquus superior, to the medial wall of the orbital cavity. Here, under the name of the *anterior ethmoidal nerve*, it passes through the anterior ethmoidal foramen and canal and, entering the cavity of the cranium, runs forwards in a shallow groove on the upper surface of the cribriform plate of the ethmoid bone, beneath the dura mater; it then descends through a slit at the side of the crista galli into the nasal cavity, and lies in a groove on the inner surface of the nasal bone. It supplies two *internal nasal branches*—a medial to the mucous membrane of the front part of the nasal septum, and a lateral to the anterior part of the lateral wall of the nasal cavity. Finally it emerges, as the *external nasal branch*, at the lower border of the nasal bone, and, passing down under cover of the transverse part of the nasalis, supplies the skin of the ala, apex and vestibule of the nose.

The nasociliary nerve communicates with the ciliary ganglion, and gives off the long ciliary, the infratrochlear and the posterior ethmoidal nerves.

The *ramus communicans* to the ciliary ganglion (p. 1058, 7.173) usually joins the nasociliary nerve as the latter enters the orbital cavity. It lies on the lateral side of the optic nerve, and emerges from the posterosuperior angle of the ciliary ganglion (7.173); it is sometimes joined by a filament from the internal carotid plexus of the sympathetic, or from the superior ramus of the oculomotor nerve.

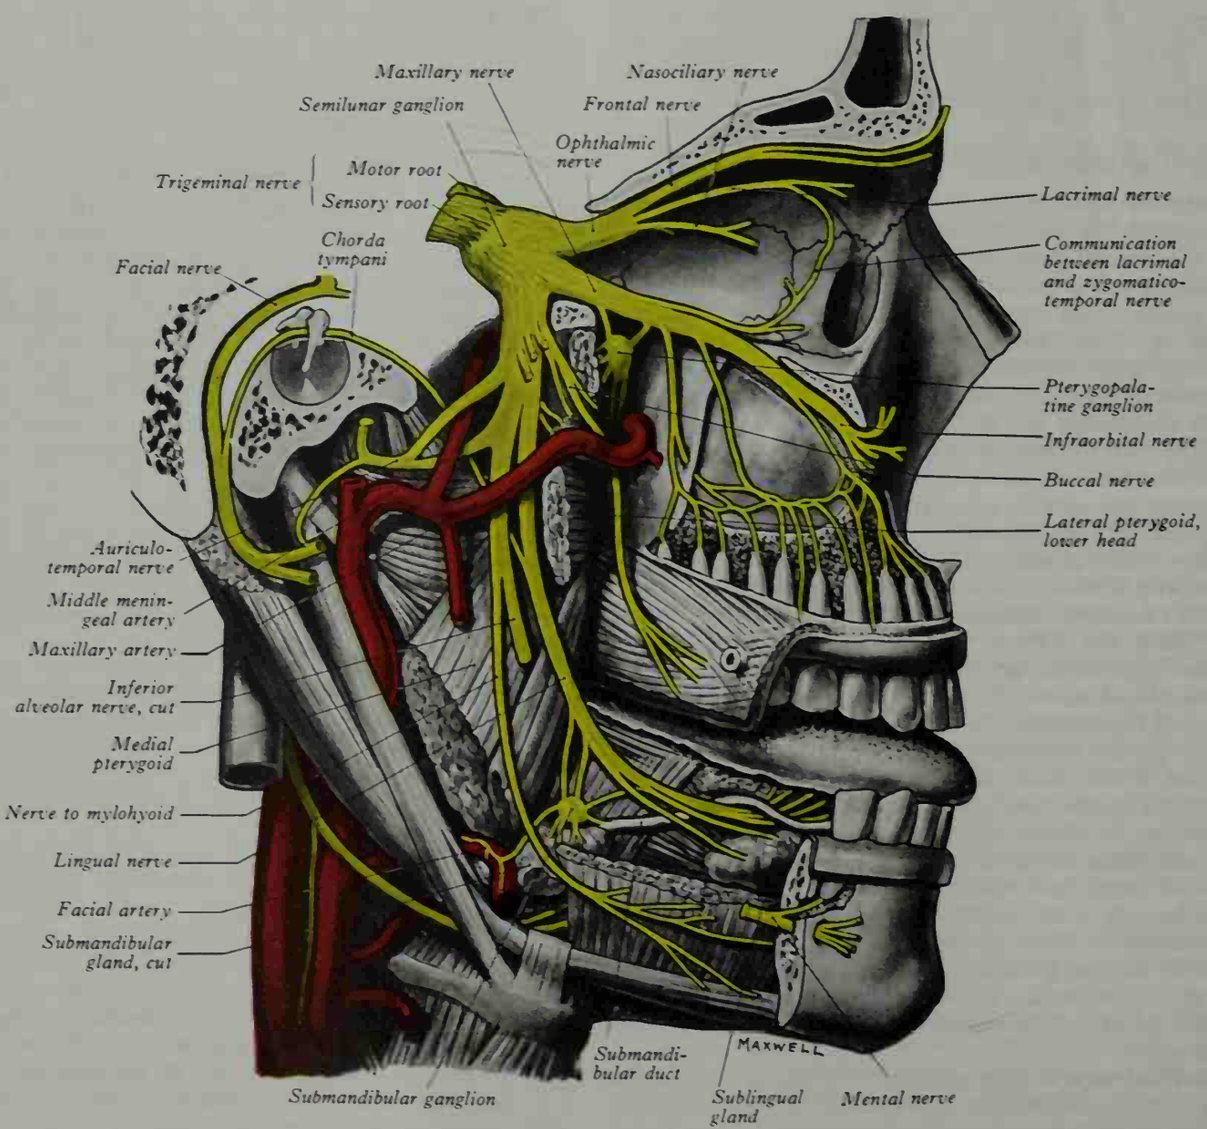
The *long ciliary nerves*, two or three in number, are given off from the nasociliary nerve, as it crosses the optic nerve. They accompany the short ciliary nerves from the ciliary ganglion, pierce the sclera near the attachment of the optic nerve, and, running forwards between the sclera and the choroid, are distributed to the ciliary body, iris and cornea. They usually contain the sympathetic fibres for the dilatator pupillae (p. 1161); these are postganglionic fibres and have their cells of origin in the superior cervical ganglion. In view of the susceptibility of the exposed epithelium of the cornea to damage, the corneal distribution of the long ciliary nerves is of pre-eminent importance.

The *infratrochlear nerve* is given off from the nasociliary nerve

near the anterior ethmoidal foramen. It runs forwards along the medial wall of the orbit above the upper border of the rectus medialis, and is joined, near the trochlea of the obliquus superior, by a filament from the supratrochlear nerve. It then escapes from the orbit below the trochlea; it supplies branches to the skin of the eyelids and side of the nose above the medial angle of the eye, the conjunctiva, lacrimal sac and lacrimal caruncle.

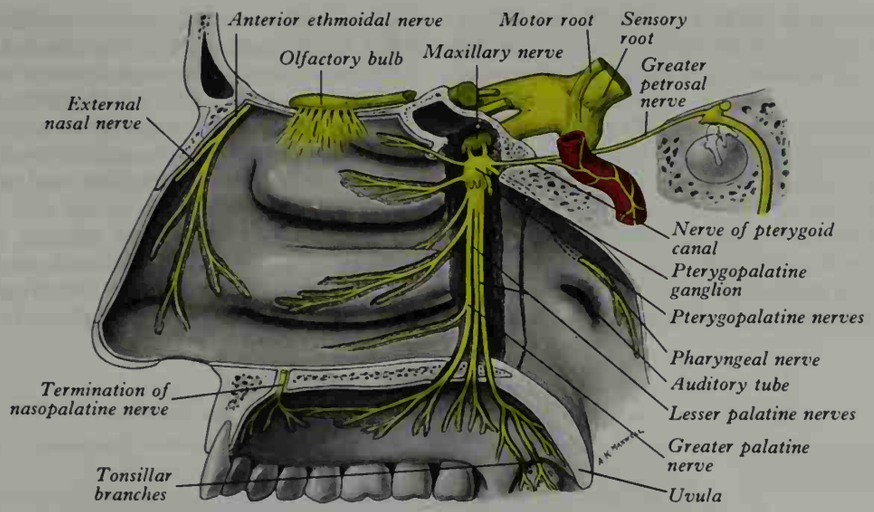
The *posterior ethmoidal nerve* leaves the orbital cavity through the posterior ethmoidal foramen and supplies the ethmoidal and sphenoidal sinuses. It is frequently inconspicuous.

THE MAXILLARY NERVE



The maxillary nerve (7.176, 177), the intermediate division of the trigeminal nerve, is wholly sensory. It is intermediate in position and size between the ophthalmic and mandibular nerves. It begins at the middle of the trigeminal ganglion as a flattened plexiform band, and, passing horizontally forwards along the lower part of the lateral wall of the cavernous sinus (6.127), leaves the skull through the foramen rotundum, where it becomes more cylindrical in form and firmer in texture. It then crosses the upper part of the pterygopalatine fossa, inclines laterally on the posterior surface of the orbital process of the palatine bone and on the upper part of the posterior surface of the maxilla, and enters the orbit through the inferior orbital fissure. It is now named the **infraorbital nerve** and, having traversed the infraorbital groove and canal in the floor of the orbit, it appears on the face through the infraorbital foramen. At its termination the nerve lies under cover of the levator labii superioris, and divides into branches which are distributed to the ala of the nose, the lower eyelid, the skin and mucous membrane of the cheek and upper lip, and which communicate with filaments of the facial nerve.

In view of the fact that the mouth is generally regarded as representing a pair of fused visceral clefts, the maxillary nerve can be described as the pretrematic and the mandibular nerve as the post-trematic branch of the trigeminal nerve. In early fetal life the maxillary nerve primarily supplies the constituent structures of the maxillary process, but later it extends its territory of innervation into the adjoining frontonasal process (*see* p. 149 and 7.182).



The *branches* of the maxillary nerve may be divided into four groups, according to their origin in the cranium, in the pterygopalatine fossa, in the infraorbital canal, or on the face.

In the cranium:	Meningeal
In the pterygopalatine fossa:	Ganglionic, Zygomatic, Posterior superior alveolar
In the infraorbital canal:	Middle superior alveolar, Anterior superior alveolar
On the face:	Palpebral, Nasal, Superior labial

The meningeal nerve (Kimmel 1961 *a* and *b*), sometimes termed the *nervus meningeus medius*, is given off from the maxillary near the foramen rotundum; it receives a communication from the internal carotid sympathetic plexus and then accompanies the

7.177 The right maxillary and mandibular nerves, and the submandibular ganglion. Note that the zygomatic and superior alveolar nerves are not labelled in this diagram.

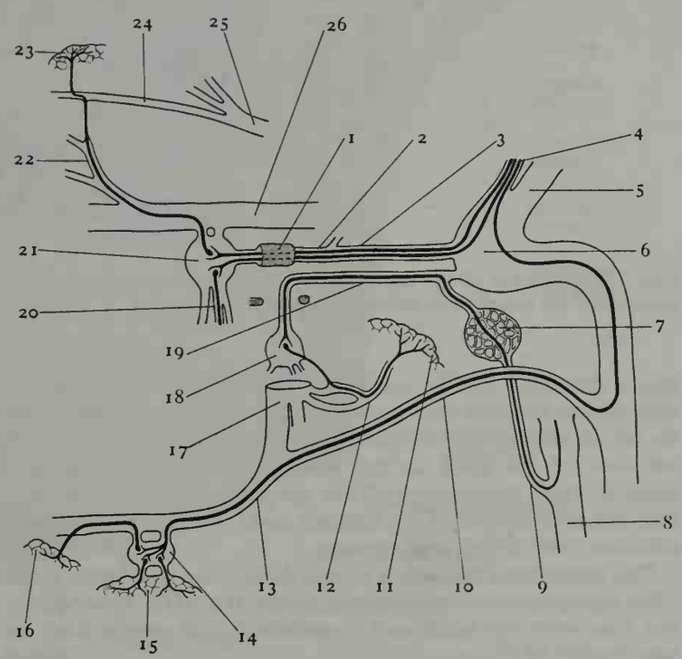
7.178 The right pterygopalatine ganglion and its branches.

frontal branch of the middle meningeal artery and supplies the dura mater of the middle cranial fossa. Its most anterior twigs, however, reach the anterior cranial fossa.

The ganglionic branches, two in number, connect the maxillary nerve to the pterygopalatine (sphenopalatine) ganglion, which lies immediately below it in the pterygopalatine fossa (7.177). They contain the secretomotor fibres for the lacrimal gland (*vide infra*), and sensory fibres from the orbital periosteum and the mucous membranes of the nose, palate and pharynx (p. 1313).

The zygomatic nerve (7.177) arises in the pterygopalatine fossa, enters the orbit by the inferior orbital fissure, courses along the lateral wall of the orbit, and divides into two branches, zygomaticotemporal and zygomaticofacial.

The *zygomaticotemporal branch* passes along the inferolateral angle of the orbital cavity, sends a branch to the lacrimal nerve (p. 1061), and, passing through a canal in the zygomatic bone, enters the temporal fossa. It ascends between the bone and the temporalis, pierces the temporal fascia about 2 cm above the zygomatic arch, and is distributed to the skin of the temple. It communicates with the facial nerve and with the auriculotemporal branch of the mandibular nerve. As it pierces the temporal fascia, it sends a slender twig between the two layers of the fascia towards the lateral angle of the eye. The communication with the lacrimal nerve conveys parasympathetic postganglionic fibres from the pterygopalatine ganglion to the lacrimal gland.



The *zygomaticofacial branch* passes along the inferolateral border of the orbit, emerges upon the face through a foramen in the zygomatic bone, and, perforating the orbicularis oculi, supplies the skin on the prominence of the cheek. It forms a fine plexus with the zygomatic branches of the facial nerve and the palpebral branches of the maxillary nerve. Occasionally this nerve is absent.

Ruskell (1974) has described an *orbito-ciliary* branch, which leaves the maxillary nerve in the pterygopalatine fossa, traverses the inferior orbital fissure, and reaches the eyeball either through the ciliary ganglion or the retro-orbital plexus (p. 1065); dissections in 25 monkeys, together with degeneration experiments, established this pathway and suggested a predominantly sensory role for its nerve fibres.

The superior alveolar (dental) nerves (7.177) arise from the maxillary nerve before it leaves the pterygopalatine fossa, or as it lies in the infraorbital groove or canal. They are termed the posterior, the middle and the anterior superior alveolar (dental) nerves.

The posterior superior alveolar (dental) nerve arises from the maxillary in the pterygopalatine fossa and runs downwards and forwards to pierce the infratemporal surface of the maxilla (p. 1289) and descend under the mucous lining of the maxillary sinus. After supplying the sinus the nerve divides into small branches which link up to constitute the molar part of the *superior dental plexus* supplying twigs to the molar teeth. In addition, it supplies a branch to the upper gum and the adjoining part of the cheek.

The middle superior alveolar (dental) nerve arises from the infraorbital as it passes along the infraorbital groove, and runs downwards and forwards in the lateral wall of the maxillary sinus. Like the posterior, it terminates in a number of small branches which link up with the superior dental plexus, and these give off

twigs to supply the upper premolar teeth. This nerve is variable in its behaviour. It may be duplicated or triplicated or it may be absent (Wood Jones 1939; Fitzgerald 1956; Pacini and Gremigri 1975).

The anterior superior alveolar (dental) nerve (7.177) leaves the lateral side of the infraorbital nerve near the midpoint of the infraorbital canal, and runs in the canalis sinuosus (p. 1287) in the anterior wall of the maxillary sinus. At first it curves beneath the infraorbital foramen and passes medially towards the nose; it then turns downwards and divides into branches which supply the incisor and canine teeth. It takes part in the formation of the superior dental plexus, and gives off a *nasal branch*, which passes through a minute canal in the lateral wall of the inferior meatus, and supplies the mucous membrane of the anterior part of the lateral wall (as high as the opening of the maxillary sinus) and the floor of the nasal cavity, communicating with the nasal branches from the pterygopalatine ganglion. Its terminal branch emerges near the root of the anterior nasal spine and supplies the adjoining part of the nasal septum.

7.180 A dissection of the left pterygoid region, showing some of the branches of the mandibular nerve and the maxillary artery.

The palpebral branches ascend deep to the orbicularis oculi. They soon pierce the muscle to supply the skin of the lower eyelid, and join with the facial and zygomaticofacial nerves near the lateral angle of the eye.

The nasal branches supply the skin of the side of the nose and of the movable part of the nasal septum, and join with the external nasal branch of the anterior ethmoidal nerve.

The superior labial branches are large and numerous; they descend behind the levator labii superioris, and supply the skin of the anterior part of the cheek, the skin of the upper lip, the mucous membrane of the mouth, and the labial glands. They are joined by branches from the facial nerve, and form with them the *infraorbital plexus*.

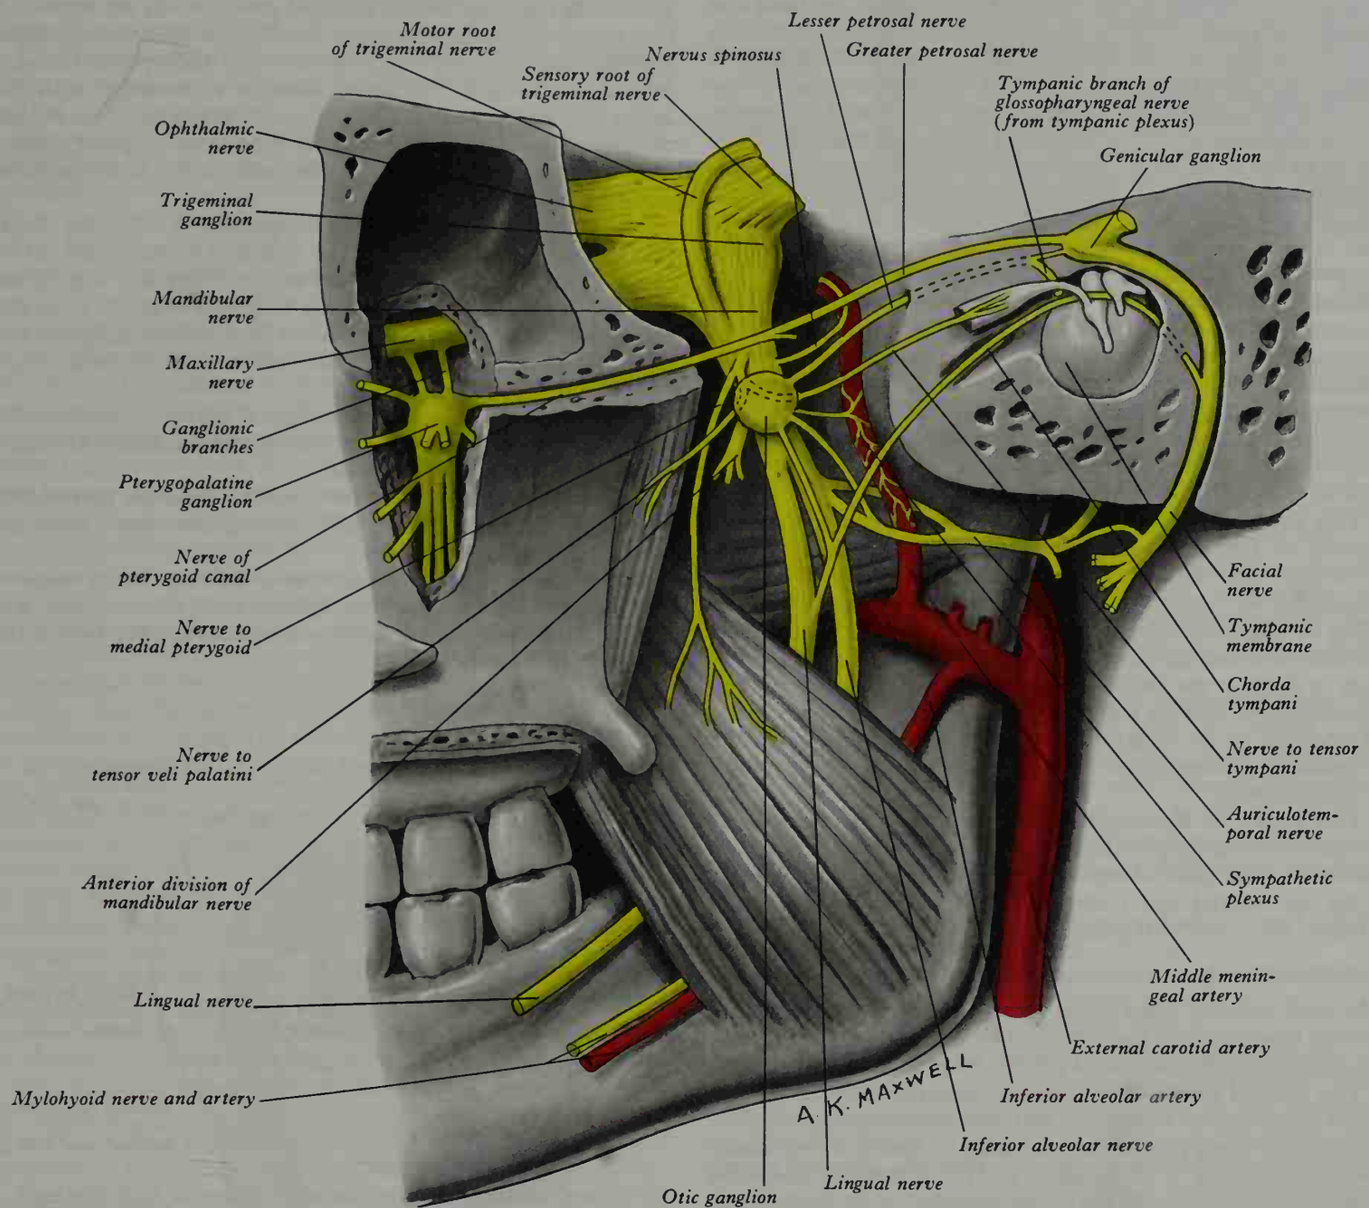
The pterygopalatine (sphenopalatine) ganglion (7.177, 179) is the largest of the peripheral ganglia of the parasympathetic system. It is deeply placed in the pterygopalatine fossa, close to the sphenopalatine foramen and in front of the pterygoid canal. It is somewhat flattened, of a reddish-grey colour, and is situated just below the maxillary nerve as it crosses the fossa. Although it is *connected functionally with the facial nerve*, its topographical relations with the maxillary nerve and its branches are so intimate that it may conveniently be described at this stage.

The *motor* or *parasympathetic root* is formed by the *nerve of the pterygoid canal* (p. 1072), which enters the ganglion posteriorly. Its fibres are believed to arise from a special lacrimatory nucleus in the lower part of the pons and they run in the sensory root of the facial nerve (nervus intermedius) and its greater petrosal branch (p. 1071) before the latter unites with the deep petrosal nerve (7.179) to form the nerve of the pterygoid canal. These preganglionic fibres are relayed in the ganglion and the postganglionic fibres follow a complicated course to gain their destination. Leaving the ganglion in one of the ganglionic branches, they join the maxillary nerve and pass into its zygomatic branch. Thence they are usually considered to run in the zygomaticotemporal nerve and later leave it in the communicating branch by which it is connected to the lacrimal nerve (p. 1123). In this way they may reach the lacrimal gland, supplying it with secretomotor fibres (*see*, however, below). In addition, secretomotor fibres—of uncertain origin—for the palatine, pharyngeal and nasal glands are believed to follow a similar route to the ganglion, where they are relayed. Their postganglionic fibres run in the palatine and nasal branches of the ganglion (7.179).

The *sympathetic root* is also incorporated in the nerve of the pterygoid canal. Its fibres, which are postganglionic, arise in the superior cervical ganglion and travel in the internal carotid plexus and the deep petrosal nerve.

The *branches* which appear to arise from the pterygopalatine ganglion (7.178) are, for the most part, derived from the maxillary nerve through its ganglionic branches, and, though intimately related to the ganglion, do *not* establish any synaptic connexions with its cells. They include orbital, palatine, nasal and pharyngeal branches.

The *orbital branches* are two or three delicate filaments which enter the orbit by the inferior orbital fissure, and are distributed to the periosteum and the orbitalis muscle; some twigs pass through the posterior ethmoidal foramen to the sphenoidal and ethmoidal sinuses. The fibres which supply the orbitalis are directly continuous with the fibres of the sympathetic root of the ganglion. Experiments in monkeys and dissections of human material



suggest that the orbital rami of the pterygopalatine ganglion form a plexus with branches of the internal carotid sympathetic nerve. This '*retro-orbital*' *plexus* (Ruskell 1970, 1971) is said to supply parasympathetic and sympathetic branches to various orbital structures, including the lacrimal gland (p. 1123).

The *palatine nerves* (7.178) are distributed to the roof of the mouth, the soft palate, the tonsil and the lining membrane of the nasal cavity.

The *greater (anterior) palatine nerve* descends through the greater palatine canal, emerges upon the hard palate through the greater palatine foramen, and runs forwards in a groove on the inferior surface of the bony palate, nearly as far as the incisor teeth. It supplies the gums, and the mucous membrane and glands of the hard palate, and communicates in front with terminal filaments of the nasopalatine nerve. While in the greater palatine canal, it gives off *posterior inferior nasal branches*, which emerge through openings in the perpendicular plate of the palatine bone, and ramify over the inferior nasal concha and the walls of the middle and inferior meatuses; at its exit from the canal, palatine branches are distributed to both surfaces of the soft palate.

The *lesser (middle and posterior) palatine nerves* descend through the greater palatine canal, emerge through the lesser palatine foramina and supply branches to the uvula, tonsil and soft palate. The fibres conveying taste impulses from the palate probably pass via the palatine nerves to the pterygopalatine ganglion and thence, without interruption, via the nerve of the pterygoid canal and the greater petrosal nerve to the facial ganglion, where their cells of origin are situated. The central processes of these cells pass through the sensory root of the facial nerve (nervus intermedius) to reach the nucleus of the tractus solitarius (p. 903).

The *nasal branches* enter the nasal cavity through the sphenopalatine foramen. They comprise two sets of nerves. (*a*) About six *lateral posterior superior nasal nerves* innervate the mucous membrane covering the posterior parts of the superior and middle nasal conchae and lining the posterior ethmoidal sinuses. (*b*) The *medial posterior superior nasal nerves*, two or three in number, cross the roof of the nasal cavity below the opening of the sphenoidal sinus to supply the mucous membrane of the posterior part of the roof of the cavity and of the nasal septum. The largest of these nerves is the *nasopalatine (long sphenopalatine) nerve*, which runs downwards and forwards on the posterior part of the nasal septum, lying in a groove on the vomer. It descends to the roof of the mouth through the incisive fossa in the anterior part of the hard palate. When an anterior and a posterior incisive foramen (p. 304) are present in this fossa, the

7.181 The right otic ganglion and its branches displayed from the medial side.

left nasopalatine nerve passes through the anterior and the right nerve through the posterior foramen. The nasopalatine nerves furnish a few filaments to the nasal septum and end by supplying the mucous membrane of the anterior part of the hard palate, where they communicate with the anterior palatine nerves.

The *pharyngeal nerve*, a small branch, arises from the posterior part of the ganglion, passes through the palatinovaginal canal with the pharyngeal branch of the maxillary artery, and is distributed to the mucous membrane of the nasal part of the pharynx, behind the auditory tube.

THE MANDIBULAR NERVE

The mandibular nerve (7.177, 181, 182) supplies the teeth and gums of the mandible, the skin of the temporal region, part of the auricle, the lower lip, the lower part of the face, and the muscles of mastication; it also supplies the mucous membrane of the anterior, pre-sulcal part of the tongue and the floor of the mouth. The largest division of the trigeminal nerve, it is made up of two roots: a large, sensory root, which proceeds from the lateral part of the semilunar ganglion and emerges almost immediately through the foramen ovale of the sphenoid bone, and a small motor root (the motor part of the trigeminal) which passes below the ganglion, and unites with the sensory root, just outside the foramen ovale, where the nerve lies between the tensor veli palatini medially and the lateral pterygoid laterally. Immediately beyond the junction of the two roots the nerve sends off from its medial side its meningeal branch and the nerve to the medial pterygoid, and then divides into a small anterior and a large posterior trunk. As it descends from the foramen ovale, the mandibular nerve lies at a depth of 4 cm from the surface and a little in front of the neck of the mandible.

The meningeal branch (*nervus spinosus*) enters the skull through the foramen spinosum with the middle meningeal artery. It divides into two branches, anterior and posterior, which accompany the main divisions of the artery and supply the dura mater of the middle cranial fossa, and to a lesser extent that of the anterior fossa and calvarium; the posterior branch also supplies a twig to the mucous lining of the mastoid air cells; the anterior communicates with the meningeal branch of the maxillary nerve. In addition to its sensory fibres the nervus spinosus carries sympathetic postganglionic fibres from the plexus on the middle meningeal artery.

The nerve to the medial pterygoid is a slender branch which enters the deep surface of the muscle; it gives one or two filaments which pass through the otic ganglion (p. 1076) without being interrupted and emerge from it to supply the tensor tympani and tensor veli palatini (7.181).

Anterior Trunk

The small anterior trunk of the mandibular nerve gives off (*a*) a sensory branch named the buccal nerve, and (*b*) motor branches—the masseteric, deep temporal and lateral pterygoid nerves.

The buccal nerve (7.180) passes forwards between the two heads of the lateral pterygoid, and then downwards beneath or through the lower part of the temporalis; it emerges from under cover of the ramus of the mandible and the anterior border of the masseter, and unites with the buccal branches of the facial nerve. It furnishes a branch to the lateral pterygoid during its passage through that muscle, and may give off the anterior deep temporal nerve. The buccal nerve supplies the skin over the anterior part of the buccinator, and the mucous membrane lining its inner surface and the posterior part of the buccal surface of the gum.

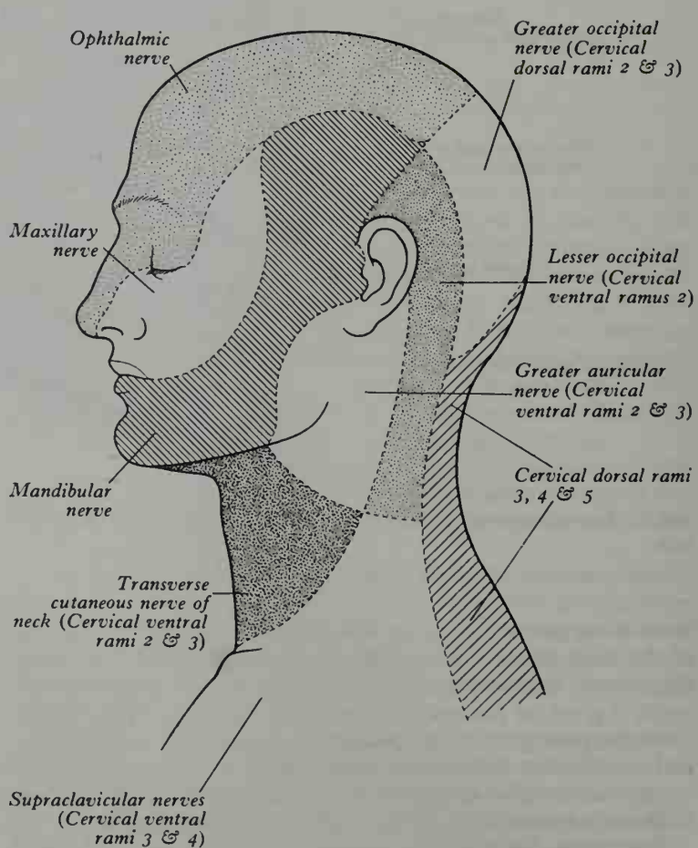
The masseteric nerve (7.180) passes laterally, above the lateral pterygoid, in front of the temporomandibular joint, and behind the tendon of the temporalis; it crosses the posterior part of the mandibular incisure with the masseteric artery, ramifies in the deep surface of the masseter, and gives a filament to the joint.

The deep temporal nerves are usually two in number, anterior and posterior. They pass above the upper border of the lateral pterygoid and enter the deep surface of the temporalis. The *posterior branch*, of small size, is placed at the posterior part of the temporal fossa, and sometimes arises in common with the masseteric nerve. The *anterior branch* is frequently given off from the buccal nerve, and then ascends over the upper head of the lateral pterygoid. A third, or middle, branch is often present.

The nerve to the lateral pterygoid enters the deep surface of the muscle. It may arise separately from the anterior division of the mandibular nerve, or in conjunction with the buccal nerve.

Posterior Trunk

The posterior trunk of the mandibular nerve is for the most part sensory, but receives a few filaments from the motor root. It divides into auriculotemporal, lingual and inferior alveolar (dental) nerves.



The auriculotemporal nerve generally arises by two roots, which encircle the middle meningeal artery (7.177). It runs backwards under cover of the lateral pterygoid on the surface of the tensor veli palatini and passes between the sphenomandibular ligament and the neck of the mandible. It then passes laterally behind the temporomandibular joint in relationship with the upper part of the parotid gland. Finally, emerging from behind the joint, it ascends, posterior to the superficial temporal vessels, over the posterior root of the zygoma, and divides into superficial temporal branches.

The auriculotemporal nerve communicates with the facial nerve and the otic ganglion. The branches to the facial nerve, usually two in number, pass forwards and laterally behind the neck of the mandible and join the facial nerve at the posterior border of the masseter. The filaments from the otic ganglion join the roots of the auriculotemporal nerve close to their origin (7.184).

The *branches* of the auriculotemporal nerve are the anterior auricular, branches to the external acoustic meatus, articular, parotid, and superficial temporal.

There are usually two *anterior auricular branches*: they supply the skin of the tragus (7.182) and, sometimes, a small part of the adjoining portion of the helix.

The *branches to the external acoustic meatus*, two in number, pass between the bony and cartilaginous parts of the meatus, and supply the skin of the meatus; the upper one sends a twig to the tympanic membrane.

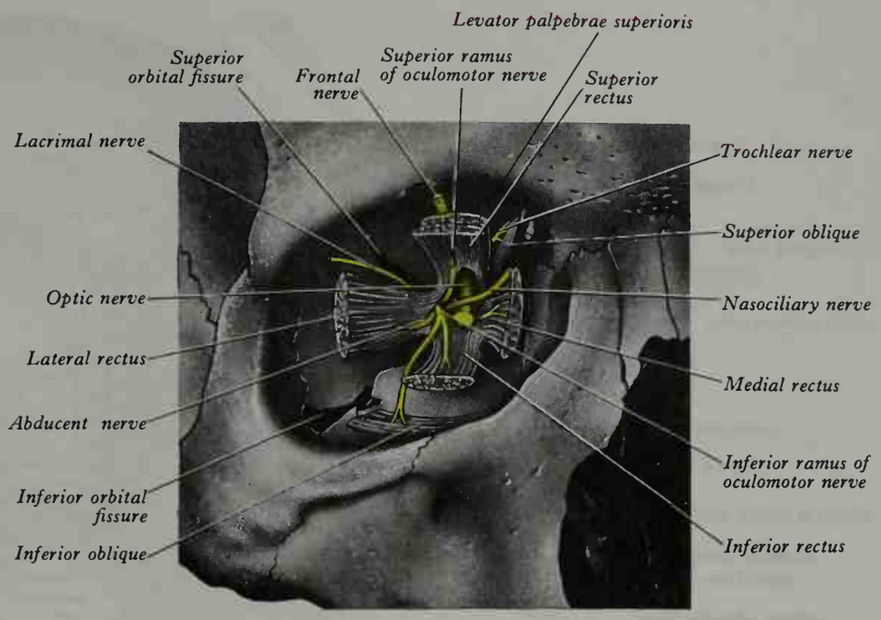
7.182 A diagram showing the cutaneous nerve supply of the face, scalp and neck. Compare with 7.186.

The *articular branches* consist of one or two twigs which enter the posterior part of the temporomandibular joint.

The *parotid branches* convey secretomotor fibres to the parotid gland. The preganglionic fibres are originally derived from the glossopharyngeal nerve through its tympanic branch and travel by the lesser petrosal nerve to the otic ganglion, whence the postganglionic fibres pass to the auriculotemporal nerve and so reach the gland (7.179). They also convey vasomotor fibres to the blood vessels of the parotid gland. These fibres are directly continuous with the fibres of the sympathetic root of the otic ganglion (p. 1076).

The *superficial temporal branches* accompany the superficial temporal artery and its terminal branches; they supply the skin of the temporal region and communicate with the facial and zygomaticotemporal nerves.

The lingual nerve (7.177) is sensory to the mucous membrane of the pre-sulcal part of the tongue, and to the floor of the mouth and the mandibular gums.



It arises from the posterior trunk of the mandibular nerve, and lies at first between the tensor veli palatini and the lateral pterygoid, where it is joined by the chorda tympani branch of the facial nerve, and frequently by a branch of the inferior alveolar nerve. Emerging from under cover of the lateral pterygoid the lingual nerve proceeds downwards and forwards between the ramus of the mandible and the medial pterygoid, lying anterior to, and slightly deeper than the inferior alveolar nerve. It then passes below the mandibular origin of the superior constrictor of the pharynx, and lies against the deep surface of the mandible on the medial side of the roots of the third molar tooth, where it is covered only by the mucous membrane of the gum and can be pressed against the bone by a finger placed inside the mouth. It then leaves the gum and passes on to the side of the tongue, where it crosses the styloglossus, and runs on the lateral surface of the hypoglossus and deep to the mylohyoid; here it is placed above the deep part of the submandibular gland and its duct. It then proceeds forwards on the side of the tongue, lying lateral to the hyoglossus and genioglossus, and divides into its terminal branches, which lie directly under cover of the mucous membrane of the tongue. In the latter part of its course the nerve is in close relation with the submandibular duct; it passes from above downwards and forwards on the lateral side of the duct, and then, winding below it, runs upwards and forwards on its medial side (7.177).

In addition to receiving the chorda tympani and the branch from the inferior alveolar nerve, already referred to, the lingual nerve is connected to the submandibular ganglion (p. 1072) by two or three branches (7.177), and, at the anterior margin of the hyoglossus, forms loops of communication with twigs of the hypoglossal nerve.

The *branches* of the lingual nerve supply the mucous membrane of the floor of the mouth, the lingual surface of the gums, and the mucous membrane of the pre-sulcal part of the tongue, being overlapped to a slight extent by the lingual fibres of the glossopharyngeal nerve (p. 1076); the terminal filaments join, at the tip of the tongue, with those of the hypoglossal nerve. In addition it carries postganglionic fibres from the submandibular ganglion (p. 1072) to the sublingual and anterior lingual glands.

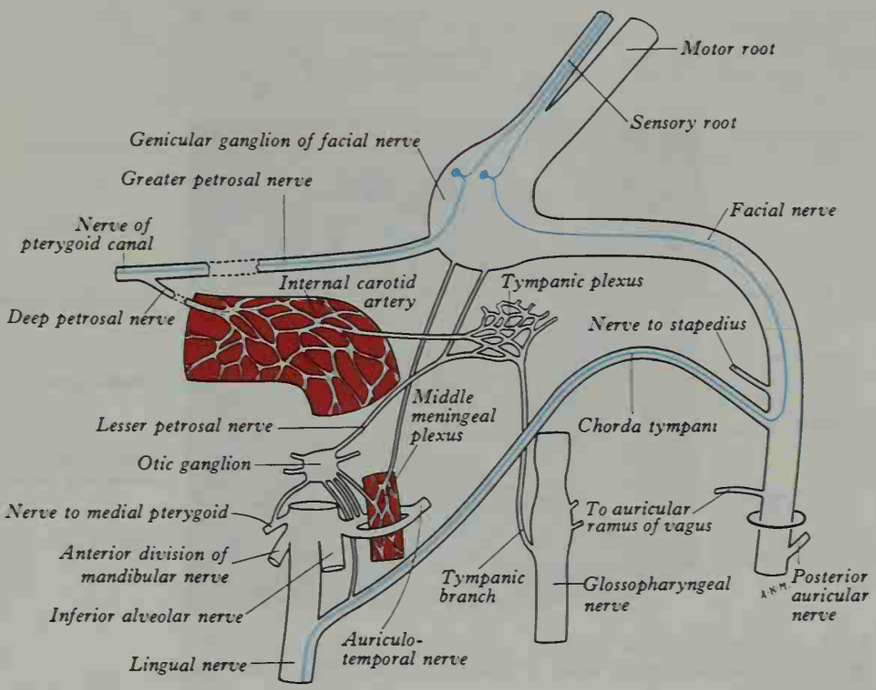
The inferior alveolar (dental) nerve descends deep to the lateral pterygoid, and then, at the lower border of the muscle, it passes between the sphenomandibular ligament and the ramus of the mandible to the mandibular foramen. Here it enters the mandibular canal, and runs below the teeth as far as the mental foramen, where it divides into an incisive and a mental branch. Below the lateral pterygoid the nerve is accompanied by the inferior alveolar artery. Dissection and radiographic studies show that in a majority of mandibles the inferior dental nerve does not occupy a single canal, but is *plexiform* in arrangement. It is also joined, directly, or through its plexiform branches, by rami entering the bone as parts of neurovascular bundles, derived from attached muscles such as masseter. Such '*accessory*' *dental nerves* ramify particularly in a plane lateral to the molar teeth, and their common occurrence accounts for the incomplete abolition of pain by inferior dental nerve block (Carter and Keen 1971).

The inferior alveolar nerve gives off the mylohyoid nerve,

7.183 A dissection of the right orbit viewed from in front, to show the origins of the orbital muscles and the relative positions of the nerves of the orbit.

branches to the molar and premolar teeth of the mandible and the incisive and the mental nerves.

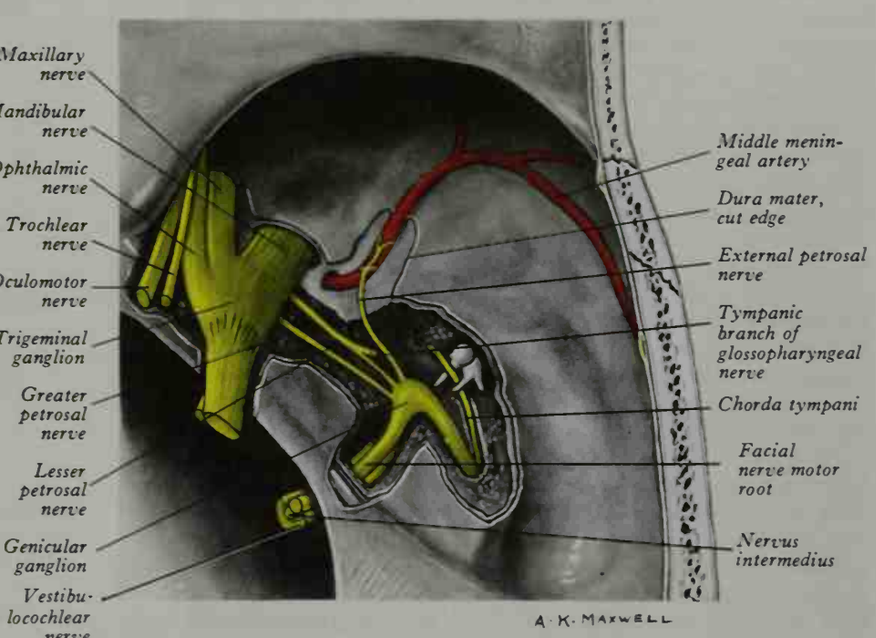
The *mylohyoid nerve* is derived from the inferior alveolar nerve just before the latter enters the mandibular foramen. It pierces the sphenomandibular ligament, descends in a groove on the medial surface of the ramus of the mandible and, passing below the mylohyoid line, it reaches the inferior surface of the mylohyoid, which it supplies together with the anterior belly of the digastric.



The branches to the molar and premolar teeth supply the adjoining gum also. Before they enter the roots of the teeth they communicate with one another and form an inferior dental plexus.

The *incisive nerve* is often described as continuing within the bone to supply the canine and incisor teeth. Alternative views have, however, been expressed: the nerves which supply the incisor teeth form an elaborate plexus on the external aspect of the mandible after emerging from the mental foramen and before they re-enter the bone (Starkie and Stewart 1931). The canine tooth may be supplied either from this incisor plexus or the plexus which innervates the premolars.

The *mental nerve* emerges at the mental foramen, and divides beneath the depressor anguli oris into three branches; one descends to the skin of the chin, and two ascend to the skin and mucous membrane of the lower lip; these branches communicate freely with the facial nerve (mandibular branch).



Applied Anatomy. A lesion of the whole trigeminal nerve causes anaesthesia of the corresponding anterior half of the scalp, of the face (excepting a small area near the angle of the mandible supplied by the great auricular nerve), of the cornea and conjunctiva, and of the mucous membranes of the nose, mouth and pre-sulcal part of the tongue. Paralysis and atrophy occur in the muscles supplied by the nerve, and when the mouth is opened the mandible is thrust over to the paralysed side. Lesions of the divisions of the nerve give a more limited sensory loss and, if affecting the lingual nerve below the point at which it is joined by the chorda tympani, will be accompanied by loss of taste in the corresponding half of the anterior part of the tongue.

Pains referred to various branches of the trigeminal nerve are of very frequent occurrence. As a general rule the diffusion of pain over the various branches of the nerve is at first confined to one only of the main divisions, although in severe cases pain may radiate over the branches of the other main divisions. The commonest example of this condition is the neuralgia which is so often associated with dental caries. Here, although the tooth itself may not appear to be painful, the most distressing referred pains may be experienced, and these are at once relieved by treatment directed to the affected tooth.

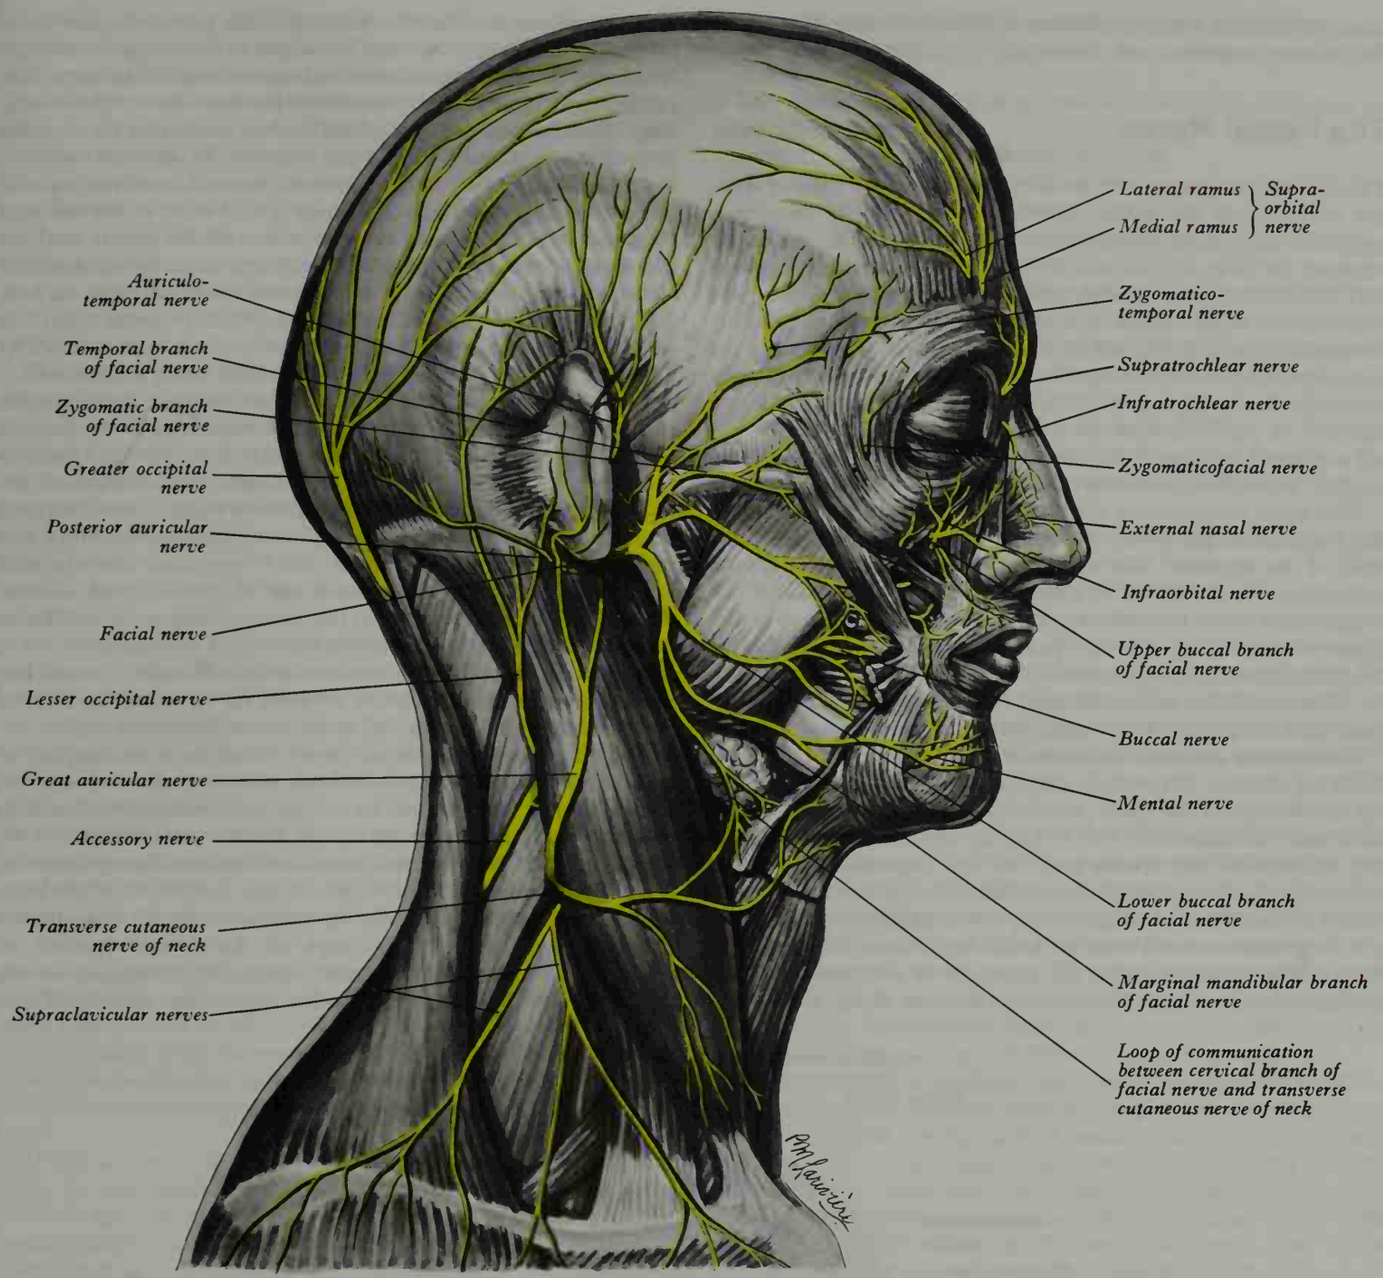
7.184 A plan of the intrapetrous section of the facial nerve, its branches and communications. The course of the taste fibres from the mucous membrane of the palate and from the anterior, oral, or presulcal part of the tongue is represented by the blue lines.

In the area of the ophthalmic nerve, severe supraorbital pain is commonly associated with acute glaucoma or with frontal or ethmoidal sinusitis. Malignant growths or empyema of the maxillary sinus, or unhealthy conditions about the inferior conchae or the septum of the nose, are often found giving rise to 'second division' (maxillary) neuralgia, and should be always looked for in the absence of dental disease in the maxilla. It is in the mandibular nerve, however, that some of the most striking examples are seen. It is quite common to meet with patients who complain of pain in the ear, in whom there is no sign of aural disease, and the cause is usually to be found in a carious tooth in the mandible. Moreover, with an ulcer or cancer of the tongue, often the first pain to be experienced is one which radiates to the ear and temporal fossa, over the distribution of the auriculo-temporal nerve.

7.185 A dissection of the right middle cranial fossa, showing the course and some of the connexions of the facial nerve within the temporal bone.

The lingual nerve is occasionally divided with a view to relieving the pain in cancer of the tongue. This may be carried out where the nerve lies in direct contact with the mandible below and behind the last molar tooth, covered only by the mucous membrane (p. 317).

In cases of intractable neuralgia of the trigeminal nerve various operative procedures have been introduced from time to time. The trunks of the maxillary and mandibular nerves and the trigeminal ganglion itself have been injected with alcohol with varying degrees of success, and excision of the ganglion, in whole or in part, has frequently been performed successfully, but the last-named operation involves serious risks (laceration of the cavernous sinus, etc.) and is now rarely undertaken. The sensory root of the nerve may be divided behind the ganglion, and this is now the operation of election when the pain is confined to the maxillary and mandibular nerve areas (7.182). Complete division of the sensory root necessarily denervates the cornea completely, and the resulting loss of the corneal reflex leads to neuropathic keratitis. Consequently, in these cases an endeavour is made to preserve the ophthalmic fibres, which lie in the upper and medial part of the root and can be spared if the incision is restricted to the lower and lateral fibres. The motor root of the nerve is left intact.



When the pain is limited to the ophthalmic area or to the ophthalmic and maxillary areas, the operation of election (Falconer 1949) consists in the division of the fibres of the spinal tract of the nerve, where it is most superficial (p. 901) and sometimes forms a recognizable elevation (p. 902) between the lateral margin of the fasciculus cuneatus and the posterior border of the lower part of the olive. Section of the tract 4–5 mm caudal to the obex preserves most, if not all, of the mandibular fibres, because they have entered the cranial part of the nucleus of the tract and so escape injury. Following the operation painful and thermal sensibility are lost over the ophthalmic and maxillary areas, but tactile sensibility is retained and the corneal reflex is not abolished.

The Abducent Nerve

The abducent nerve (7.176) supplies the lateral rectus muscle of the eyeball. Its fibres arise from a small nucleus situated in the cranial part of the floor of the fourth ventricle, close to the median plane and beneath the colliculus facialis (7.62, 64, 68, 69; p. 933). They descend ventrally through the pons, and emerge in the sulcus between the caudal border of the pons and the cranial end of the pyramid of the medulla oblongata (7.55).

The *abducens nucleus* consists of large and small multipolar neurons, the former being sources of the abducent nerve, the latter being known collectively as the *nucleus para-abducens*, which is considered to project to the oculomotor nucleus via the medial longitudinal fasciculus. The total number of cells in the nucleus has been stated to be about 22,000, and only a minority of these can be radicular, since the nerve contains about 6,600 fibres (Konigsmark *et al.* 1969). Claims that all abducent neurons react to division of the nerve (Warwick 1964 and others) are clearly based on inadequate concepts of what cells should be included as 'abducent'. A study in the kitten using the retrograde horseradish peroxidase technique (Gacek 1974) indicated that 50–90 per cent of the cells were radicular. Other studies have clearly demonstrated that some, at least, of the abducent neurons project to the oculomotor and perhaps the trochlear nuclei. (*See* Steiger and Büttner-Ennever 1978, for literature.) Büttner-Ennever (1977) has identified neurons in the pontine reticular formation, just rostral to the abducent nucleus, which project to regions of the oculomotor nucleus reputedly concerned with innervation of the lateral and inferior recti. He has discussed the considerable evidence for the view that these neurons mediate horizontal and perhaps also vertical integration of binocular movement.

Connexions. The nucleus of the abducent nerve receives prominent afferent connexions from: (1) the corticonuclear tract principally, but not wholly, of the contralateral side; some of these fibres are aberrant pyramidal fibres which descend from the midbrain to this level in the medial lemniscus (p. 901), and interneurons may link them to the nucleus; (2) the medial

7.186 The nerves of the right side of the scalp, face and neck. Compare with 7.182.

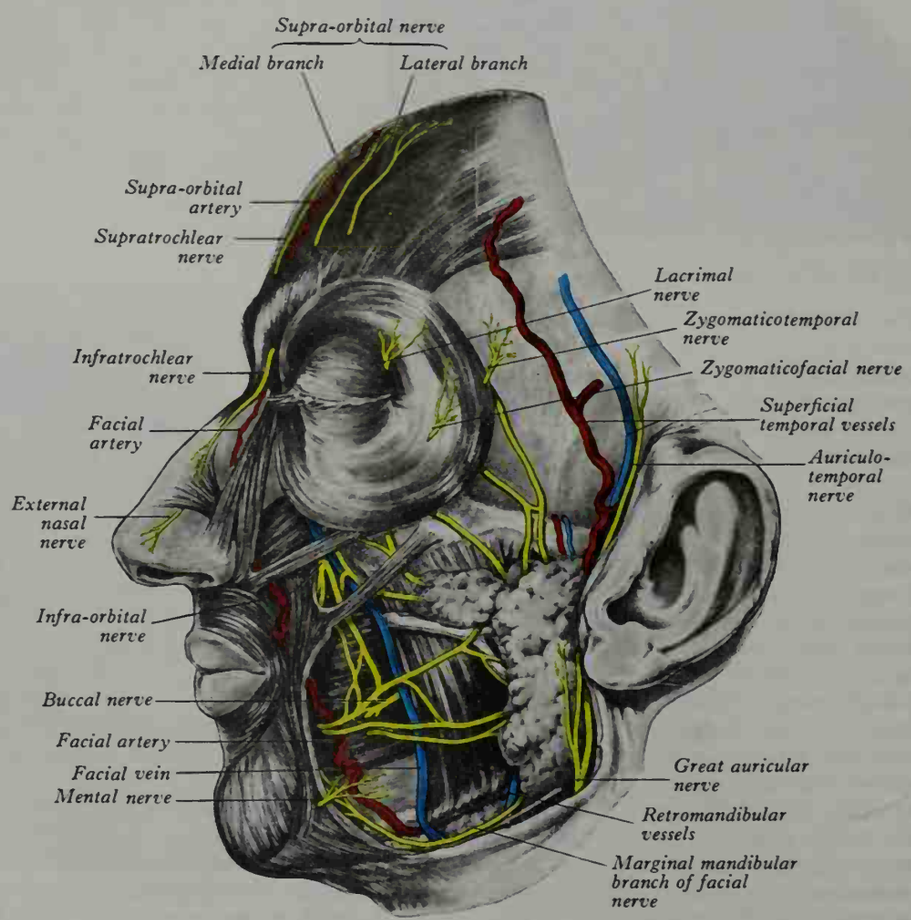
longitudinal fasciculus, by which it is connected with the nuclei of the third, fourth and eighth cranial nerves; (3) the tectobulbar tract, by which it is connected with the visual cortex and other centres through the medium of the superior colliculus. (See also p. 941).

Course. After leaving the surface of the brainstem, the abducent nerve runs upwards, forwards and laterally through the cisterna pontis, and usually dorsal to the anterior inferior cerebellar artery. It pierces the dura mater lateral to the dorsum sellae of the sphenoid bone and then bends sharply forwards as it crosses the superior border of the petrous part of the temporal bone close to its apex. In this situation it is inferior to the petrosphenoidal ligament—a fibrous band which connects the lateral margin of the dorsum sellae to the upper border of the petrous part of the temporal bone near its medial end. It next traverses the cavernous sinus, lying at first lateral and then inferolateral to the internal carotid artery (**6**.127) and enters the orbital cavity through the medial end of the superior orbital fissure. It passes within the common tendinous ring from which the recti of the eyeball arise, lying inferolateral to the oculomotor and nasociliary nerves, and finally sinks into the ocular surface of the lateral rectus (7.183, 269).

In the cavernous sinus the abducent nerve is joined by a considerable branch from the termination of the internal carotid plexus. This communication was originally described by Monro (1746), confirmed by Meckel (1832), but has subsequently been frequently omitted from textbooks and even denied (Sunderland and Hughes 1946). The existence of this connexion has been re-emphasized by Johnston and Parkinson (1974), and Parkinson *et al.* (1978). These workers have also described a branch of similar calibre which leaves the abducent nerve a few millimetres distal to its reception of the sympathetic communication, to join the ophthalmic nerve; they believe that the sympathetic postganglionic fibres which thus join the abducent nerve are thereby diverted into the ophthalmic division of the trigeminal. If confirmed, this observation would accord with the passage of sympathetic nerve fibres to the eyeball through the long ciliary branches of the nasociliary nerve, as suggested by some authorities.

Applied Anatomy. The abducent nerve is occasionally involved in fractures of the base of the skull. The result of paralysis of this nerve is medial or convergent squint. Diplopia hence follows. The long course forwards of the sixth cranial nerve through the cisterna pontis and its sharp bend over the superior border of the petrous part of the temporal bone make the nerve particularly liable to damage in conditions producing raised intracranial pres-

sure, as a result of which the brainstem is pushed caudally towards the foramen magnum with consequent stretching of the nerve.



The Facial Nerve

The facial nerve (7.184, 187) possesses a motor and a sensory root, the latter called the *nervus intermedius* (7.55). The two roots appear at the caudal border of the pons just lateral to the recess between the olive and the inferior cerebellar peduncle, the motor part being the more medial; the vestibulocochlear nerve lies immediately to the lateral side of the sensory root. The nervus intermedius usually cleaves to the latter nerve rather than the facial, passing from the eighth to the seventh nerve as they approach the internal acoustic meatus, often as more than one filament. In one-fifth of a series of seventy-three dissections it was not a separate nerve until the meatus was reached, a point of some surgical importance (Rhoton *et al.* 1968).

The *motor root* supplies the muscles of the face, scalp, auricle, the buccinator, platysma, stapedius, stylohyoid, and posterior belly of the digastric. The *sensory root* conveys from the chorda tympani nerve the fibres of taste for the presulcal area of the tongue, and from the palatine and greater petrosal nerves the fibres of taste from the soft palate; in addition, it transmits the preganglionic parasympathetic (secretomotor) innervation of the submandibular and sublingual salivary glands, the lacrimal gland and the glands of the nasal and palatine mucosae.

The motor nucleus from which most of the motor fibres of the facial nerve are derived lies deeply in the reticular formation of the caudal part of the pons (p. 910). It is posterior to the dorsal nucleus of the trapezoid body (7.62, 64, 68) and ventromedial to the nucleus of the spinal tract of the trigeminal nerve. It represents the branchial efferent column, but it lies much more deeply in the pons than might be expected, and its outgoing fibres pursue a most unusual course (7.69). Both these features have been explained by invoking the principle of neurobiotaxis (but *see*, however, p. 164). The nucleus receives fibres from both corticonuclear tracts in the lower part of the pons or reputedly by aberrant pyramidal fibres which descend in the medial lemniscus. The fibres from the contralateral side contribute to that part of the nucleus which supplies the muscles of the lower part of the face (p. 910). The fibres to that part of the nucleus supplying the muscles around the eyes and forehead are bilateral. In addition, some of the efferent fibres of the facial nerve proceed from the *superior salivatory nucleus* (*see* p. 911), which is said to be in the reticular formation, dorsolateral to the caudal end of the motor nucleus. The cells of the nucleus have been described as being clustered along the intrapontine part of the facial nerve distal to its loop around the abducens nucleus (Crosby and Dejonge 1963). It represents the general visceral efferent column, and it sends its fibres to join the sensory root, by which they are ultimately distributed through the chorda tympani to the submandibular and sublingual salivary glands, and perhaps also to the parotid gland (*see* p. 1123). Further preganglionic fibres having issued via the sensory root are destined for ultimate distribution to the pterygopalatine ganglion which they reach in the greater petrosal nerve and nerve of the pterygoid canal (*vide infra*). From this double origin the fibres of the *motor root* pass dorsally and medially, and, reaching the caudal end of the abducent nucleus, they run rostrally superficial to this nucleus deep to the colliculus facialis. At the cranial end of the nucleus of the abducent nerve they make a second bend, and run caudoventrally through the pons to the point of emergence between the olive and the inferior cerebellar peduncle (7.55, 69) at the cerebellopontine angle.

Topographically the facial motor nucleus is a complex of smaller nerve cell groups—lateral, intermediate and medial, which have been identified in various mammals including man (Marinesco 1899; Papez 1927). A further subdivision of the medial nucleus into ventral, dorsal and intermediate sub-nuclei has also been described. (For details and discussion of the large literature concerning the facial nucleus, consult Vraa-Jensen 1942.) These subsidiary groups of nerve cells extend as craniocaudal columns through the facial nuclear complex, like the columnar groups of the spinal cord or oculomotor nucleus. There

7.187 The terminal branches of the left trigeminal and facial nerves in the face.

is general agreement that the facial subnuclei innervate muscles supplied by individual branches of the facial nerve, or even single muscles, but different observers disagree in details. Retrograde changes due to division of these branches in dogs (Vraa-Jensen 1942; Yagita 1910) or cats (Papez 1927; Courville 1966) have provided most of the evidence, but the effects on motor terminals due to selective lesions of the nucleus have also been studied in cats. General results were that the lateral sub-nucleus innervates the buccal musculature, the intermediate sends axons into the temporal, orbital and zygomatic facial branches, and the medial into the posterior auricular and cervical rami and probably also into the stapedial nerve. Nuclear lesions produced a roughly similar but more detailed schema (Szentágothai 1948).

The sensory nucleus of the facial nerve is the upper part of the *nucleus of the tractus solitarius* of the medulla oblongata (p. 905). It receives afferent fibres from the sensory root and sends efferent fibres to the ventral group of nuclei of the lateral part of the thalamus of the opposite side. As they ascend through the midbrain and subthalamic regions, these fibres are closely related to the median plane (Harris 1952). From the thalamus they are relayed to the inferior part of the postcentral gyrus. (For further details of projections from the nucleus of the solitary tract *see* p. 1085.)

The sensory root (*nervus intermedius*) consists of the central processes of the unipolar cells of the genicular ganglion, which leave the trunk of the facial nerve in the internal acoustic meatus and pass centrally as one or more slender bundles between the motor root and the vestibulocochlear nerve or adhering to the latter, to enter the brainstem at the lower border of the pons. The peripheral branches from the processes of the ganglion cells are the taste fibres contained in the chorda tympani and the greater petrosal nerves, and also a few somatic afferent fibres from the concha of the auricle (p. 1192). As already stated, the sensory root also contains the efferent preganglionic parasympathetic fibres for the submandibular and sublingual salivary glands, the lacrimal gland, and pharyngeal, nasal and palatine glands.

From their attachments to the brain, the two roots of the facial nerve pass laterally and forwards with the vestibulocochlear nerve to the opening of the internal acoustic meatus. In the meatus the motor root lies in a groove on the upper and anterior surface of the vestibulocochlear nerve, the sensory root being placed between them.

At the bottom of the meatus, the facial nerve enters the facial canal. In this canal the nerve runs at first laterally above the vestibule and, reaching the medial wall of the epitympanic recess, bends sharply backwards above the promontory, and arches downwards in the medial wall of the aditus to the mastoid antrum. Finally it descends to reach the stylomastoid foramen. The point where it bends sharply backwards is named the *geniculum*; it presents a reddish asymmetric swelling named the *genicular ganglion* (7.184). On emerging from the stylomastoid foramen, the facial nerve runs forwards in the substance of the parotid gland (p. 1272), crosses the styloid process, the retromandibular vein and the external carotid artery, and divides behind the neck of the mandible into branches which pierce the anteromedial surface of the parotid gland and diverge from one another under cover of it. They form a network (*parotid plexus*) and are distributed to the musculature of the face. As it emerges from the stylomastoid foramen, the facial nerve lies about 2 cm deep to the middle of the anterior border of the mastoid process. Its course through the parotid gland can be represented by a short horizontal line drawn across the upper part of the lobule of the auricle (**6**.47).

The angular measurements of the frequent changes in direction of the facial nerve in the intra-osseous part of its course are of considerable surgical importance. Kudo and Nori (1974) and Guerrier (1975) have recorded highly detailed metrical studies of this part of the nerve.

The facial nerve is supplied by the anterior inferior cerebellar artery in the intracranial part of its course, by the superficial petrosal branch of the middle meningeal artery and the stylomastoid branch of the posterior auricular or occipital arteries in the intrapetrous part, by branches from the stylomastoid, posterior auricular, occipital, superficial temporal and transverse facial arteries extracranially. Its venous drainage is into the venae comitantes of the superficial petrosal and stylomastoid arteries (Blunt 1954).

The branches of communication of the facial nerve may be arranged as follows:

Intracranial:	Vestibulocochlear
Genicular ganglion:	Pterygopalatine ganglion via the greater petrosal nerve
	Otic ganglion via the lesser petrosal nerve
	Middle meningeal sympathetic plexus
Facial canal:	Auricular branch of vagus
At exit from stylomastoid foramen:	To glossopharyngeal, vagus, great auricular and auriculotemporal nerves
Post-auricular:	To lesser occipital nerve
Facial:	With trigeminal nerve
Cervical:	With transverse cervical nerve

In the internal acoustic meatus some minute filaments connect the facial nerve with the vestibulocochlear nerve.

The greater petrosal nerve arises from the genicular ganglion, and consists chiefly of taste fibres which are distributed to the mucous membrane of the palate; but it also contains preganglionic parasympathetic fibres which are travelling to the pterygopalatine ganglion; they are said to be relayed through the zygomatic and lacrimal nerves to the lacrimal gland (but *see* p. 1065), and through the nasal and palatine nerves to the nasal and palatine mucosal glands (**7**.179). It receives a twig from the tympanic plexus, passes forwards through the hiatus on the anterior surface of the petrous portion of the temporal bone and runs in a groove on the bone. It passes beneath the trigeminal ganglion and reaches the foramen lacerum. In this foramen it is joined by the **deep petrosal nerve** (**7**.184) from the sympathetic plexus on the internal carotid artery, and forms the **nerve of the pterygoid canal**, which passes forwards through the pterygoid canal and ends in the pterygopalatine ganglion. The taste fibres pass without interruption through or over the surface of the ganglion into the palatine branches which spring from it.

From the trunk of the facial nerve near the genicular ganglion, from the ganglion itself, or from the root of the greater petrosal nerve (Vidić and Young 1967) a branch runs to join the lesser petrosal nerve (**7**.184), and is conveyed through this nerve to the otic ganglion. However, the fibres constituting this small communicating nerve do not stem from the facial nerve itself, but from the auricular branch of the vagus. In twenty-four out of twenty-five human dissections the fibres approached the facial nerve through the stapedius muscle, travelling in the muscle's fascial sheath almost as far as the genicular ganglion, before departing to join the lesser superficial petrosal nerve (Vidić 1968).

The sympathetic plexus on the middle meningeal artery is joined to the genicular ganglion by an inconstant branch, sometimes named the *external petrosal nerve*.

Before the facial nerve emerges from the stylomastoid foramen, it receives another twig from the auricular branch of the vagus.

After its exit from the stylomastoid foramen, the facial nerve receives a twig from the glossopharyngeal nerve, and communicates with the great auricular and auriculotemporal nerves in the parotid gland, with the lesser occipital nerve behind the ear, with the terminal branches of the trigeminal nerve on the face, and with the transverse cutaneous cervical nerve in the neck.

The branches of distribution (**7**.184, 186) of the facial nerve may be grouped as follows:

In the facial canal:	Nerve to the stapedius
	Chorda tympani
At exit of the stylomastoid foramen:	Posterior auricular
	Digastric, posterior belly
	Stylohyoid
On the face:	Temporal
	Zygomatic
	Buccal
	Marginal mandibular
	Cervical

The nerve to the stapedius arises from the facial nerve opposite the pyramidal eminence on the posterior wall of the tympanic cavity; it passes forwards through a small canal to reach the muscle (*vide supra*, and also p. 1199).

The chorda tympani nerve (7.181) arises from the facial nerve about 6 mm above the stylomastoid foramen. It runs upwards and forwards in a canal, and perforates the posterior bony wall of the tympanic cavity through the posterior canaliculus for the chorda tympani nerve, which is situated close to the posterior border of the medial surface of the tympanic membrane and on a level with the upper end of the handle of the malleus. Passing forwards between the fibrous and mucous layers of the membrane, it crosses the medial aspect of the handle of the malleus, and re-enters the bone through the anterior canaliculus for the chorda tympani nerve, which is placed at the medial end of the petrotympanic fissure. The nerve now descends ventrally on the medial surface of the spine of the sphenoid bone (which it sometimes grooves) and passes deep to the lateral pterygoid. In this part of its course the nerve lies lateral to the tensor veli palatini and is crossed by the middle meningeal artery, the roots of the auriculotemporal nerve and the inferior alveolar nerve. Finally it joins the posterior border of the lingual nerve at an acute angle. It contains efferent preganglionic parasympathetic (secretomotor) fibres which enter the submandibular ganglion, and are there relayed as postganglionic fibres to the submandibular and sublingual glands; the majority of its fibres are afferent from the mucous membrane covering the anterior, presulcal part of the tongue, save the vallate papillae; they constitute the nerve of taste for this region of the tongue. Before uniting with the lingual nerve the chorda tympani is joined by a small branch from the otic ganglion.

The posterior auricular nerve arises close to the stylomastoid foramen and runs upwards in front of the mastoid process; here it is joined by a filament from the auricular branch of the vagus nerve, and communicates with the posterior branch of the great auricular nerve, and with the lesser occipital nerve. As it ascends between the external acoustic meatus and the mastoid process it divides into an auricular and an occipital branch. The *auricular branch* supplies the auricularis posterior and the intrinsic muscles on the cranial surface of the auricle. The *occipital branch*, the larger, passes backwards along the superior nuchal line of the occipital bone, and supplies the occipital belly of the occipitofrontalis.

The digastric branch arises close to the stylomastoid foramen, and divides into several filaments which supply the posterior belly of the digastric; one of these filaments joins the glossopharyngeal nerve.

The stylohyoid branch, long and slender, frequently arises in conjunction with the digastric branch; it enters the middle part of the stylohyoid.

The temporal branches cross the zygomatic arch to the temporal region. They supply the intrinsic muscles on the lateral surface of the auricle, the anterior and superior auricular muscles, and join with the zygomaticotemporal branch of the maxillary nerve, and with the auriculotemporal branch of the mandibular nerve. The more anterior branches supply the frontal belly of the occipitofrontalis, the orbicularis oculi and the corrugator, and join the supraorbital and lacrimal branches of the ophthalmic nerve.

The zygomatic branches run across the zygomatic bone to the lateral angle of the eye; they supply the orbicularis oculi, and join with the filaments of the lacrimal nerve and the zygomaticofacial branch of the maxillary nerve.

The buccal branches pass horizontally forwards to be distributed below the orbit and around the mouth. The *superficial branches* run between the skin of the face and the superficial muscles, and supply the latter; some are distributed to the procerus, joining with the infratrochlear and external nasal nerves. The *upper deep branches* pass under cover of the zygomaticus major and the levator labii superioris, supplying them and forming an *infraorbital plexus* with the superior labial branches of the infraorbital nerve; they also supply the levator anguli oris, the zygomaticus minor, the levator labii superioris alaeque nasi and the small muscles of the nose. These branches are sometimes described as lower zygomatic branches. The *lower deep branches* supply the buccinator and orbicularis oris, and join with filaments of the buccal branch of the mandibular nerve.

The marginal mandibular branch runs forwards below the angle of the mandible under cover of the platysma. It lies at first superficial to the upper part of the digastric triangle and then turns upwards and forwards across the body of the mandible to lie under cover of the depressor anguli oris (7.187). It supplies the risorius and the muscles of the lower lip and chin, and joins the mental nerve (p. 1067).

The cervical branch issues from the lower part of the parotid gland, runs forwards and downwards under cover of the platysma to the front of the neck. It supplies the platysma and communicates with the transverse cutaneous cervical nerve.

The submandibular ganglion is a small, somewhat fusiform ganglion which lies on the upper part of the hyoglossus. There are further ganglion cells in the hilum of the submandibular gland. Like the ciliary, pterygopalatine and otic ganglia, these are peripheral ganglia of the parasympathetic system. The submandibular ganglion is superior to the deep part of the submandibular gland and below the lingual nerve, from which it is suspended by an anterior and a posterior filament (7.177). Although so intimately related to the lingual nerve, the ganglion is connected functionally with the facial nerve and its chorda tympani branch.

The *motor* or *parasympathetic root* is formed by the posterior filament connecting the ganglion to the lingual nerve. It conveys preganglionic fibres which leave the superior salivatory nucleus and run in the facial, chorda tympani and lingual nerves to reach the ganglion. There the fibres establish synaptic relations with the cells of the ganglion, and the postganglionic fibres are secretomotor to the submandibular and the sublingual salivary glands. (Some of these fibres may reach the parotid gland. *See* p. 1274). The *sympathetic root* is derived from the plexus on the facial artery. It consists of postganglionic fibres which commence in the superior cervical ganglion and pass through the submandibular ganglion without being interrupted. They are vasomotor to the blood vessels of the submandibular and sublingual glands.

Five or six branches arise from the ganglion and supply the submandibular gland and its duct. Other fibres from the ganglion pass through the anterior filament which connects it to the lingual nerve and are carried to the sublingual and the anterior lingual glands.

The cutaneous fibres of distribution of the facial nerve accompany those of the auricular branch of the vagus and probably innervate skin on both aspects of the auricle, in the conchal depression and over its eminence. Details of this innervation are, however, uncertain, as is the question of whether facial fibres reach the external acoustic meatus and tympanic membrane.

Applied Anatomy. Facial paralysis is commonly unilateral and may be due to: (1) *supranuclear lesions* of the corticonuclear fibres from the frontal lobe, and variably combined with numerous other descending fibres that converge on the facial nucleus; (2) *nuclear* or *infranuclear lesions* involving the lower motor neurons.

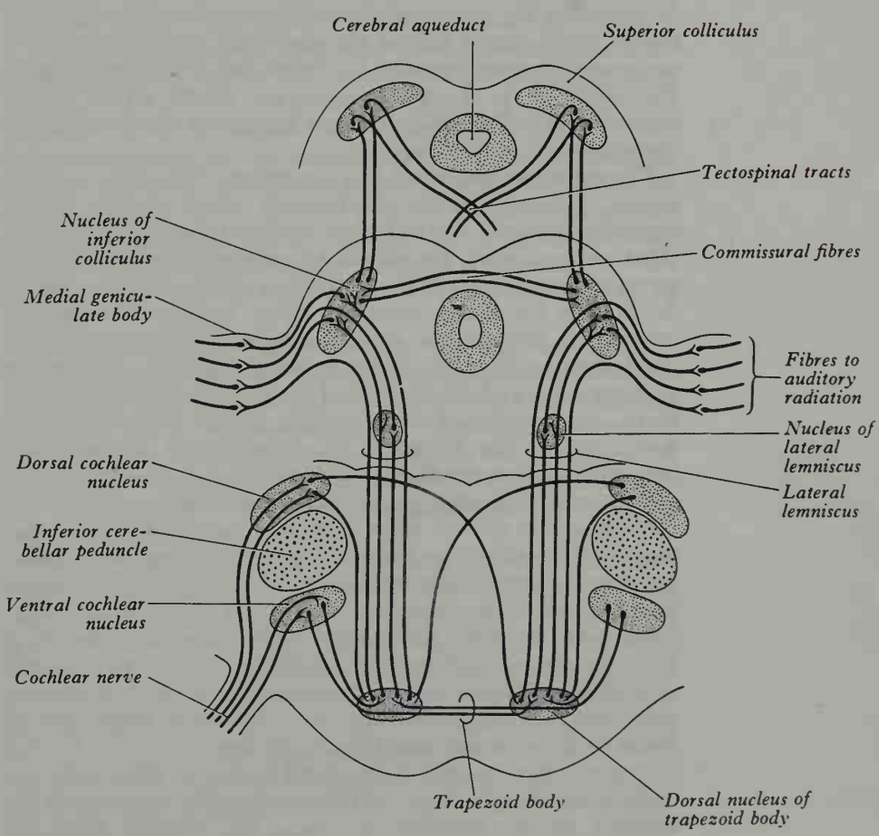
Facial paralysis due to a *supranuclear lesion* involving 'upper motor neuron' pathways is usually part of a hemiplegia. The movements of the lower part of the face are usually more severely affected than those of the upper part and voluntary movements are weak or absent whilst emotional and associated movements are little affected. The electrical reactions of the muscles on the affected side are not altered. Occasionally supranuclear lesions result in abolition or weakness of emotional movements with retention of voluntary movements. The dissociation in these forms of paralysis suggests that the supranuclear pathway concerned with emotional movements is distinct from that of the corticonuclear fibres which are concerned with voluntary movements.

The effects of *nuclear* or *infranuclear lesions* vary according to the point on its course at which the facial nerve is injured. If the facial nucleus or facial nerve fibres in the pons are involved, neighbouring structures are inevitably involved as well. The facial muscles are represented in cell groups in the nucleus and

their degree of involvement will govern the extent of the paralysis which will be ipsilateral: otherwise the symptoms are identical with those seen in more peripheral lesions of the nerve. The associated lesions may thus include paralysis of the lateral rectus muscle of the eyeball due to involvement of the abducent nerve nucleus, around which the facial nerve fibres loop, paralysis of the muscles of mastication due to involvement of the motor nucleus of the trigeminal nerve, sensory loss on the face from implication of the principal sensory nucleus or of the nucleus of the spinal tract of the trigeminal nerve or spinothalamic tract and paralysis of the upper or lower limbs due to lesions of the corticospinal tracts. Due to the proximity of the sensory root of the facial nerve and of the vestibulocochlear nerve, lesions in the posterior cranial fossa or in the internal acoustic meatus may be accompanied by loss of taste in the anterior two-thirds of the tongue and deafness on the same side as the facial paralysis. When the facial nerve is damaged within the temporal bone the chorda tympani nerve is usually involved and in fractures of the petrous temporal bone the vestibulocochlear nerve is also usually implicated. The most common cause of facial palsy is inflammation of the nerve close to the stylomastoid foramen (Bell's paralysis). The cause of this is uncertain, but it results in oedema of the nerve and compression of its fibres in the facial canal or at the stylomastoid foramen. If the lesion is complete the facial muscles are all equally affected, and voluntary, emotional and associated movements of the face suffer equally. There is asymmetry of the face and the affected side is immobile. The eyebrow droops, the lines on the forehead and nasolabial fold are smoothed out and the palpebral fissure is wider than on the normal side due to the unopposed action of the levator palpebrae. Tears fail to enter the lacrimal puncta because they are no longer in contact with the conjunctiva, the conjunctival reflex is absent and efforts to close the eye merely cause the eyeball to roll upwards until the cornea lies under the upper lid. The ala nasi does not move properly on respiration. The lips remain in contact on the paralysed side, but cannot be pursed for whistling; when a smile is attempted the angle of the mouth is drawn up on the unaffected side but on the affected side the lips remain nearly closed, and the mouth assumes a characteristic triangular form. During mastication food accumulates in the cheek, from paralysis of the buccinator, and dribbles or is pushed out from between the paralysed lips. On protrusion the tongue seems to be thrust over towards the paralysed side, but verification of its position by reference to the incisor teeth will show that this is not really so. The platysma and the muscles of the auricle are paralysed; in severe cases the articulation of labials is impaired. The electrical reactions of the affected muscles are altered (reaction of degeneration), and the degree to which this alteration has taken place after a week or ten days gives a valuable guide to the prognosis. Most cases of Bell's palsy recover completely. For details of variations in the course of the facial nerve in the vicinity of the middle ear, and their surgical importance, consult Durcan *et al.* (1967). Degeneration studies (Naoris 1968) have shown that the facial nerve contains no fascicular or other pattern corresponding to its peripheral branches, a finding of some significance in suturing the nerve after injury.

The Vestibulocochlear Nerve

The vestibulocochlear nerve (7.62, 63, 66, 68) appears in the groove between the pons and medulla oblongata, behind the facial nerve and in front of the inferior cerebellar peduncle (7.55). It consists of two sets of fibres, which although differing in their principal central connexions, are both concerned in the transmission of afferent impulses from the internal ear to the brain. One set of fibres forms the vestibular nerve, or nerve of equilibration, and arises from the cells of the vestibular ganglion situated in the outer part of the internal acoustic meatus; the other set constitutes the cochlear nerve, or nerve of hearing, and takes origin from the cells of the spiral ganglion of the cochlea. Both ganglia consist of bipolar nerve cells; from each cell a central fibre passes to the brain, and a peripheral fibre to the internal ear.



The peripheral arrangement of the vestibulocochlear nerve is described on pp. 1202, 1213–1216.

THE VESTIBULAR NERVE

The fibres of the vestibular nerve enter the brain superomedial to those of the cochlear nerve. They pass backwards through the pons between the inferior cerebellar peduncle and the spinal tract of the trigeminal nerve and divide into ascending and descending branches which mostly end in the vestibular nuclei, although some proceed direct to the cerebellum along the inferior cerebellar peduncle (p. 916).

The vestibular nuclear complex comprises the following: (1) The *medial vestibular nucleus* (p. 933), which lies in the vestibular area of the floor of the fourth ventricle, crossed dorsally by the striae medullares. It is the largest subdivision and extends upwards from the medulla oblongata into the pons. (2) The *inferior vestibular nucleus* (p. 905) lies lateral to the medial nucleus and reaches to a lower level in the medulla oblongata. It is placed between the medial nucleus and the inferior cerebellar peduncle, and the descending branches of the incoming vestibular fibres are interspersed among its cells. (3) The *lateral nucleus* (p. 908) lies ventrolateral to the upper part of the medial nucleus, and it is characterized by the large size of its constituent cells. Its upper end becomes continuous with the lower end of (4) the *superior nucleus*, which extends higher into the pons than the other subdivisions and occupies the upper part of the vestibular area. A number of minor subdivisions have been described in the main vestibular nuclei in the cat (Brodal and Pompeiano 1957), and a somatotopic pattern has been tentatively suggested in the lateral vestibular nucleus (Løken and Brodal 1970).

Connexions. All the vestibular nuclei receive *radicular fibres* from the vestibular nerve and it is believed that they receive *afferent cerebellovestibular fibres* through the inferior cerebellar peduncle. These fibres are derived, for the most part, from the flocculus and nodule (posterior lobe), but others have been ascribed to the uvula, the lingula and the fastigial nucleus.

7.188 A simplified diagram to show some of the central connexions of the cochlear nerve and the auditory pathway through the brainstem. Although they are shown in the figure as being of comparable size, the trapezoid body constitutes a much more important and larger commissural bundle than the fibres connecting the nuclei of the two inferior colliculi. *Efferent* fibres in the cochlear nerve, and *descending* fibres in the auditory pathway have been omitted.

From the nuclei *efferent fibres* enter the inferior cerebellar peduncle, most of them being destined for the flocculus and the nodule, though some may pass to the uvula and the lingula, and some have been described as terminating in the fastigial nucleus. As already stated, numbers of fibres of the vestibular nerve 'bypass' the nuclei and traverse the inferior cerebellar peduncle to reach the flocculus and the nodule directly.

As a whole, the vestibular nuclear complex acts as a relay station on an afferent cerebellar pathway, and is in turn a distributing station for efferent cerebellar fibres.

In addition, fibres from the vestibular nuclei enter the medial longitudinal fasciculus (7.94), in which they ascend, or descend, to reach the motor nuclei of the eye muscles and muscles of the neck. This connexion, the '*octavo-oculomotor system*', has attracted much attention (*see* pp. 909, 946), but much dissension exists between accounts regarding the vestibular nuclei involved, the route of their projections, the degree of decussation, and their particular destinations. Tarlov (1972, 1975) has described a detailed projection from the medial and superior vestibular nuclei to specific motor pools in the oculomotor nucleus of the cat (see also p. 1057). He has also reviewed the literature on this highly interesting topic. It is suggested that an excitatory and an inhibitory projection exists, capable of mediating the complex and subtle integration between vestibular signals and eye movements. From the large cells of the lateral vestibular nucleus, efferent fibres descend to form the vestibulospinal tract (p. 875) and fibres from the other nuclei are believed to join the lateral lemniscus and so may reach the inferior colliculus and the medial geniculate body and, probably, the cerebral cortex.

Speaking broadly, through its connexions the vestibular system is able to influence the movements of the eyes and head and the muscles of the trunk and limbs, so as to maintain equilibrium when loss of balance is threatened.

THE COCHLEAR NERVE

As it reaches the brainstem the cochlear nerve (7.62, 63, 66) is placed on the lateral side of the vestibular nerve, but the two nerves soon become separated by the inferior cerebellar peduncle. The cochlear nerve passes round the lateral aspect of the peduncle, while the vestibular nerve penetrates the brainstem on the medial side of that structure.

The cochlear nuclei are two in number. The *ventral cochlear nucleus* is placed on the ventrolateral aspect of the inferior cerebellar peduncle, and it receives the larger, ascending branches of the cochlear nerve. The *dorsal cochlear nucleus* lies on the dorsal aspect of the peduncle in the lateral part of the vestibular area of the floor of the fourth ventricle, where it forms the auditory tubercle. It receives the smaller, descending branches of the cochlear nerve. For a detailed experimental analysis of the modes of termination and distribution of the primary cochlear afferent fibres, and a review of the literature, consult Osen (1970) and Kane (1974). The former study demonstrated a consistency between the above details and the tonotopical organization in the cochlear nuclei (p. 909); both studies concern the cat.

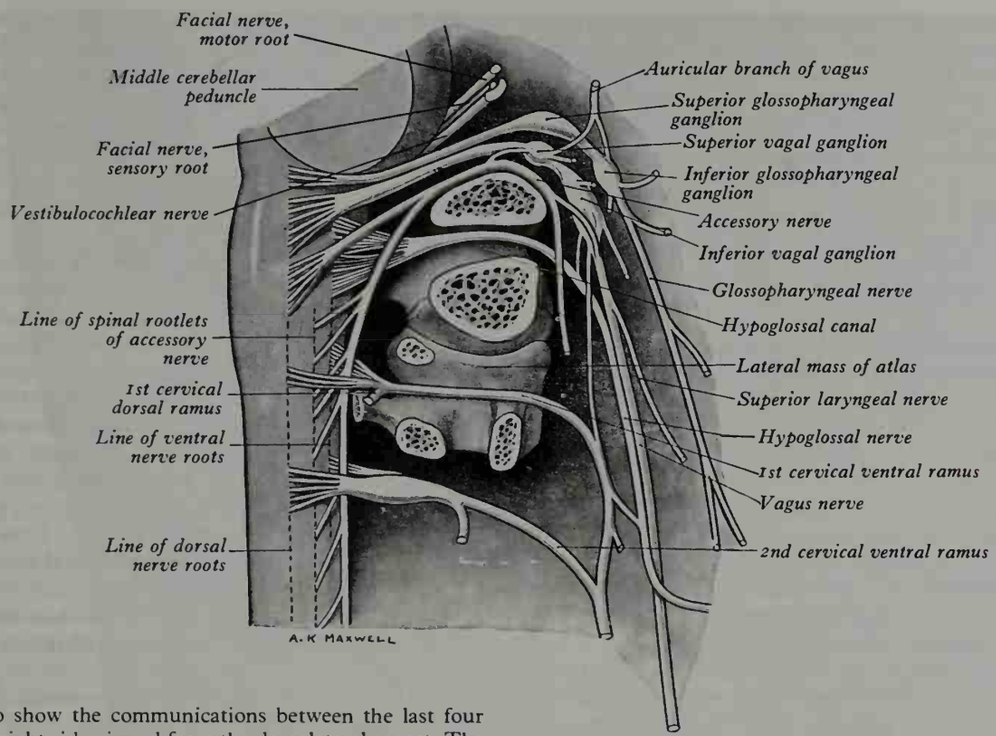
Many of the *efferent fibres* from the *ventral cochlear nucleus* (second neuron fibres on the auditory pathway) end in the dorsal nucleus of the trapezoid body, either of the same or of the opposite side. There they are relayed and the tertiary fibres turn upwards, forming an ascending tract, termed the *lateral lemniscus* (7.70, 188). The secondary fibres of the opposite side behave in the same way, and the intersections of the contralateral fibres of the two sides form the *trapezoid body* (7.188). The *efferent fibres* from the *dorsal cochlear nucleus* establish similar connexions (7.188) and the tertiary fibres ascend in the lateral lemniscus of the same and of the opposite side. Many of the cochlear efferents relay in the superior olivary complex (p. 904), the majority from the ipsilateral cochlear nuclei. After relay these pathways join both lateral lemnisci.

Each lateral lemniscus, therefore, consists of tertiary neurons from both sides, and on its upward course to the midbrain some of these have a cell station in a small group of nerve cells, intimately related to the tract and termed the *nucleus of the lateral lemniscus*. On reaching the midbrain, some of the fibres end in the nucleus of the inferior colliculus, but others 'bypass' the nucleus and run in the inferior brachium to reach the medial geniculate body, where they are relayed to the auditory cortex (areas 41, 42 and 22). Ferraro and Minckler (1977) have estimated the fibre count of the human lateral lemniscus at about 203,000 (right side) and 185,000 (left side), these being averages from 15 brains (newborn to over 90 years).

Commissural fibres link the two auditory pathways at the level of the inferior colliculi, and auditory reflexes are mediated via the colliculi, tectospinal and tectobulbar tracts, and the medial longitudinal fasciculi (7.94, 188). An *efferent* component in the acoustic pathway has been noted already (p. 910). Its peripheral fibres are derived from nerve cells in or near the superior olivary complex (Rasmussen 1942, 1960), forming in their central course the *olivocochlear fasciculus*. These fibres terminate in relation to the hair cells of the spiral organ of the cochlea. Functionally, they are probably inhibitory in their actions (Whitfield 1967). The existence of sympathetic and possibly parasympathetic fibres in the vestibulocochlear nerve has received some support (Ross 1969).

The vestibulocochlear nerve is soft in texture; the axons are ensheathed in *glial* cells in its proximal part. After leaving the medulla oblongata it passes forwards across the posterior border of the middle cerebellar peduncle, in company with the facial nerve, from which it is partially separated by the labyrinthine artery. It then enters the internal acoustic meatus with the facial nerve. At the outer end of the meatus it receives one or two filaments from the facial nerve, and splits into its *cochlear* and *vestibular* parts, the distribution of which will be described with the anatomy of the internal ear (pp. 1202, 1213–1216).

The Glossopharyngeal Nerve



The glossopharyngeal nerve (7.55, 62, 66, 190, 191) contains motor and sensory fibres. It supplies motor fibres to the stylopharyngeus, secretomotor fibres to the parotid gland, and sensory fibres to the pharynx, the tonsil and the posterior (postsulcal) part of the tongue; it is also the nerve of taste for this part of the tongue. It emerges as three or four rootlets from the cranial part of the medulla, in the groove between the olive and inferior cerebellar peduncle above the rootlets of the vagus nerve.

The sensory nuclei receive the central processes of the unipolar nerve cells in the superior and inferior ganglia of the nerve; the fibres concerned with taste end in the *nucleus of the tractus solitarius* (p. 903) and those concerned with common sensation probably in the *nucleus of the spinal tract of the trigeminal nerve* (Brodal 1947, and *see* pp. 902, 1060).

The motor nucleus is formed by the rostral part of the *nucleus ambiguus* (pp. 905, 1077), which lies deeply in the reticular formation of the medulla oblongata. It is connected with the corticonuclear tracts of *both* sides directly and through interneurons. The corticonuclear fibres leave the tract at the level of the nucleus ambiguus or in the pons whence they descend in the medial lemniscus (aberrant pyramidal fibres, p. 905). The glossopharyngeal part of the nucleus ambiguus sends its efferent fibres to the stylopharyngeus.

In addition, parasympathetic fibres join the motor part of the glossopharyngeal nerve from a representative of the general visceral efferent column which is termed the *inferior salivatory nucleus* (*see* p. 911). This nucleus lies in the reticular formation below the superior salivatory nucleus, and sends its fibres via the tympanic branch of the glossopharyngeal nerve and the tympanic plexus (p. 1075) to the lesser petrosal nerve and the otic ganglion, where they are relayed. The postganglionic fibres pass to the auriculotemporal nerve and so reach the parotid gland (7.179) (but see also pp. 1073, 1274).

From the medulla oblongata the glossopharyngeal nerve passes forwards and laterally towards the triangular depression into which the aqueductus cochleae opens, on the inferior surface of the petrous portion of the temporal bone. It lies at first under cover of the flocculus, and rests on the jugular tubercle of the occipital bone, which is sometimes grooved by it. It leaves the skull by bending sharply downwards through the central part of

7.189 A diagram to show the communications between the last four cranial nerves of the right side viewed from the dorsolateral aspect. The hypoglossal canal has been split in its long axis, and the transverse process of the atlas has been divided close to the lateral mass. The descending branch of the hypoglossal nerve is not shown.

the jugular foramen, anterior to the vagus and accessory nerves, and in a separate sheath of dura mater (7.189). In its transit through the jugular foramen it is lodged in a deep groove leading from the triangular depression for the cochlear aqueduct, and here it is separated by the inferior petrosal sinus from the vagus and accessory nerves. The deep groove is converted into a canal by a bridge which is usually composed of fibrous tissue, but consists of bone in about 25 per cent of skulls. After its exit from the skull it passes forwards between the internal jugular vein and internal carotid artery; it descends in front of the latter vessel, deep to the styloid process and the muscles connected with it, to reach the posterior border of the stylopharyngeus. It then curves forwards, lying upon the stylopharyngeus and either pierces the lower fibres of the superior constrictor of the pharynx or passes between the adjoining borders of the superior and middle constrictors (5.25) to be distributed to the tonsil, the mucous membrane of the pharynx and posterior part of the tongue, and the mucous glands of the mouth.

Two ganglia, named the superior and the inferior, are situated on that part of the nerve which traverses the jugular foramen (7.189).

The superior ganglion is situated in the upper part of the groove in which the nerve is lodged during its passage through the jugular foramen. It is very small, gives off no branches, and is usually regarded as a detached portion of the inferior ganglion.

The inferior ganglion is larger than the superior ganglion and is situated in a notch in the lower border of the petrous portion of the temporal bone (p. 329). Its cells are typical unipolar cells. Their peripheral branches convey taste and general sensibility from the mucous membrane of the posterior third of the tongue, including the sulcus terminalis and the vallate papillae, and general sensibility from the mucous membrane of the oropharynx, soft palate and the fauces.

The glossopharyngeal nerve communicates with the sympathetic trunk, and with the vagus and facial nerves.

The inferior ganglion is connected by a filament with the superior cervical ganglion of the sympathetic. The branches to the vagus consist of two filaments which arise from the inferior ganglion; one joins the auricular branch, and the other the superior ganglion, of the vagus. The branch to the facial arises from the trunk of the glossopharyngeal nerve below the inferior ganglion; it perforates the posterior belly of the digastric and joins the facial nerve near the stylomastoid foramen.

The *branches of distribution* of the glossopharyngeal nerve are: tympanic, carotid, pharyngeal, muscular, tonsillar and lingual.

The tympanic nerve arises from the inferior ganglion of the glossopharyngeal nerve, and ascends to the tympanic cavity through the inferior tympanic canaliculus (p. 329). In the tympanic cavity it divides into branches which form the **tympanic plexus** and are contained in grooves upon the surface of the promontory. This plexus gives off: (1) a branch to join the greater petrosal nerve (p. 1071); (2) branches to supply the mucous membrane lining the tympanic cavity, the auditory tube and the mastoid air cells; and (3) the lesser petrosal nerve. For a critique of the final distribution and connexions of this nerve, *see* Winckler and Cochet (1967).

The lesser petrosal nerve contains the secretomotor fibres for the parotid gland (*vide infra*). It enters a small canal inferior to that for the tensor tympani, receives a connecting branch from the ganglion of the facial nerve and reaches the anterior surface of the temporal bone through a small opening on the lateral side of the hiatus for the greater petrosal nerve. It then passes through the foramen ovale or the canaliculus innominatus (p. 323) and joins the otic ganglion.

The carotid branch, often double, arises just below the skull, and descends on the internal carotid artery to be distributed to the wall of the carotid sinus and to the carotid body. It may communicate with the vagus (inferior ganglion or one of its branches) and with a branch from the sympathetic (superior cervical ganglion). Another branch, either from the preceding or from the main trunk, joins a fine plexus which also supplies the carotid body. The other branches to this plexus spring from the sympathetic (superior cervical ganglion) and the vagus (p. 1079). For details of the terminal distribution of the carotid nerve consult Willis and Tange (1959), and also p. 1462.

The pharyngeal branches are three or four filaments which unite, opposite the middle constrictor muscle of the pharynx, with the pharyngeal branch of the vagus nerve and the laryngopharyngeal branches of the sympathetic trunk to form the *pharyngeal plexus*; through this plexus the glossopharyngeal nerve supplies the mucous membrane of the pharynx with sensory branches.

The muscular branch supplies the stylopharyngeus.

The tonsillar branches supply the tonsil, and form around it a plexus with branches of the middle and posterior palatine nerves; from this plexus filaments are distributed to the soft palate and the region of the fauces.

The lingual branches are two in number: one supplies the vallate papillae and the mucous membrane near the sulcus terminalis of the tongue (p. 1306); the other supplies the mucous membrane of the posterior (postsulcal) part of the tongue, communicating with the lingual nerve. It is the nerve of special sense (taste) and of general sensibility to the posterior region of the tongue.

The otic ganglion (7.181, 184) is a small, oval, somewhat flattened ganglion of a reddish-grey colour, situated immediately below the foramen ovale. It is a peripheral ganglion of the parasympathetic system; topographically it is intimately related to the mandibular nerve but, functionally, it is connected with the glossopharyngeal nerve.

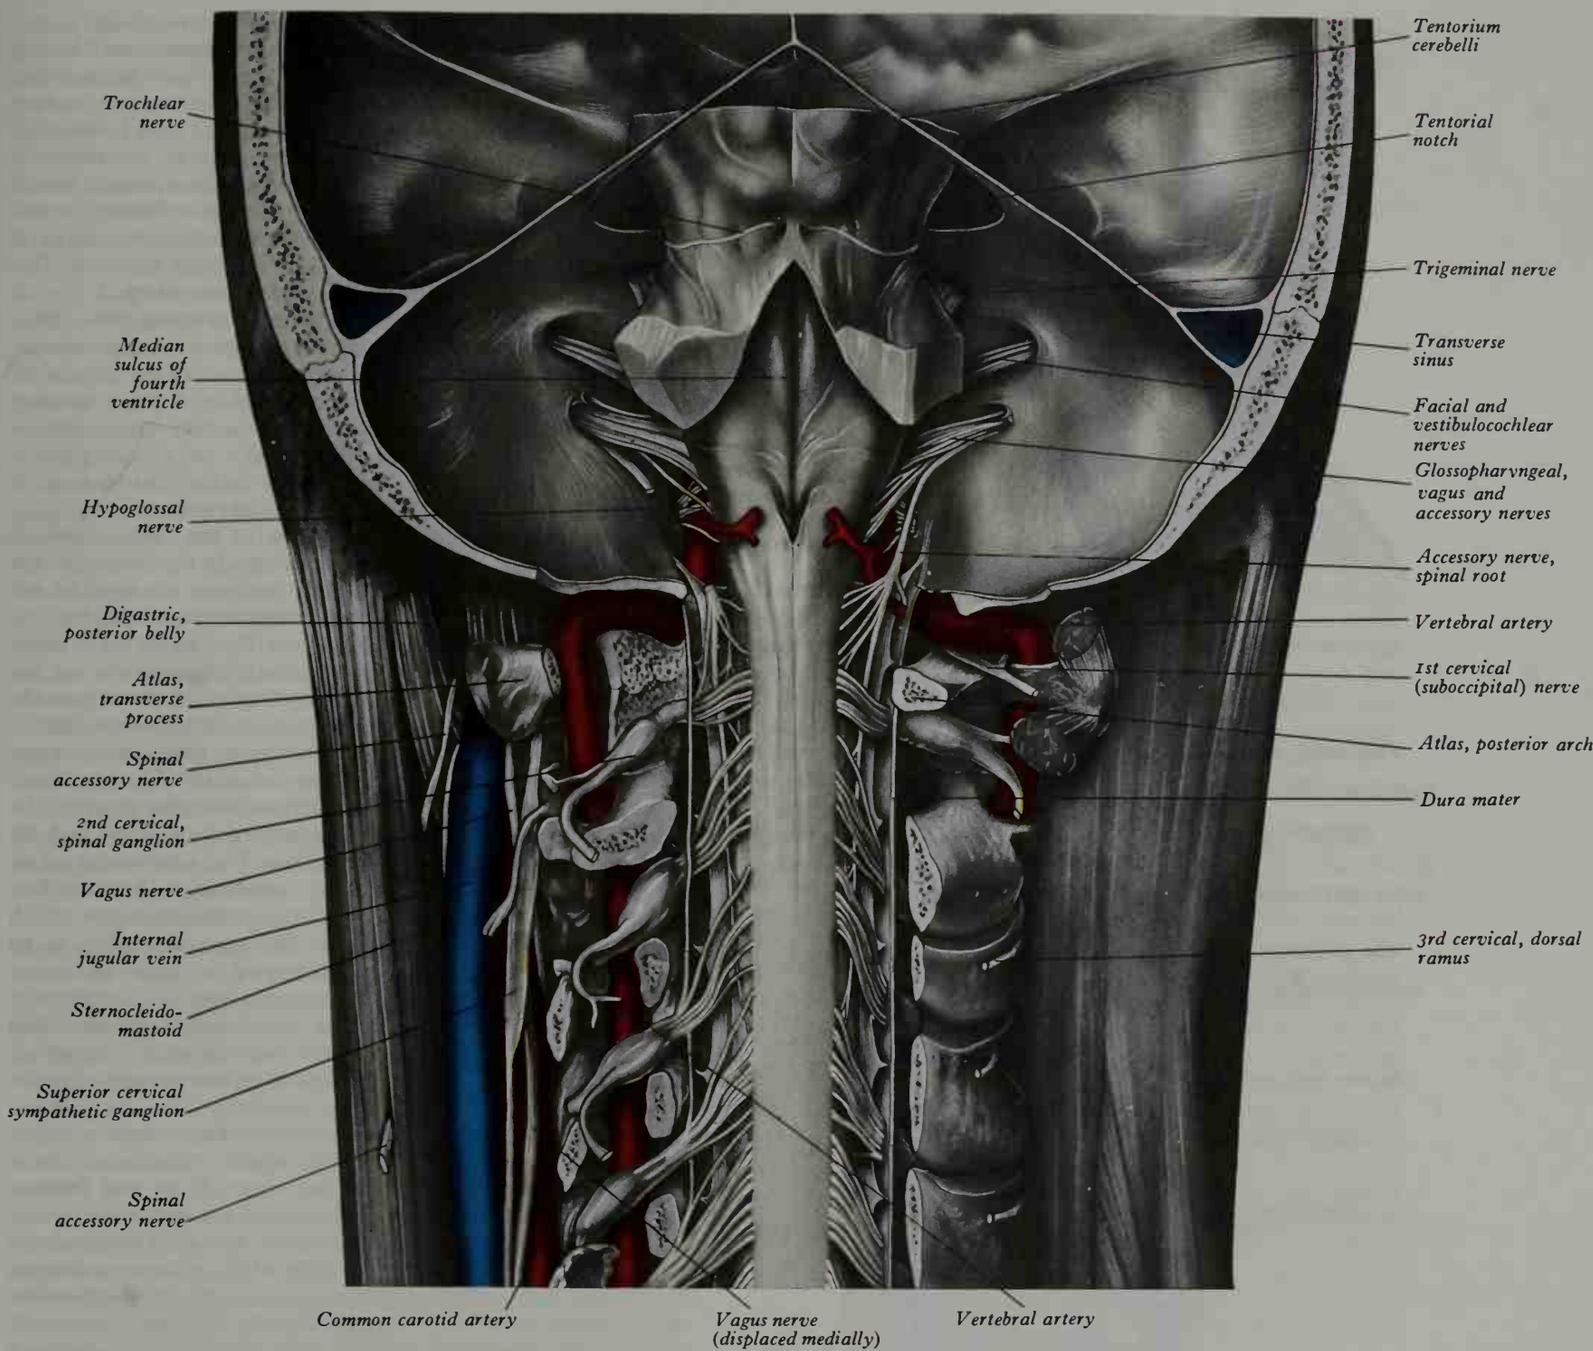
It is in relation *laterally* with the trunk of the mandibular nerve at or near the point where it is joined by the motor root of the trigeminal, and it usually surrounds the origin of the nerve to the medial pterygoid; *medially*, with the tensor veli palatini, by which it is separated from the cartilaginous part of the auditory tube; *posteriorly*, with the middle meningeal artery.

The *motor* or *parasympathetic root* of the ganglion is formed by the lesser petrosal nerve, which conveys preganglionic fibres from the glossopharyngeal nerve. These fibres have their origin in the cells of the inferior salivatory nucleus. They are relayed in the otic ganglion and the postganglionic fibres pass by a *communicating branch* to the auriculotemporal nerve. By it they are conveyed to the parotid gland (7.179), to which they supply secretomotor fibres. The *sympathetic root* is derived from the plexus on the middle meningeal artery. It contains postganglionic fibres which arise in the superior cervical ganglion and pass through the otic ganglion without being interrupted. Emerging with the parasympathetic fibres in the communicating branch to the auriculotemporal nerve, they are destined for the supply of the blood vessels of the parotid gland.

Branches. A twig connects the ganglion with the chorda tympani nerve and another ascends from it to join the nerve of the pterygoid canal. According to some neurologists these form an additional pathway by which taste fibres from the anterior, presulcal area of the tongue may reach the facial ganglion without passing through the middle ear (p. 1140). The fibres concerned pass through the otic ganglion without being interrupted. Motor branches are supplied to the tensor veli palatini and the tensor tympani, they are derived from the nerve to the medial pterygoid (p. 1076) and have no synaptic relations with the cells of the ganglion.

The glossopharyngeal nerve is the nerve of the third branchial arch, or it would be more nearly correct to describe it as the post-trematic branch of that arch. The pretrematic branch of the second (hyoid) arch is probably the tympanic branch of the glossopharyngeal nerve, but that is uncertain. Like the trigeminal and the facial nerves, the glossopharyngeal corresponds to a dorsal nerve which has acquired special visceral efferent fibres.

The Vagus Nerve



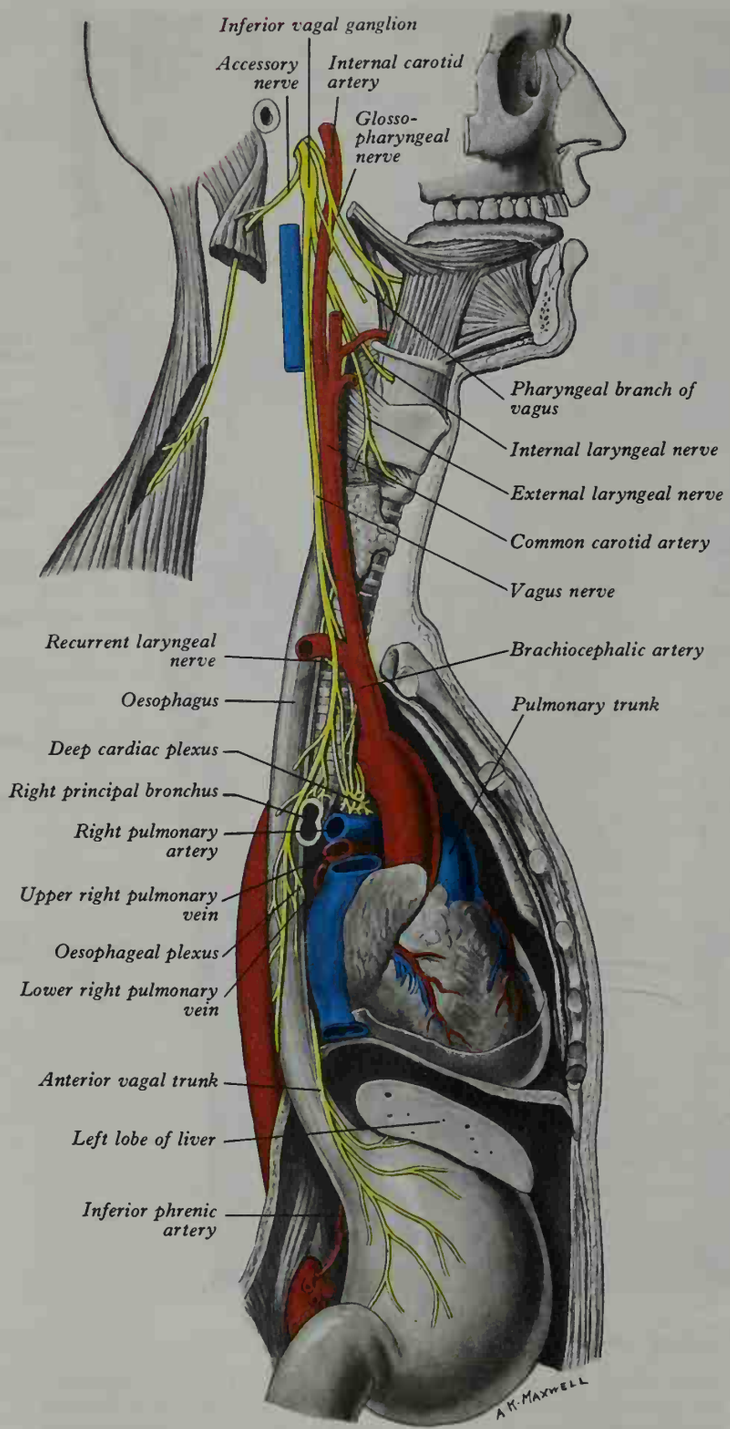
The vagus nerve (7.55, 62–66, 189–191) is composed of motor and sensory fibres, and has a more extensive course and distribution than any of the other cranial nerves, since it passes through the neck and thorax to the abdomen. It is attached by eight or ten rootlets to the medulla oblongata, below the glossopharyngeal nerve, in the groove between the olive and the inferior cerebellar peduncle.

The fibres of the vagus nerve are connected to four nuclei in the medulla oblongata. (1) **The dorsal nucleus** of the vagus is usually described as a mixed nucleus representing the fused general visceral efferent and general visceral afferent columns. It lies in the central grey matter of the lower, closed part of the medulla oblongata, and extends upwards into the upper, open part, where it is placed under the vagal triangle, separated from the hypoglossal nucleus by the nucleus intercalatus (p. 903). The *motor fibres* which arise from it are distributed to the nonstriated muscle of the bronchi, heart, oesophagus and stomach, and to the small intestine and part of the large intestine (p. 1123). A number of studies, usually based upon retrograde degeneration techniques, have suggested patterns of localization of visceral motor innervation (*see*, for example, Szentágothai 1952; Mitchell and Warwick 1955; Lewis *et al.* 1970; Rao and Sahu 1974); but the results have been conflicting and, moreover, there is doubt as to the origin of vagal visceromotor nerve fibres. Some observers (e.g. Kerr 1969) considered that most of such fibres are derived from the nucleus ambiguus and nucleus retrofacialis (Szentágothai 1952). Sugimoto *et al.* (1979) claim that neurons innervating the heart can be demonstrated in the nucleus ambiguus (and reticular formation ventrolateral to it) by injection of horseradish peroxidase into right cardiac vagal branches in cats. The particular *sensory fibres* which terminate in the nucleus are uncertain. Although some authorities regard the nucleus of the tractus solitarius (p. 903) as predominantly a vagal nucleus, there is considerable evidence in favour of the view that afferent fibres from the oesophagus and the abdominal part of the alimentary canal terminate in the dorsal vagal nucleus (see also p. 905). (2) Below the origin of the fibres which join the glossopharyngeal nerve, the neurons of the **nucleus ambiguus** (pp. 905 and 1074) contribute fibres to the vagus nerve which are distributed to striped muscle, viz. the constrictor muscles of the pharynx and the intrinsic muscles of the larynx. It is connected to the corticonuclear tracts of *both* sides and to many other brainstem centres (p. 1085). There have been a number of detailed studies on the architecture and regional localization which occurs in the nucleus ambiguus of man and following experimental analysis in a number of mammals (Szentágothai 1943; Getz and Sirnes 1949; Szabo and Dussardier 1964; Lawn 1966). As in the case of many of the other cranial nerve motor nuclei, the nucleus ambiguus can be divided into a number of sub-nuclei. The glossopharyngeal fibres arise from a cranial group of cells, whilst the individual laryngeal muscles are innervated by relatively discrete sub-nuclei in more caudal zones; most caudally the cells of the nucleus ambiguus send axons into the cranial part of the accessory nerve (p. 1082). (3) The lower part of the **nucleus of the tractus solitarius** (pp. 903 and 1071) receives those fibres of the vagus which are distributed through the internal laryngeal nerve to the taste buds of the epiglottis and the vallecula. The middle part of the nucleus receives the visceral afferent fibres from the tongue, tonsil, palate and pharynx (glossopharyngeal nerve). The upper part of the nucleus receives the taste fibres from the anterior two-thirds of the tongue and from the soft palate (facial nerve). (4) The vagus contains somatic afferent nerve fibres, but it is believed that when they enter the medulla oblongata they terminate in the **spinal nucleus of the trigeminal nerve**.

The rootlets of the nerve unite, and form a flat cord which passes below the flocculus of the cerebellum to the jugular foramen, through which it leaves the cranium. In emerging through this opening, the vagus nerve is accompanied by and contained in the same sheath of dura and arachnoid mater as the accessory nerve, a fibrous septum separating them from the glossopharyngeal nerve, which lies in front (7.189). In this situation the vagus nerve presents a well-marked enlargement, named the *superior ganglion*. After its exit from the jugular foramen the vagus nerve enlarges into a second swelling, named the *inferior ganglion*.

The superior ganglion is of a greyish colour, spherical in form, about 4 mm in diameter. It is joined by one or two delicate filaments with the cranial root of the accessory nerve; it is connected by a twig with the inferior ganglion of the glossopharyngeal nerve, and with the sympathetic trunk by a filament from the superior cervical ganglion; the auricular branch of the ganglion gives off an ascending twig which joins the facial nerve (p. 1071).

The inferior ganglion is cylindrical in form, of a reddish colour, and 2·5 cm long. It is connected with the hypoglossal nerve, the superior cervical ganglion of the sympathetic trunk, and the loop between the first and second cervical nerves. The cranial root of the accessory nerve passes over the ganglion, but is



7.190 A dissection exposing the brainstem and the upper part of the spinal cord after removal of large portions of the occipital and parietal bones and the cerebellum, together with the roof of the fourth ventricle. On the left side the foramina transversaria of the atlas and the third, fourth and fifth cervical vertebrae have been opened to expose the vertebral artery. On the right side the posterior arch of the atlas and the laminae of the succeeding cervical vertebrae have been divided and have been removed together with the vertebral spines and the laminae of the opposite side. The tentorium cerebelli and the transverse sinuses have been divided and their posterior portions removed.

attached to it by fibrous tissue only.

Beyond the inferior ganglion the cranial root of the accessory nerve blends with the vagus nerve; its fibres are distributed principally to the pharyngeal and recurrent laryngeal branches of the vagus nerve.

The cells of both ganglia are unipolar sensory neurons (Richardson and Hinsey 1933; Evans and Murray 1954). The only evidence to the contrary are some old and unconfirmed electrophysiological experiments and technically unsatisfactory histological observations, both of which have been subsequently refuted. (For details and discussion *see* Mitchell 1956; Lieberman 1968, 1969, 1974.) There is no reliable evidence that any significant number of the nerve cells in the ganglion are motor, nor have synapses between pre- and post-ganglionic neurons been demonstrated in it. Indeed, the preganglionic motor fibres, derived from the dorsal nucleus of the vagus, and the special visceral efferents derived from the nucleus ambiguus, which descend to the inferior vagal ganglion, commonly form a band visible to the unaided eye which skirts the ganglion in some mammals (Hoffman and Kuntz 1957; Mei and Dussardier 1966) without passing through it. The disposition of the sensory or motor fibres which do traverse the ganglion is like that of a dorsal root ganglion. It is necessary to emphasize these facts, because there is current in some textbooks an unsupported view that the parasympathetic component of the vagus relays in its inferior ganglion, based with questionable logic upon the presence of large numbers of thinly myelinated and supposedly non-myelinated fibres in the distal parts of the nerve. Even if it were a safe presumption to regard autonomic fibres as postganglionic purely on the basis of their degree of myelination, to do so in this instance would be merely to ignore another tenet of peripheral autonomic morphology, for such a view produces two relays—one in the

7.191 The course and distribution of the glossopharyngeal, vagus and accessory nerves.

inferior ganglion, and one in the wall of the target organ. (However, *see* p. 1124 for alternative modern views in relation to *sympathetic* ganglia.) Retrograde degeneration has been demonstrated in the dorsal nucleus of the vagus by division of vagal branches as remote from their origins as the gastric nerves (Mitchell and Warwick 1955). Reliable counts and analyses of the nerve fibres in the human vagus are not available, but counts in other mammals do not support the view of the inferior ganglion as a relay station, which seems to be based almost entirely upon a misguided adherence to supposed axioms of autonomic morphology. The extensive factual information quoted above with regard to the structure of the inferior vagal ganglion renders such a view untenable, and it is difficult to explain its persistence.

Both vagal ganglia are, as noted, exclusively sensory, containing somatic, special visceral, and general visceral afferent neurons. They are, however, traversed by parasympathetic and perhaps some sympathetic nerve fibres. Their cellular populations are unipolar and bipolar (Cajal 1911; Evans and Murray 1954; Gabella 1976). The occurrence of multipolar neurons in the inferior (nodose) ganglion has been suggested in the past, but this has been strongly denied by Mitchell (1956) and Lieberman (1968). Since such motor cells would almost certainly be parasympathetic postganglionic elements, their presence would imply double peripheral relay, which seems unlikely; further investigation is clearly required on this point. Synapses between pre- and post-ganglionic neurons have not been reported. The general consensus is that all efferent fibres whether special visceral (branchial) or parasympathetic preganglionic, pass uninterruptedly through both ganglia. (However, *see* comments on chromaffin cells below.) The arrangement of the somata of neurons and of nerve fibres resembles that of other sensory ganglia, the fibres being centrally disposed. The superior ganglion has been described as grey, the inferior as pink, a difference which may reflect variation in the distribution of myelinated and non-myelinated fibres or of vessels.

The superior (jugular) ganglion of the vagus nerve is rounded and about 4 mm across in mankind. In the cat (Foley and DuBois 1937) it contains about 8,700 unipolar neurons, 73 per cent of which appear to form the auricular nerve, a branch of the ganglion (p. 1079), while 15 per cent contribute axons to the vagus nerve itself. Similar counts are apparently not available for the human ganglion; but since the human vagus nerve contains, at the mid-cervical level, about 16,500 (Rt.) and 20,000 (Lt.) myelinated fibres, counted in 17 paired nerves, the human ganglionic neurons must be more numerous (Schmitzlein *et al.* 1958). The ganglion is connected by nerves of communication with the cranial root of the accessory nerve, the inferior glossopharyngeal ganglion, and the superior cervical sympathetic ganglion. The significance of all these connexions is not yet clearly established, but the first probably contains motor fibres from the nucleus ambiguus which take an aberrant course, issuing in the accessory nerve, to be finally distributed to the palatal, pharyngeal, laryngeal and upper oesophageal musculature via the vagus nerve; the sympathetic connexion may be similar to that which exists between this sympathetic ganglion and the *inferior* vagal ganglion (*vide infra*). Shortly after leaving the superior ganglion the auricular branch communicates with the facial nerve (p. 1072).

The inferior (nodose) ganglion of the vagus nerve is larger and elongate, being about 25 mm in length and about 5 mm in maximum breadth. In the cat (Jones 1937; Foley and DuBois 1937) it has been estimated to contain about 30,000 neurons, most of which are unipolar or pseudo-unipolar, but a few are fusiform or bipolar. The majority are in the range of 35–40 μm in perikaryal dimensions, but a small number measure 20–30 μm (Mohiuddin 1953). Small numbers of chromaffin cells have been observed (White 1935; Jacobs and Comroe 1951; Grillo *et al.* 1974), and these receive agranular synapses but display no efferent synapses. The ganglion is connected with the hypoglossal nerve (p. 1083), the loop between the first and second cervical anterior primary rami (p. 1091), and with the superior cervical sympathetic ganglion (p. 1027). The latter communication may be formed by the peripheral axons of a small number of sensory neurons, resembling nodose ganglion cells, which have been described in this sympathetic ganglion by Terni (1922), as a group of displaced nodose ganglion nerve cells.

While the cells of the vagal ganglia have received much less attention than those of the superior cervical sympathetic ganglion, an extensive series of observations has been contributed in regard to nerve fibre counts of the vagus nerve and its branches in the vicinity of its ganglia (*see* Gabella 1976).

While overall counts by different workers show general agreement, there are wide discrepancies between estimates of ratios between myelinated and non-myelinated fibres and between fibres of different diameters. There are a large number of thinly myelinated or non-myelinated fibres; and while most of these are pre-ganglionic parasympathetic, a few may be postganglionic sympathetic fibres. Although the cat's superior vagal ganglion contains, according to DuBois and Foley (1937), about 8,700 nerve cells, about 8,800 fibres (chiefly small and non-myelinated) pass into the auricular nerve and 1,700 to 3,500

continue into the vagus nerve caudal to the superior ganglion. Many discrepancies and uncertainties of this kind still await clarification, and it would be unprofitable at present to quote further quantitative data.

There is wide agreement that the superior ganglion is chiefly somatic in status, most of its neurons contributing to the auricular nerve. Correspondingly, the neurons in the inferior ganglion are concerned with visceral sensation in connexion with the heart, larynx and lungs, and the alimentary tract from the pharynx to the transverse colon; but some of the neurons transmit impulses from taste endings in the vallecula and epiglottis.

The vagus nerve passes vertically down the neck within the carotid sheath, lying between the internal jugular vein and internal carotid artery as far as the upper border of the thyroid cartilage, and then between the same vein and the common carotid artery until it reaches the root of the neck. The further course of the nerve differs on the two sides of the body.

On the *right side* the vagus nerve continues descending posterior to the internal jugular vein and crosses the first part of the subclavian artery. It enters the thorax and descends through the superior mediastinum, lying at first behind the right brachiocephalic vein, and then to the right of the trachea and posteromedial to the right brachiocephalic vein and the superior vena cava. The right pleura and lung are lateral to the nerve above, but are separated from it below by the azygos vein, which arches forward above the root of the right lung (**6**.133).

The nerve next passes behind the right principal bronchus to reach the posterior aspect of the root of the right lung, and there breaks up into posterior pulmonary (or bronchial) branches, which unite with filaments from the second to fifth or sixth thoracic sympathetic ganglia to form the **right posterior pulmonary plexus**. From the caudal part of this plexus two or three branches descend on the dorsal aspect of the oesophagus, where, with a branch from the left vagus, they form the **posterior oesophageal plexus**; from this a trunk is re-formed which is continued posterior to the oesophagus to enter the abdomen through the oesophageal opening in the diaphragm. This posterior vagal trunk contains fibres from both vagus nerves (*see* p. 1081).

(Note that the origin, disposition and distribution of the **cardiac plexuses** are described on pp. 1123, 1127, 1133.)

In the abdomen the **posterior vagal trunk** divides into a small gastric and a large coeliac branch. The gastric branch supplies the postero-inferior surface of the stomach with the exception of the pyloric canal. The coeliac branch ends chiefly in the coeliac plexus, but sends twigs to the splenic, hepatic, renal, suprarenal and superior mesenteric plexuses. (See also p. 1133.)

On the *left side* the vagus enters the thorax between the left common carotid and left subclavian arteries, and behind the left brachiocephalic vein. It descends through the superior mediastinum, crosses the left side of the aortic arch to pass behind the root of the left lung. Just above the aortic arch the nerve is crossed anterolaterally by the left phrenic nerve, and on the arch by the left superior intercostal vein (**7**.228).

Behind the root of the left lung it divides into posterior pulmonary (or bronchial) branches, which unite with filaments of the second, third and fourth thoracic sympathetic ganglia and form the **left posterior pulmonary plexus**. From this plexus two branches descend on the front of the oesophagus where, with a twig from the right posterior pulmonary plexus, they form the **anterior oesophageal plexus**; from this plexus a trunk, containing fibres from both vagus nerves, is continued in front of the oesophagus, and enters the abdomen through the oesophageal opening of the diaphragm (see p. 549).

In the abdomen the **anterior vagal trunk** supplies twigs to the cardiac antrum, and then divides into right and left groups of branches. The fibres of the left group follow the lesser curvature of the stomach and supply the anterosuperior surface of this viscus. The right group consists of three main branches. The first, which may be duplicated, proceeds between the layers of the lesser omentum towards the porta hepatis, and divides into (*a*) upper branches which enter the porta hepatis, and (*b*) lower rami which supply chiefly the pyloric canal, the pylorus, the superior and the descending parts of the duodendum, and the head of the pancreas. The second branch is distributed to the anterosuperior surface of the body of the stomach; the third branch follows the lesser curvature of the stomach as far as the angular notch. (See also p. 1340.)

The Branches of the Vagus Nerve

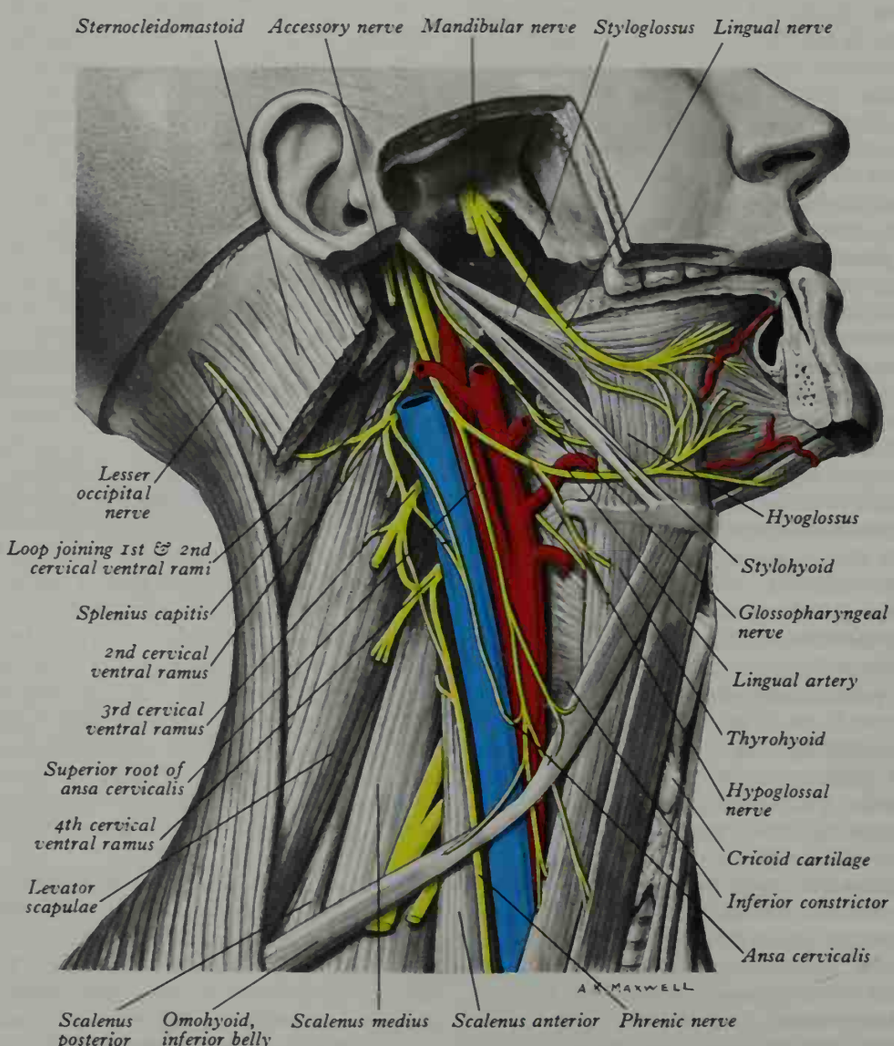
In the jugular fossa	Meningeal
	Auricular
In the neck	Pharyngeal
	Branches to carotid body
	Superior laryngeal
	Recurrent laryngeal (right)
	Cardiac
In the thorax	Cardiac
	Recurrent laryngeal (left)
	Pulmonary
	Oesophageal
In the abdomen	Gastric
	Coeliac
	Hepatic

The meningeal branch or branches appear to spring from the superior ganglion of the vagus nerve and are distributed to the dura mater in the posterior fossa of the skull. However, evidence has been presented (Kimmel 1961 *a* and *b*) which suggests that such meningeal branches are in fact recurrent sensory and sympathetic nerves derived from the upper cervical spinal nerves and the superior cervical sympathetic ganglion, which for a short distance run within the sheath of the upper part of the vagus nerve (pp. 1048, 1089).

The auricular branch arises from the superior ganglion of the vagus nerve, and is joined soon after its origin by a filament from the inferior ganglion of the glossopharyngeal; it passes behind the internal jugular vein, and enters the mastoid canaliculus on the lateral wall of the jugular fossa. Traversing the substance of the temporal bone, it crosses the canal for the facial nerve about 4 mm above the stylomastoid foramen, and here it gives off an ascending branch which joins the facial nerve. (At this point fibres of the nervus intermedius may pass to the auricular branch of the vagus, providing a possible explanation of the cutaneous vesiculation which sometimes accompanies geniculate herpes.) The auricular branch then passes through the tympanomastoid fissure, and divides into two rami; one joins the posterior auricular nerve, the other is distributed to the skin of part of the cranial surface of the auricle and to the posterior wall and floor of the external acoustic meatus and to the adjoining part of the outer surface of the tympanic membrane. The auricular branch of the vagus thus contains *somatic afferent* nerve fibres, but it is believed that when they enter the medulla oblongata they terminate in the spinal nucleus of the trigeminal nerve.

The pharyngeal branch, which is the principal motor nerve of the pharynx, emerges superficially from the upper part of the inferior ganglion of the vagus nerve, and consists principally of filaments from the cranial root of the accessory nerve. It passes between the external and internal carotid arteries to the upper border of the middle constrictor muscle of the pharynx, where it divides into numerous filaments which join with branches from the sympathetic trunk, the glossopharyngeal and external laryngeal nerves, to form the *pharyngeal plexus*. Through this plexus vagal fibres are distributed to the muscles of the pharynx, and the muscles of the soft palate, except the tensor veli palatini. A minute filament joins the hypoglossal nerve as the latter winds round the occipital artery, and is often termed the *ramus lingualis vagi*.

The branches to the carotid body (p. 1462) are variable in number. They may spring from the inferior ganglion or they may travel either in the pharyngeal branch or the superior laryngeal nerve, the latter being most unusual. They form a plexus with rami of the glossopharyngeal nerve and of the cervical part of the sympathetic trunk (*see* Sheehan *et al.* 1941; also pp. 1075, 1128).



The superior laryngeal nerve, which is larger than the pharyngeal branch, issues from the middle of the inferior ganglion of the vagus nerve, and in its course receives a branch from the superior cervical ganglion of the sympathetic trunk. It

descends, by the side of the pharynx, first posterior, then medial to the internal carotid artery, and divides into the internal and external laryngeal nerves. The human nerve contains about 15,000 fibres (Ogura and Bello 1952).

The *internal laryngeal nerve* is sensory to the mucous membrane of the larynx as far down as the level of the vocal folds. It also carries afferent fibres from neuromuscular spindles and other stretch receptors in the larynx (Keene 1961; Schever 1964). It descends to the thyrohyoid membrane, pierces this membrane at a higher level than the superior laryngeal artery, and divides into an upper and a lower branch. The upper branch is directed horizontally, and supplies twigs to the mucous membrane of the pharynx, the epiglottis, the vallecula and the vestibule of the larynx. The lower branch descends in the medial wall of the piriform recess, and gives branches to the aryepiglottic fold, and to the mucous membrane on the back of the arytenoid cartilage. It also supplies one or two branches to the arytenoideus, and these branches unite with twigs from the recurrent laryngeal nerve to the same muscle (*see* p. 1239). The internal laryngeal nerve ends by piercing the inferior constrictor muscle of the pharynx, and unites with an ascending branch from the recurrent laryngeal nerve. A number of observers (*see* Latarjet 1947, for citations) have, in the past, described small ganglia on the courses of the superior and internal laryngeal nerves. More recently Ramaswamy (1974) has revived this description in regard to the latter nerve, claiming to have observed an internal laryngeal nerve ganglion in more than 100 human larynges. Cells in the ganglia were described, but without photographic confirmation. Further observations are to be awaited with interest.

The *external laryngeal nerve*, which is the smaller of the two, descends posterior to the sternothyroid in company with the superior thyroid artery but on a deeper plane; it lies at first on the inferior constrictor of the pharynx, and then, piercing that muscle, winds closely round the inferior thyroid tubercle and reaches the cricothyroid, which it supplies. It gives branches also to the pharyngeal plexus and to the inferior constrictor; behind the common carotid artery it communicates with the superior cardiac nerve, and with the superior cervical sympathetic ganglion (Skórnicki *et al.* 1968).

The recurrent laryngeal nerve differs, as to its origin and course, on the two sides of the body. On the *right* side it arises from the vagus nerve in front of the first part of the subclavian artery; it winds from before backwards, first below and then behind that vessel, and ascends obliquely to the side of the trachea behind the common carotid artery. Near the lower pole of the lobe of the thyroid gland the nerve is always intimately related to the inferior thyroid artery; it may cross either in front of or behind the vessel, or may pass between its branches. On the *left* side, it arises from the vagus nerve on the left of the arch of the aorta, and winds below the arch immediately behind the attachment of the ligamentum arteriosum to the concavity of the arch, and then ascends to the side of the trachea. The nerve on each side ascends in or near the groove between the trachea and oesophagus, and is intimately related to the medial surface of the thyroid gland before it passes under the lower border of the inferior constrictor and enters the larynx behind the articulation of the inferior cornu of the thyroid with the cricoid cartilage. It gives branches to all the muscles of the larynx, excepting the cricothyroid; it communicates with the internal laryngeal nerve, and supplies sensory filaments to the mucous membrane of the larynx below the level of the vocal

7.192 A dissection to show the general distribution of the right hypoglossal and lingual nerves, and the position and constitution of some parts of the cervical plexus of the right side.

folds. It also carries afferent fibres from stretch receptors in the larynx.

As the recurrent laryngeal nerve curves round the subclavian artery, or the arch of the aorta, it gives several cardiac filaments to the deep part of the cardiac plexus. As it ascends in the neck it gives branches, more numerous on the left than on the right side, to the mucous membrane and muscular coat of the oesophagus; branches to the mucous membrane and muscular fibres of the trachea and some filaments to the inferior constrictor.

The variations in the relations of the recurrent laryngeal nerves as they approach the larynx are especially important in the surgery of the thyroid gland (Bowden 1955; Doyle *et al.* 1967). The nerve does not always lie in a protected position in the tracheo-oesophageal groove, but may lie a little in front of it (slightly more frequently on the right side of the neck) and it may occasionally be some distance lateral to the trachea at the level of the lower part of the lobe of the thyroid gland. On the right side there are almost equal chances of finding the nerve anterior to, or posterior to, or intermingled with the terminal branches of the inferior thyroid artery, while on the left side the nerve is most likely to be posterior to the artery and least likely to be anterior. The nerve may give off extralaryngeal branches which are distributed to the larynx, arising from the nerve before it passes behind the inferior cornu of the thyroid cartilage. In addition to its true capsule, the thyroid gland is invested with a distinct outer covering formed by the pretracheal fascia (p. 537), which splits into two layers at the posterior border of the lobe of the thyroid gland. One layer clothes the entire medial surface of the lobe and, at and just above the level of the isthmus of the gland, it has a conspicuous thickening, called the *lateral ligament* of the *thyroid gland* (p. 1449), which attaches the gland to the trachea and the lower part of the cricoid cartilage. The other layer is more posterior; it passes behind the oesophagus and pharynx and is attached to the prevertebral fascia. By this splitting of the fascia, a fascial compartment is formed on each side of the neck, just lateral to the trachea and oesophagus, and it is in the fat that occupies this space that the recurrent laryngeal nerve and the terminal parts of the inferior thyroid artery lie. The nerve may lie lateral or medial to the lateral ligament of the thyroid gland; sometimes it may be embedded in the ligament.

The cardiac branches, two or three in number, arise from the vagus nerve at superior and inferior cervical levels. The small, *superior branches* join with the cardiac branches of the sympathetic trunk. They can be traced to the deep part of the cardiac plexus.

The *inferior branches* arise at the root of the neck. That from the right vagus passes in front or by the side of the brachiocephalic artery, and proceeds to the deep part of the cardiac plexus; that from the left runs down across the left side of the arch of the aorta, and joins the superficial part of the cardiac plexus.

Additional cardiac branches arise from the trunk of the right vagus nerve as it lies by the side of the trachea, and from both recurrent laryngeal nerves. They end in the deep part of the cardiac plexus. The cardiac plexus is described on p. 1132.

The anterior pulmonary branches, two or three in number and of small size, are distributed on the anterior surface of the root of the lung. They join with filaments from the sympathetic, and form the *anterior pulmonary plexus*.

The posterior pulmonary branches, more numerous and larger than the anterior, are distributed on the posterior surface of the root of the lung; they are joined by filaments from the second to fifth or sixth thoracic ganglia of the sympathetic trunk, and form the *posterior pulmonary plexus*. Branches from this plexus accompany the ramifications of the bronchi and supply their constrictor muscles and other pulmonary tissues. (See also pp. 1133, 1251, 1267.)

The oesophageal branches are given off both above and below the pulmonary branches; the lower are more numerous and larger than the upper. They form, as already described (p. 1079), the *oesophageal plexus*. From this plexus filaments are distributed to the oesophagus and to the back of the pericardium.

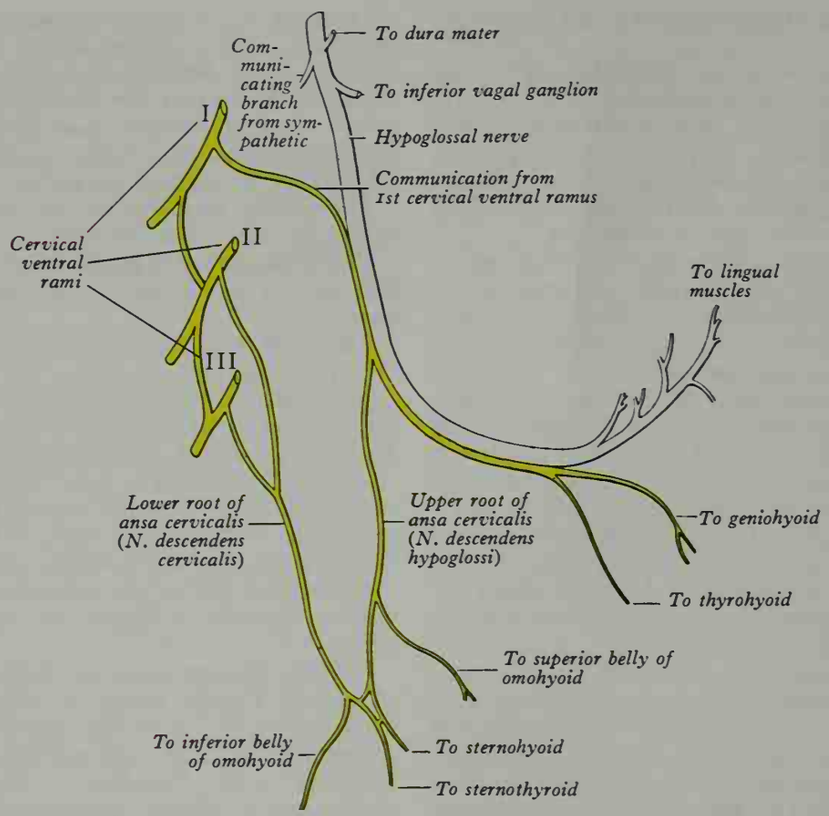
The gastric branches are distributed to the stomach, the anterosuperior surface of which is mainly supplied by the left vagus, and the postero-inferior surface mainly by the right. (*See* pp. 1134, 1340.) Brizzi *et al.* (1973) investigated the detailed distribution of the gastric nerves, and of the branches of the autonomic nervous system to the stomach. They described separate 'cardiac' branches of the vagus supplying the cardia; but while both gastric branches did supply the fundus and body, the pylorus received a complex innervation mainly from the anterior gastric nerve and the hepatic branches of the vagus, and less frequently from the posterior gastric nerve.

The coeliac branches are derived from the posterior vagal trunks: they join the coeliac plexus.

The hepatic branches arise from both vagus nerves (p. 1134): they join the hepatic plexus and through it are conveyed to the liver.

The renal branches arise from both vagus nerves and join the renal plexus (p. 1134).

For details of the ultimate distribution of the branches of the vagus nerves in the abdomen, see the section on the Autonomic Nervous System, pp. 1123, 1133, 1134.



Applied Anatomy. The trunk of the vagus is not commonly injured, but the functions of the nerve may also be interfered with by damage to its radicular nuclei in the medulla, or during its intracranial course. The symptoms produced by non-functioning of the nerve are palpitation, with increased frequency of the pulse, constant vomiting, slowing of the respiration, and a sensation of suffocation.

'Reflexes' in connexion with the branches of the vagus are not infrequent. The 'ear cough' is perhaps one of the commonest, where a plug of wax in the external acoustic meatus may, by irritating the filaments of the auricular nerve, be responsible for a persistent cough. Syringing the meatus frequently produces cough, and, in children, vomiting is not uncommon. Moreover, syringing of the ear has occasionally been responsible for a sudden fatal reflex cardiac inhibition. Another common example is the persistent cough due to enlarged bronchial lymph nodes in children, which may irritate the recurrent laryngeal nerve.

The anatomy of the laryngeal nerves may also be correlated with some of the morbid conditions of the larynx. When the peripheral terminations of the superior laryngeal nerve are irritated by a foreign body passing over them reflex spasm of the glottis is the result. When the nerve is not functioning there is anaesthesia of the mucous membrane of the upper part of the larynx, so that foreign bodies can readily enter the cavity; since the nerve supplies the cricothyroid, the vocal folds cannot be made tense, and the voice is deep and hoarse. Irritation of the recurrent laryngeal nerves produces spasm of the muscles of the larynx. When both recurrent laryngeal nerves are interrupted, the vocal folds are motionless, in the so-called 'cadaveric position'—in the position in which they also are found in ordinary tranquil respiration—neither closed as in phonation, nor widely open as in deep inspiratory efforts. When one recurrent laryngeal nerve is affected, the vocal fold of the same side is motionless, while the opposite one crosses the median plane to accommodate itself to the affected one; hence phonation is possible, but the voice is altered and weak in timbre. It is generally maintained that in progressive lesions of the recurrent laryngeal nerve the movements of abduction of the vocal cord are abolished before the movements of adduction; conversely, during recovery the movements of adduction are regained before those of abduction (*Semon's law*). There is no direct evidence, however, that the nerve fibres to the abductor muscles have any special grouping in the trunk of the recurrent laryngeal nerve.

The Accessory Nerve

The accessory nerve (7.62, 64, 189–191) is formed by the union of cranial and spinal roots, but these constituent parts are associated with each other only for a very short part of their course before the cranial part joins the vagus to be distributed through its branches. The cranial moiety should be considered as a part of the vagus nerve; it is a branchial or special visceral efferent nerve in constitution. The spinal 'root' may be either somatic, special visceral efferent, or mixed, depending upon the view taken of the evolutionary origin of the sternocleidomastoid and trapezius, which it supplies. This controversy is not likely to be solved, and

7.193 A plan of the right hypoglossal nerve and ansa cervicalis.

hence the custom of describing the two parts as a single cranial nerve has been followed here. It is usually assumed that the spinal part of the accessory nerve is purely motor, but evidence for the presence of afferent fibres is provided by the occurrence of ganglia upon the spinal accessory in prenatal and early postnatal human material (Pearson *et al.* 1964). The nerve may also communicate with the dorsal roots of the upper cervical spinal nerves. Such observations have not been confirmed in adult material.

The cranial root is the smaller; its fibres arise from the cells of the lower end of the **nucleus ambiguus** (p. 1076) and possibly from the **dorsal vagal nucleus**. The former is connected with the corticonuclear tracts of *both* sides. Some of the fibres from this source descend from the midbrain in the medial lemniscus (aberrant pyramidal fibres, p. 905). The fibres of the cranial root emerge as four or five delicate rootlets from the side of the medulla oblongata, below the roots of the vagus. The nerve runs laterally to the jugular foramen, where it is said to interchange fibres with the spinal root, with which it becomes united for a short distance; here it is also connected by one or two filaments with the superior ganglion of the vagus. It passes through the jugular foramen, separates from the spinal portion, and is continued over the inferior ganglion of the vagus, to the surface of which it is adherent. It is distributed principally in the pharyngeal and recurrent laryngeal branches of the vagus. It is probably the source of the motor fibres which run in the former to supply the muscles of the soft palate, with the exception of the tensor veli palatini. Some filaments from it are continued into the trunk of the vagus below the ganglion, to be distributed with the recurrent laryngeal nerve and possibly also with the cardiac nerves.

The spinal root is firm in texture, and its fibres arise from an elongated column of motor neurons, *the spinal nucleus*, which is situated in the lateral part of the anterior grey column of the spinal cord, and extends downwards as low as the level of the fifth cervical segment (p. 870). Passing through the lateral white column of the spinal cord, they emerge on its surface midway between the ventral and dorsal nerve roots of the upper cervical nerves (7.189), and unite to form a trunk, which ascends between the ligamentum denticulatum and the dorsal roots of the spinal nerves, and enters the skull through the foramen magnum, behind the vertebral artery (7.190). It is then directed upwards and laterally to the jugular foramen, through which it passes in the same sheath of dura mater as the vagus nerve, but separated from that nerve by a fold of the arachnoid mater. In the jugular foramen, it may receive one or two filaments from the cranial root, or else join it for a short distance and then parts from it again. At its exit from the jugular foramen, it runs laterally and backwards posterior to the internal jugular vein in about two-thirds of subjects, and anterior to it in about one-third; in rare cases it may pass through the vein. In this situation the accessory nerve crosses the transverse process of the atlas and is itself crossed by the occipital artery. The nerve then descends obliquely, passing medial to the styloid process, the stylohyoid and the posterior belly of the digastric. Together with the superior sternocleidomastoid branch of the occipital artery, it reaches the upper part of the sternocleidomastoid and pierces its deep surface, supplying it and joining with branches from the second cervical nerve. Emerging a little above the middle of the posterior border of the sternocleidomastoid, the nerve crosses the posterior triangle of the neck lying on the levator scapulae (7.186), from which it is separated by the prevertebral layer of the deep cervical fascia and the adipose tissue occupying the triangle. Here it is comparatively superficial, being related to the superficial cervical lymph nodes and receiving communications from the second and third cervical nerves (Raveau 1968). Finally, about 5 cm above the clavicle, the accessory nerve disappears under the anterior border of the trapezius and, together with branches from the third and fourth cervical nerves, forms a plexus on the deep surface of the muscle. From this plexus the trapezius receives its innervation. The course of the accessory nerve in the neck can be represented by a line drawn downwards from the lower and anterior part of the tragus to the tip of the transverse process of the atlas, and then downwards and backwards, across the elevation produced by the sternocleidomastoid and the depression corresponding to the posterior triangle of the neck, to a point on the anterior border of the trapezius 5 cm above the clavicle. For a discussion of the possible significance of the double nerve supply to trapezius and sternocleidomastoid *see* McKenzie (1955), and p. 565.

The cranial and spinal roots, after separating from each other, are also known respectively as the *internal* and *external rami* of the accessory nerves. There is general agreement that the spinal root is the sole motor supply to the sternocleidomastoid, the second and third cervical nerves conveying proprioceptive fibres from the muscle. Whether the spinal root is the sole motor supply to the trapezius is uncertain, some maintaining that the third and fourth

cervical nerves are purely proprioceptive, while others believe that they supply motor fibres to the lower part of the muscle.

Applied Anatomy. The functions of the accessory nerve may be interfered with by central changes, or at its exit from the skull, by fractures running across the jugular foramen, or in the neck, by inflamed lymph nodes, etc. Acute torticollis in children is most commonly due to inflamed lymph nodes. Central irritation causes clonic spasm of the sternocleidomastoid and trapezius, or, as it is termed, spasmodic torticollis. In cases of this affection in which all previous palliative treatment has failed, division or excision of a section of the accessory nerve has been resorted to.

In cases where extensive dissections are undertaken in the posterior triangle of the neck for the excision of pathological nodes, it is essential that this nerve should be sought at the outset and isolated from the mass of diseased nodes so as to preserve its continuity.

The Hypoglossal Nerve

The hypoglossal nerve (7.62, 64, 192, 193) is the motor nerve of the tongue. It is in series with the oculomotor, trochlear and abducent nerves and the ventral nerve roots of the spinal nerves, and represents the fused ventral roots of, probably, four precervical or spino-occipital nerves, the dorsal roots of which have disappeared entirely.

The hypoglossal nucleus from which its fibres arise is in line with the modified anterior grey column of the spinal cord. This nucleus is about 2 cm long, and its rostral part corresponds with the hypoglossal triangle of the floor of the fourth ventricle (p. 933). The lower part of the nucleus extends downwards into the closed part of the medulla oblongata, and there lies in the ventral part of the central grey matter, close to the median plane (7.61). The fibres from its cells pass ventrally through the medulla oblongata, and emerge as a linear series of 10–15 rootlets through the anterolateral sulcus between the pyramid and the olive (7.55).

The hypoglossal nucleus displays a longitudinal division into dorsal and ventral laminae, each of which may be further divided into a mediolateral sequence of relatively discrete sub-nuclei. The latter are considered to correspond to the individual muscles innervated (Kosaka and Yagita 1903; Sturman 1916; Barnard 1940). More recently, Jansen and Korneliussen (1977) have described a particularly clear division into four longitudinal columns in Cetacea, and they suggest that these correspond to four occipito-cervical somites and hence, perhaps, to individual lingual muscles.

Connexions. The nucleus of the hypoglossal nerve receives fibres from the precentral gyrus and adjacent areas of mainly the *opposite* cerebral hemisphere through the corticonuclear tract; some of the latter leave the tract in the pons and travel in the medial lemniscus. They are connected to the nucleus directly or through internuncial neurons. Some evidence has been presented, however, that the most medially situated sub-nuclei receive projection fibres from *both* cerebral hemispheres. The hypoglossal nucleus may connect with the cerebellum via neighbouring perihypoglossal nuclei (*see* Torvik and Brodal 1954; also p. 903), and may also be connected with the medullary reticular formation, the sensory nuclei of the trigeminal, and the nucleus solitarius.

The rootlets of the hypoglossal nerve run laterally behind the vertebral artery, and are collected into two bundles, which perforate the dura mater separately opposite the hypoglossal (anterior condylar) canal in the occipital bone, and unite together after their passage through it; in some cases the canal is divided into two by a small bony spicule. The fact that each fascicle acquires a separate sheath from the dura mater is confirmatory evidence of the composite character of the nerve. On emerging from its canal the nerve lies on a deeper plane than the internal jugular vein, the internal carotid artery, the ninth, tenth and eleventh cranial nerves. It passes laterally, with a downward inclination, behind the internal carotid artery and the glossopharyngeal and vagus nerves to gain the interval between the artery and the internal jugular vein. In this part of its course it makes a half-spiral turn round the inferior ganglion of the vagus, to which it is united by connective tissue. It then descends almost vertically, lying between the vessels and in front of the vagus nerve, to a point corresponding with the angle of the mandible, and becomes superficial below the posterior belly of the digastric, emerging from between the internal jugular vein and the internal carotid artery. The nerve loops round the inferior sternocleidomastoid branch of the occipital artery (p. 681) and, having crossed the internal and external carotid arteries, it crosses the loop of the lingual artery a little above the tip of the greater cornu of the hyoid bone (7.192), being itself crossed by the facial vein. It inclines upwards as it runs forwards on the hyoglossus, passing deep to the tendon of the digastric, the stylohyoid and the posterior border of the mylohyoid. In the interval between the hyoglossus and mylohyoid the nerve is related above to the deep part of the submandibular gland, the submandibular duct and the lingual nerve. It passes next on to the lateral aspect of the genioglossus and is continued forwards in its substance as far as the tip of the tongue, distributing branches to the muscle.

The hypoglossal nerve communicates with the sympathetic trunk, and with the vagus, first and second cervical, and lingual nerves.

Opposite the atlas the nerve receives branches from the superior cervical ganglion of the sympathetic trunk, and at the same level is joined by a filament from the loop connecting the first and second cervical nerves. This filament soon leaves the hypoglossal and descends as the *upper root* of the *ansa cervicalis* (7.193).

The communications with the vagus nerve take place close to the skull, numerous filaments passing between the hypoglossal nerve and the inferior ganglion of the vagus nerve through the mass of connective tissue which unites them. As the nerve winds round the occipital artery it receives a filament from the pharyngeal plexus, which is termed the *ramus lingualis vagi* (p. 1079).

Near the anterior border of the hyoglossus it is connected with the lingual nerve by numerous filaments which ascend upon the muscle (p. 1067).

The *branches of distribution* of the hypoglossal nerve are, meningeal, thyrohyoid, descending, muscular.

The meningeal branch or branches leave the hypoglossal nerve as it passes through the hypoglossal canal; they pursue a recurrent course and then ramify to be distributed to the diploë of the occipital bone, to the dural walls of the occipital sinus, and neighbouring structures including the dura of the inferior petrosal sinus and much of the floor and anterior wall of the posterior cranial fossa. As discussed elsewhere (pp. 1048, 1127) these meningeal rami may not be branches of the hypoglossal nerve itself, but ascending, mixed sensory and sympathetic nerves derived from the upper cervical nerves and superior cervical sympathetic ganglion (Kimmel 1961 *a* and *b*).

The descending branch leaves the hypoglossal nerve where the latter turns round the occipital artery, and descends anterior to or in the sheath of the internal and common carotid arteries. It contains no fibres from the hypoglossal nucleus, but only fibres from C1, which constitute the upper root of the ansa cervicalis. After giving a branch to the superior belly of the omohyoid, this nerve is joined by the lower root of the ansa cervicalis from the second and third cervical nerves. The union of the two forms a loop, which is termed the *ansa cervicalis* (*ansa hypoglossi*). From the convexity of this loop branches pass to supply the sternohyoid, the sternothyroid and the inferior belly of the omohyoid. Another filament has been described which descends in front of the vessels into the thorax, and joins the cardiac and phrenic nerves.

The nerve to the thyrohyoid arises from the hypoglossal nerve near the posterior border of the hypoglossus; it runs obliquely across the greater cornu of the hyoid bones, and supplies the thyrohyoid. It is derived from the communication with the first cervical spinal nerve.

The muscular branches are distributed to the styloglossus, hyoglossus, geniohyoid and genioglossus. Numerous slender branches pass upwards into the substance of the tongue to supply its intrinsic muscles. Most of these muscular branches are true hypoglossal fibres, but those to geniohyoid stem from the first cervical nerve.

Applied Anatomy. When the hypoglossal nerve is injured or diseased, unilateral lingual paralysis follows, together with hemiatrophy of the tongue; the tongue, when protruded, is directed to the paralysed side owing to the unopposed action of the opposite muscles. On retraction, the wasted and paralysed side of the tongue rises up higher than the other. The larynx may deviate towards the sound side on swallowing, due to unilateral paralysis of the depressors of the hyoid bone. If the paralysis is bilateral, the tongue lies motionless in the mouth; taste and tactile sensibility of the organ are perfect, articulation is slow; swallowing is very difficult.

MORPHOLOGY OF THE CRANIAL NERVES

It is now possible to group the cranial nerves in a manner which conforms with their phylogenetic history, their individual components and their functions.

Group I includes the oculomotor, trochlear, abducent and hypoglossal nerves. These all arise from the cells of the somatic efferent column, and they are distributed to the musculature derived from the *cranial myotomes*. They correspond, therefore, to the *ventral* nerve roots of the spinal nerves, and with the exception of the trochlear, they emerge from the brainstem in line with them. The identification of the individual segments with which each nerve is associated is a matter of considerable difficulty and is not susceptible of proof in the present state of our knowledge, for the precise number of segments represented by the head is still uncertain (p. 117).

Group II includes the trigeminal, facial, glossopharyngeal, vagus and accessory nerves. These nerves are concerned with the innervation of the derivatives of the *branchial arches*. They differ from the spinal nerves in possessing motor roots which are distributed to the musculature derived from the *neural crest* (p. 150) and the *lateral plate mesoderm* of the branchial region. Some of these cranial nerves (the trigeminal, vagus and accessory), are compound nerves and have been formed by the fusion of two or more dorsal nerves (p. 1052). In the process cutaneous branches, originally connected with the facial, glossopharyngeal and vagus nerves, have been taken over by the trigeminal, so that these nerves in man bear but little resemblance to their homologues in the lower forms of vertebrates and still less to the dorsal nerve roots of the spinal nerves.

On account of the complexity of their components, each nerve may possess more than one nucleus of origin and more than one nucleus of termination. It is noteworthy that neurons of the ganglion of the facial, the inferior ganglion of the glossopharyngeal and the inferior ganglion of the vagus nerve, though derived to a large extent from the neural crest, owe their origin in part to *ectodermal epibranchial placodes* which develop at the dorsal ends of the first three branchial clefts in close relation to the ganglia (p. 175).

Although there are certain difficulties in the way, the homologies of the nerves in Groups I and II are generally accepted, but the allocation of the three remaining cranial nerves is entirely uncertain. On account of its mode of development, the optic nerve is usually regarded as having nothing in common with any of the other cranial nerves except its function as a *special somatic afferent*. The retinal cells, from which its fibres are derived, really constitute an outlying part of the brain, although it may be urged that they are derivatives of the forerunners of the neural crest cells.

The olfactory and the vestibulocochlear nerves may be grouped together or separately, or the vestibulocochlear nerve may be regarded as being homologous with a dorsal nerve. Both nerves arise, in part at least, from ectodermal cells outside the area of the neural tube and crest, but whereas the olfactory cells remain intercalated amongst the epithelial cells of the nasal mucous membrane, the cochlear cells migrate a short distance away from the otic vesicle. It must be explained, however, that many authorities believe that the contribution made by the neural crest is responsible for the formation of the whole of the vestibulocochlear nerve ganglion, and on this account they prefer to regard the vestibulocochlear as a modified dorsal nerve. In comparing the olfactory and vestibulocochlear nerves it must be remembered that the olfactory nerves are restricted in all forms to the region of the head, whereas the vestibulocochlear nerve in man is the sole survivor of a whole series of nerves of the organs of the lateral line, which in lower forms are distributed not only to the head but also to the whole length of the trunk. There is, therefore, considerable justification for the allocation of the olfactory and vestibulocochlear nerves to separate groups.

For a discussion of the phylogeny of the vertebrate cranial nerves consult Black (1917); Herrick (1922); Bolk *et al.* (1934); Kappers *et al.* (1936); Kappers (1947); Young (1950); Grassé (1954); Goodrich (1958).

General Considerations of the Cranial Nerves

Because of the extremely complex three-dimensional organization of the brainstem, which changes continuously with the level concerned, and the fact that innumerable cell groups and fibre systems exist in relatively small volumes of nervous tissue, the difficulties of investigation are multiplied, and less detail is known of the intimate arrangement and connexions of many cranial nerve nuclei than is the case with the spinal nerves. Accordingly, the account given of the regional localization and connectivity patterns of many of these cranial nuclei, in general neuroanatomical texts, often conveys a simplicity which is undoubtedly far from reality. It may prove helpful, therefore, at this point to summarize briefly some of the general organizational features which are either emerging, or are suspected by analogy with spinal cord organization, but some of which have not yet been established with certainty in the primate brain. The olfactory, optic and vestibulocochlear nerves, however, are considered in some detail elsewhere in the present volume and will not be pursued further here.

The motor nuclei of the cranial nerves, as indicated above, include somatic efferent, special visceral efferent (branchiomotor) and general visceral efferent (autonomic) groups. However, the somatic and special visceral efferent nuclei of the oculomotor, trochlear, trigeminal, abducent, facial glossopharyngeal, vagus, accessory and hypoglossal nerves may, for present purposes, be grouped, since all innervate *striated muscle*. It will be recalled that the ventral grey matter of the spinal cord consists of a series of longitudinal columns of neurons, as judged by the position of their cell somata; and although their significance is not completely understood (p. 873), they exhibit some degree of somatotopic organization. The cells of the columns include three varieties of motor neuron α, β and γ—p. 885) related to the innervation of extrafusal and intrafusal muscle fibres, and further, the α motor neurons to extrafusal muscle may be divided into 'tonic' and 'phasic' types, whilst 'static' and 'dynamic' types of fusimotor γ neurons are also recognized. Between and around these motor neurons are numerous small interneurons, some excitatory, others inhibitory, the latter including the well-known Renshaw cells. Converging on these cell varieties are numerous pathways, completing a wide array of local control loops, both contralateral and ipsilateral, and others descending from supraspinal sources such as the vestibular nuclei, brainstem reticular formation, red nucleus, tectum and tegmentum of the midbrain, and the cerebral cortex. In turn, these parts of the nervous system, which project directly to the lower motor centres, are themselves in receipt of essential control systems from the cerebellum, the corpus striatum, the thalamus and hypothalamus, and many parts of the cerebral neocortex and the limbic system. These have all been considered in detail elsewhere in the present section and no

attempt will be made to describe them here. Despite our lack of detailed knowledge of cranial nerve connexions, it seems most probable that comparable control systems operate, and in view of the precision of integrated muscle action involved in phonation, facial expression and ocular movements, the control systems may well be of a *higher* order of complexity than those obtaining at spinal levels.

The trochlear and abducent nerves each innervate a single small muscle, and reflecting this, their motor nuclei are relatively small single groups of neurons. In contrast the oculomotor, trigeminal, facial, glossopharyngeal-vagus-cranial accessory group, and the hypoglossal all innervate complex musculature capable of a highly refined and precise three-dimensional control of their movement patterns. In each case their nuclei can be divided into a series of sub-nuclei which may be related to the major branches of the nerve, or to the innervation of single muscles within the group. In some cases the sub-nuclei show a longitudinal columnar arrangement, the columns varying in their mediolateral and dorsoventral positioning and in their rostrocaudal extent. This somatotopic localization, in terms of the position of cell *somata*, is reminiscent of that existing in the ventral grey column of the spinal cord, and whilst it seems plausible that the delicacy of control may be in some way increased by such grouping, as discussed more fully elsewhere (p. 873); the precise ontogenetic, phylogenetic and functional significance of these groups must await the results of future researches. Also, much less is known in cranial nerve motor nuclei, than in the spinal cord, concerning the quantitative degree of longitudinal and transverse overlap and interlocking of the receptive *dendritic trees* of motor neurons in adjacent nuclei and sub-nuclei. Further, although muscle spindles were for long considered to be absent, or extremely sparse, in facial, masticatory, lingual, laryngeal and extrinsic ocular muscles, their presence has now been amply confirmed in most of these sites (the facial muscles apparently having the least dense population). Nevertheless, the anatomical siting and physiological characteristics of their associated γ efferent neurons has not yet been clarified. Similar uncertainty exists concerning the smaller multipolar neurons often found within or in the neighbourhood of cranial nerve motor nuclei, many of which are presumably excitatory or inhibitory interneurons, including Renshaw cells.

The afferent connexions of the motor nuclei of the cranial nerves include components which correspond to all those which converge upon the spinal grey matter, but some are recognized only in outline. The best recognized tract systems associated with these nuclei are: (1) the *medial longitudinal fasciculus*, interlinking the vestibular nuclear complex, a longitudinal series of cranial nerve nuclei and the cervical spinal cord (*see* p. 939); (2) *tectotegmental*, *tectopontine* and *tectobulbar* projections from the superior and inferior colliculi (p. 941); (3) projections from the *red nucleus* (p. 938); (4) interconnexions with the *brainstem reticular formation* (p. 946); (5) *corticonuclear* projections from the various sensorimotor areas of the cerebral cortex (p. 1011); (6) projections from the *sensory nuclei* of other cranial nerves.

It must be emphasized, however, that little is known concerning the detailed mode of termination of these afferent systems, for example, whether they terminate directly on α and/or γ motor neurons, or through the intermediary of interneurons, and to what extent they mediate pre- or post-synaptic facilitatory or inhibitory effects. The cortico*spinal* tracts, it will be recalled (p. 877), contain fibres predominantly derived from the contralateral cerebral hemisphere, but they also carry a variable proportion of ipsilateral fibres. Similar considerations apply in varying degree to the cranial nerve motor nuclei. Thus, it is widely held that although the cortico*nuclear* fibres to most parts of the hypoglossal nucleus, and that part of the facial nucleus innervating the lower face, are mainly contralateral in origin, whilst those to the trochlear nucleus are predominantly ipsilateral, the remainder, including the most medial parts of the hypoglossal nuclei, receive a *bilateral* corticonuclear projection. The cerebellum, diencephalic centres, and corpus striatum are considered to influence the cranial nerve nuclei through indirect pathways similar to those proposed for the control of spinal motor centres (see the sections devoted to these regions).

The general visceral efferent nuclei of the oculomotor, facial, glossopharyngeal and vagus nerves are incompletely understood in terms of their central connexions. (The specific connexions of the accessory oculomotor nucleus related to visual reflexes are discussed elsewhere.) It is presumed that the dorsal nucleus of the vagus and salivatory nuclei receive the terminals of ascending tracts, and those from other cranial nerve nuclei (particularly the nucleus of the solitary tract), conveying both somatic and visceral information. It is also considered that they establish interconnexions with the brainstem reticular formation, and receive descending pathways, probably polysynaptic, from the hypothalamus, through which, indirectly, the frontal neocortex, the limbic structures, and the thalamus exert their effects. These descending pathways have not been satisfactorily analysed with the neuroanatomical methods currently available. The same uncertainty attaches to the central connexions of the **general visceral afferent pathways** (p. 1136), which physiological studies have shown to influence many brainstem centres, including particularly the brainstem reticular formation, the hypothalamus, the limbic lobe, and the prefrontal neocortex (consult the sections devoted to the connexions of these regions). The proportion of primary general visceral afferent fibres which terminate in either the dorsal nucleus of the vagus, or in the nucleus of the solitary tract, is undetermined, but the latter are accompanied by the **special visceral afferent** (gustatory) fibres of the facial, glossopharyngeal and vagus nerves. These end in a rostrocaudal sequence of overlapping zones in the solitary nucleus, where, after synaptic relays, secondary gustatory fibres cross the midline and ascend to terminate in the nucleus ventralis posterior medialis of the thalamus, and also in a number of hypothalamic nuclei. The detailed routes taken by these *solitariothalamic* and *solitariohypothalamic* fibres have not been established in the human brain, but it is thought likely that the former accompany the medial fibres of the *medial lemniscus*, whilst the latter may join the *dorsal longitudinal fasciculus* (p. 940), and the *mamillary peduncle* (p. 968). Collateral branches probably leave these ascending fibres to end in association with the brainstem reticular formation and the nuclei of other cranial nerves. From the caudal regions of the nucleus solitarius fibres descend to the spinal cord as a *solitariospinal tract*. The nucleus solitarius, however, is not to be regarded as a simple relay on the visceral afferent pathways. Other systems converge on the nucleus including ascending fibres from the spinal cord, fibres from the vestibulocerebellum, and descending corticonuclear fibres. Accordingly, interaction between these various information channels probably occurs in the nucleus, and its transmission characteristics are likely to be modulated by activity in the descending fibres from the cerebral cortex.

The somatic afferent nuclei of the brainstem constitute the spinal, principal sensory, and mesencephalic nuclei of the trigeminal nerve.

The unique character of the *mesencephalic nucleus* of the trigeminal, which consists of unipolar *primary* sensory neurons, and its probable role as a proprioceptive nucleus have already been described (p. 1060). Electrophysiological investigations support the latter view since rapid responses have been recorded from the nucleus following stretching of the masticatory muscles, during passive jaw movement, and following application of pressure to the teeth. Thus, the peripheral processes of the mesencephalic unipolar cells are considered to innervate the muscle spindles of the masticatory muscles, the articular tissues of the temporomandibular joint and the periodontal tissues. Possibly they are also the source of the fibres which innervate the muscle spindles of the facial, lingual and laryngeal muscles, but this remains uncertain, as does the siting of the neuron somata of the proprioceptive fibres derived from extraocular muscles (*see* p. 1058). Since the cell somata of these primary afferent neurons are deeply embedded in the midbrain, and are arranged as a long, thin, curved lamina of cells on each side, they present particular difficulties to the neuroanatomical investigator, because even the smallest experimental lesions inevitably involve surrounding tissues. Hence, relatively little is known of the central projections of these cells. It has been claimed, however, that some of their central processes descend towards the principal sensory nucleus.

Others are thought to project to the motor nucleus of the trigeminal, completing a masticatory reflex loop, whilst collateral branches have been described as entering the cerebellum in a trigeminocerebellar tract (p. 916). Their other connexions remain conjectural.

The manner in which the primary sensory fibres of the three divisions of the trigeminal nerve, which have their cell somata in the trigeminal ganglion, terminate in the *principal sensory* and *spinal nuclei* of the trigeminal nerve have already been described, and only a few further points need be mentioned here. The view, stemming largely from disease of the brainstem or from neurosurgical manœuvres, that the principal sensory nucleus is a simple relay station for tactile information, and the spinal nucleus for thermal and nociceptive information, is certainly an oversimplification. The observation that a large proportion of the sensory radicular fibres *bifurcate* on entering the pons, one branch entering the principal nucleus, and the other the spinal nucleus, has previously been referred to. The *spinal nucleus*, which is continuous caudally with the substantia gelatinosa of the cervical spinal cord, shows a regional variation in its cytoarchitecture (and is sometimes divided for convenience into a rostrocaudal sequence of three subnuclei termed *oralis, interpolaris* and *caudalis*). Further, the spinal and principal nuclei not only receive the terminals of somatic afferent *trigeminal* fibres, but those of the *facial*, *glossopharyngeal* and *vagus* nerves, in addition to others which ascend from the cervical spinal cord. Both nuclei establish interconnexions with the brainstem reticular formation, and both receive numerous descending corticonuclear fibres from the sensorimotor cortex.

Thus, many information paths converge on both these nuclei, and unit recording with intracellular microelectrodes has confirmed the *wide range* of different types of cell response in the two nuclei. These vary from rapidly-adapting cells with modality-specific, small receptive fields, to others with multimodal responses and larger receptive fields. Cells responding to light tactile stimuli, and others to nociceptive stimuli were found in *both* nuclei. Some of the units show the phenomenon of inhibitory 'surround' (p. 808), and detailed analyses have shown that both pre- and post-synaptic inhibition and facilitation occur in the nuclei. Their impulse transmission characteristics are modified by stimulation or ablation of the descending corticonuclear tracts, and areas of the brainstem reticular formation. Evidently, the clinical impression of the two nuclei as relatively simple, functionally segregated relay stations, is not supported by experimental evidence, which suggests that they are complex, cooperative, integration centres. In this regard, an interesting analogy has been drawn between the principal sensory nucleus of the trigeminal and the nuclei gracilis and cuneatus, and between the spinal nucleus of the trigeminal and the substantia gelatinosa of the spinal cord, in terms of their structural and functional organization. (*See* pp. 870, 887, 889–890 for further details of these regions, and a proposed theory of action of the substantia gelatinosa as possibly modulating sensory input.) Future researches will determine how far such a comparison is justified.

Finally, the statement on p. 1060 that the ascending efferent connexions from the principal and spinal nuclei of the trigeminal consist of crossed fibres which pass to the thalamus as a 'trigeminal lemniscus' may be amplified. Both animal experimentation and observations on human material have shown that multiple trigeminothalamic pathways exist. From the principal sensory nucleus a substantial bundle of fibres cross the midline, whilst a smaller component remains on the ipsilateral side, and they ascend through the upper pons, midbrain and subthalamus, as the *dorsal trigeminothalamic tract* (dorsal division of the trigeminal lemniscus). In the midbrain this tract lies dorsomedial to the red nucleus and medial lemniscus, and it terminates in the nucleus ventralis posterior medialis (VPM) of the thalamus (p. 958). Other fibres from the principal sensory nucleus and from the length of the spinal nucleus mainly cross the midline and ascend in close company with the fibres of the medial lemniscus; these constitute the *ventral trigeminothalamic tract* (ventral division of the trigeminal lemniscus). Many of these ventral ascending fibres also end in the VPM, but others, mainly from the caudal parts of the spinal nucleus, are described as ending in the medial geniculate body and in the intralaminar nuclei. Collateral branches are considered to leave these ascending pathways to terminate in the brainstem reticular formation, on other cranial nerve nuclei, and some collaterals probably enter into the cerebellum (p. 916).

THE SPINAL NERVES

The spinal nerves are formed by the union of ventral and dorsal spinal nerve roots which are attached in series to the sides of the spinal cord. There are 31 pairs of these nerves grouped as follows: cervical, 8; thoracic, 12; lumbar, 5; sacral, 5; coccygeal, 1. The abbreviations C, T, L, S and Co., followed by the appropriate numeral are commonly used to identify the individual nerves. They emerge through the intervertebral foramina. The first cervical nerve escapes from the vertebral canal between the occipital bone and the atlas, and is therefore called the *suboccipital nerve*; the eighth issues between the seventh cervical and first thoracic vertebrae.

Each nerve is connected with the spinal cord by ventral and dorsal roots, the latter being characterized by the presence of a *spinal ganglion*.

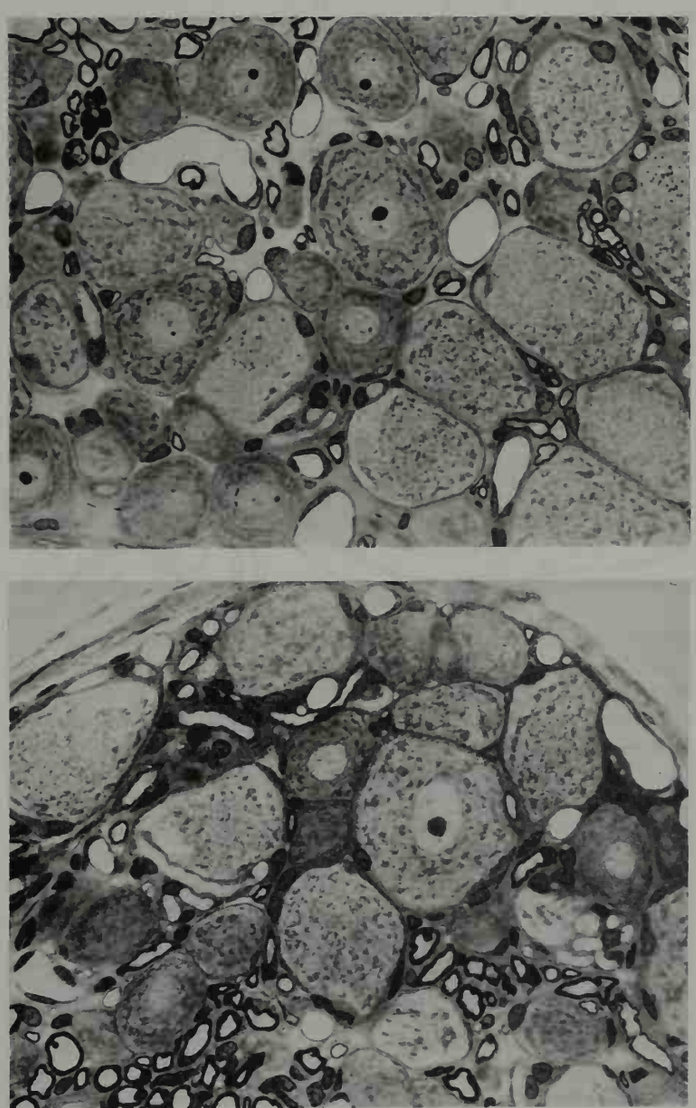
The ventral (anterior) roots contain the axons of cells in the anterior and lateral grey columns of the spinal cord. Each root emerges as a series of rootlets arranged in two or three irregular rows over a distance of about 3 mm across the anterolateral aspect of the spinal cord.

The dorsal (posterior) roots contain the processes of cells in the spinal ganglia which are swellings on the roots. Each *root* consists of two fascicles, medial and lateral, each of which diverges into *rootlets* entering along the posterolateral sulcus. Dissections in a number of different mammals, including man, have shown that the dorsal nerve rootlets of adjacent segments are often interconnected by fine, oblique bundles of nerve fibres, particularly in the lower cervical and lumbosacral regions of the cord (Pallie and Manuel 1968).

The spinal ganglia are collections of nerve cells on the dorsal roots of the spinal nerves. Each ganglion is oval, reddish, and in its size related to that of the nerve root on which it is situated; it is bifid medially where the two bundles of the dorsal nerve root emerge from it to approach and enter the cord. The ganglia are usually in the intervertebral foramina, immediately lateral to the sites where the nerve roots perforate the dura mater (7.37); the ganglia of the first and second cervical nerves, however, lie on the vertebral arches of the atlas and axis, and those of the sacral nerves are inside the vertebral canal, while that of the coccygeal nerve is usually within the dura mater.

The ganglia of the first pair of cervical nerves may be absent, while small *aberrant ganglia* consisting of groups of nerve cells are sometimes found on the dorsal roots of the upper cervical nerves between the spinal ganglia and the spinal cord. (Heterotopic ganglionic neurons are also found in other sites—*see* p. 838.)

Each nerve root receives a covering from the pia mater, and is loosely invested by the arachnoid mater, the latter being prolonged as far as the points where the roots pierce the dura mater. The two roots pierce the dura mater separately, each receiving a sheath from this membrane (7.163, 167); where the roots join to form the spinal nerve this sheath is continuous with the epineurium of the nerve.

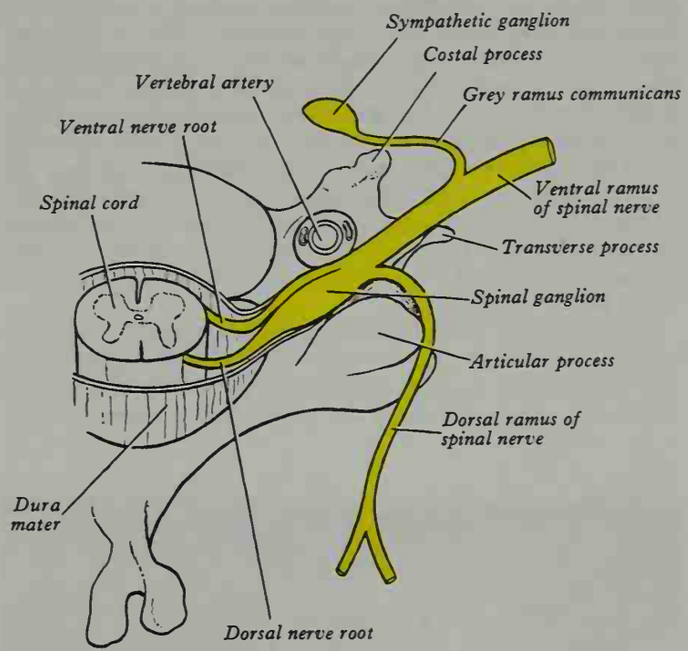


The internal structure of sensory ganglia, cranial and spinal, shows a general similarity of pattern (*see* p. 838). (For pertinent literature consult Van Gehuchten 1892; Marinesco 1909; Cajal 1911; De Castro 1932; Scharf 1958; and Lieberman 1976.) Each ganglion has a laminated connective tissue capsule which is

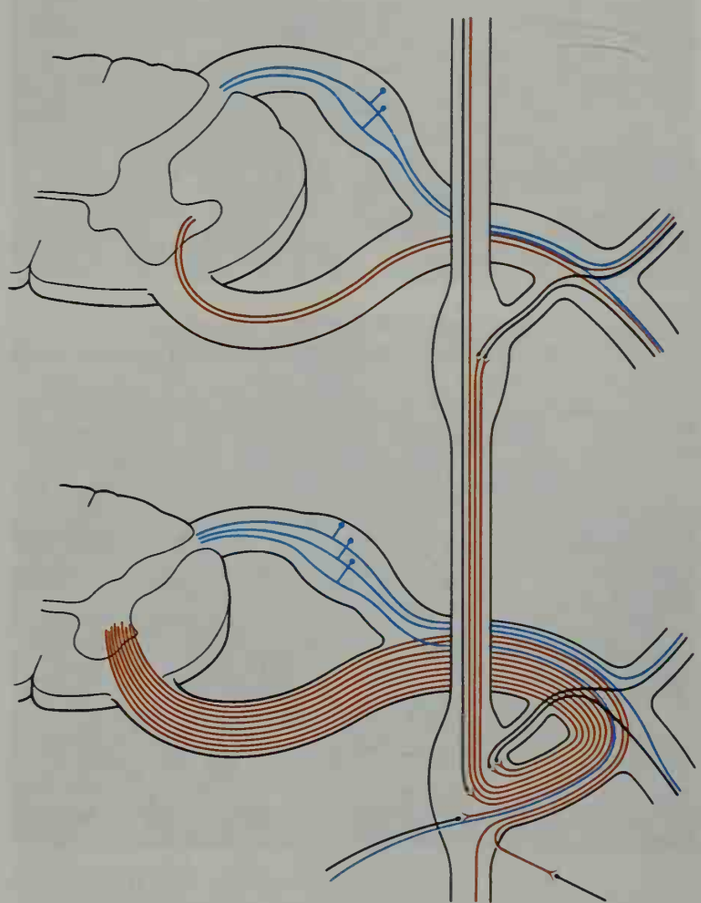
continuous with the epineurium of the associated spinal root. An endoneurial stroma permeates the ganglion, surrounding and supporting its neuronal and axonal population, and trabeculae of perineurium extend between groups of these elements from the capsule. This stroma is intimately related to the satellite cells (amphicytes); it contains scattered mast cells and a dense vascular network, which is denser in the vicinity of ganglion cells, into which capillary loops may be actually invaginated (Scharf 1958). These capillaries are non-fenestrated (Lieberman 1968) in rodents, but have been described as commonly fenestrated in primates (Olsson 1971). The vascular permeability in sensory ganglia shows much species variation, amounting to a 'blood-nerve' barrier in some, largely dependent upon the junctional complexes between the endothelial cells, but details are not available for mankind. Ganglionic neurons exhibit a great variation in size (15–110 μm in man—Ohta *et al.* 1974); most are spheroidal, but smaller cells appear ellipsoidal or display angular profiles in section, the different sizes being randomly distributed in space. In general cytological features ganglion cells resemble other neurons, but they exhibit very marked variation in the distribution of cytoplasmic chromatin from fine dispersal to concentration in the large masses known as Nissl granules. These variations have been used as the chief basis of many classifications, which remain conflicting. Melanin and lipofuchsin pigments occur in some cells, but not as frequently as in some sensory ganglia of cranial nerves. Dense-cored vesicles are commonly observed (Lieberman 1968), despite the apparent absence of catecholamines from such cells. A common feature of agreement in attempts at classification is the occurrence of two extreme types: large 'light' cells (A cells) and small 'dark' cells (B cells). In the light cells the granular endoplasmic reticulum is more dispersed, but highly concentrated in the dark cells. The latter type are sometimes mimicked by artefact, perhaps due to poor fixation. Both types have been identified in prenatal material; and although the functional differences between the two types of nerve cell remain unclarified, it is claimed that the axons of the larger type are myelinated, those of the smaller cells non-myelinated. It has been suggested that the latter are visceral afferent neurons, but this has not been confirmed. So-called 'atypical' cells of various kinds have been described in dorsal root ganglia (and other sensory ganglia) from time to time, the most interesting of which were reputed multipolar neurons; but since synapses have never been satisfactorily identified in dorsal root ganglia, this view is improbable and has not been further confirmed. All, or almost all the ganglion cells are unipolar (*see* p. 821), many exhibiting marked coiling of the 'stem' process, close to the parent soma—the so-called axonal glomerulus, before branching into peripheral and central parts of the axon (p. 838). Recently, renewed interest in typing of spinal ganglion cells has been engendered by ultrastructural studies (Duce and Keen 1977) and observations of specific intracellular substances (Hökfelt *et al.* 1976), preferential glutamine absorption (Duce and Keen 1978), and by specific reactions to neurotoxins (Jancso *et al.* 1977). Collectively, these observations, while confirming the occurrence of 'light' and 'dark' cells, suggest further subdivision into different types, particularly as regards the latter. Small dark cells may occur in at least two populations, differentiated by producing one or other of two substances (substance P and somatostatin). Similarly, different cells respond to different neurotoxins, or differ in their glutamine metabolism.

Counts of ganglion cells in dorsal root ganglia show great specific variation, as would be expected, but few estimates are recorded for human ganglia. There is some evidence that the maximal number is not reached until about three years after birth, but a supposed loss of cells in subsequent life has not been corroborated. The distribution of perikarya and fibres is variable, the former often being concentrated in the periphery of a ganglion; but grouping of the cells between large fascicles of nerve fibres is described as a more usual pattern in human ganglia. This grouping has some interest, for somatotopic organization has been described in dorsal root ganglia, in terms of both neuronal perikarya and processes. Burton and McFarlane (1973), by micro-injection of labelled amino acids into ganglia, were able to associate local groups of ganglion cells, in cats lumbar ganglia, with particular branches of distribution of the associated spinal nerves and also with particular spinal radicles. Horseradish peroxidase injections near peripheral receptor endings have produced more exact results in certain sensory ganglia of rodents, but no results are yet available for primates.

Size and direction of the spinal nerve roots. The roots of the upper four *cervical* nerves are small; those of the lower four are large. The dorsal roots of the cervical nerves bear a proportion to the ventral of three to one, which is greater than in the other regions. The dorsal root of the first cervical is an exception to this, being smaller than the ventral root; in about 8 per cent of cases it is absent. The roots of the first and second cervical nerves are short, and run nearly horizontally to their points of exit from the vertebral canal. From the third to the eighth cervical they are directed obliquely downwards, the obliquity and length of the roots successively increasing; the distance, however, between the level of attachment of any of these roots to the spinal cord and the points of exit of the corresponding nerves never exceeds the height of one vertebra.



The roots of the *thoracic* nerves, with the exception of the first, are of small size, and the dorsal roots only slightly exceed the ventral in thickness. They increase successively in length, from above downwards, and, in the lower part of the thoracic region,



7.194 Two photographs of fields in normal rat cervical dorsal root ganglion to show contrasting features of light and dark neuronal somata Note capsules of satellite cells; the darkly stained multiple profiles between many of the nerve cells represent glomeruli in repeated transverse section. Interneuronal capillary profiles are also visible. Cresyl fast violet staining of semi-thin sections of material embedded in araldite. (Photographs kindly supplied by Doctor J. M. Jacobs, National Hospital for Nervous Diseases, Queen's Square, London.)

descend in contact with the spinal cord for a distance equal to the height of at least two vertebrae before they emerge from the vertebral canal (but *vide infra*).

Kubik and Müntener (1969) consider that the cervico-thoracic part of the spinal cord grows more in length than other parts, and they thus explain their observations, which differ from the above remarks but confirm the following description of the more caudal spinal nerve roots. They state that the upper cervical roots *descend*, the fifth being horizontal, and that the sixth to eighth actually *ascend*. They describe the first two thoracic roots as horizontal, the next three as ascending, the sixth as horizontal, and the rest as descending.

7.195A Scheme showing the relations of a cervical nerve and its ganglion to a cervical vertebra.

7.195B A scheme showing the constitution of a typical spinal nerve. In the upper part of the diagram the spinal nerve roots show the somatic components; in the lower part of the diagram the spinal roots show the visceral components. *Red:* somatic efferent and preganglionic sympathetic fibres. *Blue*: somatic afferent and visceral afferent fibres. *Black:* post-ganglionic sympathetic fibres.

The roots of the lower *lumbar* and upper *sacral* nerves are the largest, and their individual filaments the most numerous of all the spinal nerves, while the roots of the *coccygeal* nerve are the smallest.

The roots of the lumbar, sacral and coccygeal nerves descend with an increasing degree of obliquity to their respective exits, and since the spinal cord ends near the level of the lower border of the first lumbar vertebra, the lengths of successive roots rapidly increases. As already mentioned (7.35B), the term *cauda equina* is applied to this collection of *nerve roots*.

From the description given it will be seen that the largest nerve roots, and consequently the largest spinal nerves, are attached to the cervical and lumbar swellings of the spinal cord; these nerves are distributed to the upper and lower limbs.

Immediately beyond the spinal ganglia, the ventral and dorsal nerve roots unite to form the *spinal nerve*, which emerges through the intervertebral foramen, gives off recurrent meningeal branches (*vide infra*), and then divides immediately into a *dorsal* and a *ventral ramus* (7.207). (On the data derived from a limited series of dissections to clarify the precise innervation of intertransverse and costal levator muscles Sato (1974) has described a *trifurcation* of the spinal nerves at some cervical and thoracic levels, the third branch being a *ramus intermedius*.) At or immediately distal to its origin the ventral ramus of each spinal nerve is joined by a *grey ramus communicans* from the corresponding ganglion of the sympathetic trunk, while the ventral rami of the thoracic and the first and second lumbar nerves each contribute a *white ramus communicans* joining the corresponding sympathetic ganglion (7.194, 195). The second, third and fourth sacral nerves also give off visceral branches; these, however, are not connected with the ganglia of the sympathetic trunk, but belong to the parasympathetic part of the autonomic system and run directly into the pelvic plexuses (pp. 1123, 1135).

The cervical spinal nerves increase in size from the first to the sixth. The seventh and eighth cervical and first thoracic nerves are similar in size to that of the sixth cervical. The remaining thoracic nerves are relatively small. The lumbar nerves are large and increase in size from the first to the fifth. The first sacral nerve is the largest of all the spinal nerves, which thereafter decrease in size to the coccygeal, which is the smallest of all the spinal nerves.

In the intervertebral foramen the spinal nerves have important relations. *Anteriorly* are the intervertebral discs and adjacent regions of the bodies of the vertebrae. *Posteriorly* are the synovial zygapophysial joints. *Superiorly* and *inferiorly* are the vertebral notches of the pedicles of the adjoining vertebrae. Each nerve accompanied by a spinal artery, a plexus of small veins and its own meningeal branch or branches.

Applied Anatomy. The nerve roots may be compressed or otherwise irritated in their course from the spinal cord to their exit through the intervertebral foramina. In the cervical region, disease of a vertebral body, degeneration of an intervertebral disc or osteoarthrosis of the intervertebral joints may affect nerve roots as they traverse the intervertebral foramen, causing pain, diminished cutaneous sensibility and some muscular weakness in the field of supply. In the lumbar region, posterior protrusion of an intervertebral disc or rupture of its annular fibres with herniation of the nucleus pulposus is very common, affecting particularly the disc between the fifth lumbar and the first sacral vertebrae, or that between the fourth and fifth lumbar vertebrae. The posterior disc lesions may compress one or more nerve roots as they pass towards their intervertebral foramina, resulting in low back pain ('lumbago'), with or without radiation of the pain to one or both lower limbs ('sciatica'), diminished cutaneous sensibility in the area of supply and weakness of the muscles innervated (e.g. tibialis anterior L. 4; extensor hallucis longus L. 5; flexor hallucis longus S. 1). Less commonly, tumours in the vertebral canal, or spina bifida with meningomyelocoele, may cause lesions of one or more nerve roots of the cauda equina.

Functional Components and Branches of Spinal Nerves

Each typical spinal nerve contains both somatic and visceral fibres.

The somatic components consist of efferent and afferent fibres. The *somatic efferent* fibres for the innervation of skeletal muscles are the axons of α, β and γ neurons in the anterior grey column of the spinal cord. The *somatic afferent* fibres convey impulses towards the central nervous system from a variety of receptors in the skin, subcutaneous tissue, muscles, fasciae, joints, etc. (*see* pp. 849, 860), and are the peripheral processes of the unipolar cells in the spinal ganglia.

The visceral components are also afferent and efferent and belong to the autonomic nervous system (p. 1121). They include sympathetic or parasympathetic fibres at different spinal levels. The preganglionic *visceral efferent* fibres of the sympathetic component are the axons of cells in the lateral grey column of the thoracic and upper two or three lumbar segments of the spinal cord; they join the sympathetic trunk through the corresponding white ramus communicans and form synapses with postganglionic neurons that are distributed to non-striated muscle or glands. The preganglionic visceral efferent fibres of the parasympathetic component are the axons of cells in the lateral grey column of the second, third and fourth sacral segments of the spinal cord. They leave the ventral rami of the corresponding sacral nerves to pass to ganglion cells in the pelvis, where they synapse. The postganglionic axons of the latter are distributed principally to muscle or glands in the walls of the pelvic visceral organs. The *visceral afferent* fibres are also derived from the cells of the spinal ganglia. Their peripheral processes are carried through the white rami communicantes, and after passing without synaptic interruption through one or more sympathetic ganglia end in the tissues of the viscera. Some visceral afferent fibres may enter the spinal cord by the *ventral* roots; Coggeshall *et al.* (1973) have claimed that almost 30 per cent of the fibres in the seventh lumbar and first sacral ventral roots in cats are non-myelinated afferents, which possibly project *into* the cord from nerve cells in corresponding dorsal root ganglia. These interesting observations require confirmation.

The central processes of the various ganglionic unipolar cells enter the spinal cord through the posterior nerve roots and form synapses around either somatic or sympathetic efferent neurons, usually through interneurons, thus completing reflex loops, or they synapse with other neurons in the grey matter of the spinal cord or brainstem which give origin to a variety of ascending pathways.

Surprisingly little detail has been recorded in regard to the dendrites of spinal autonomic neurons. Schramm *et al.* (1976), have shown that sympathetic efferent neurons display predominantly horizontal dendritic arrays in newborn rats, which become re-orientated into longitudinal arrangement in the next five or six postnatal weeks. No such data appear to be available for the human spinal cord.

After emerging from the intervertebral foramen, each spinal nerve supplies small *meningeal* branches and then splits almost immediately into a *dorsal* and a *ventral ramus*, each receiving fibres from both spinal nerve roots.

The meningeal branches of the spinal nerves (also known as the *recurrent meningeal nerves* or *sinu-vertebral nerves*) number two to four filaments on each side and are present at all vertebral levels (Kimmel 1961 *a* and *b*). Each receives one or more communications from a neighbouring grey ramus communicans or from a thoracic sympathetic ganglion directly, and the majority then pursue a recurrent (often perivascular) course to re-enter the spinal canal through the intervertebral foramen, passing ventral to the dorsal root ganglion. Here, these mixed sensory and sympathetic nerves divide into transverse, ascending and descending branches which are distributed to the dura mater, the walls of blood vessels, and to the periosteum, ligaments and intervertebral discs in the ventrolateral region of the spinal canal. Occasionally, fine meningeal branches pass dorsal to the spinal ganglion to be distributed to the dorsally situated dura, periosteum and ligaments, whilst others pass ventrally to reach the posterior longitudinal ligament.

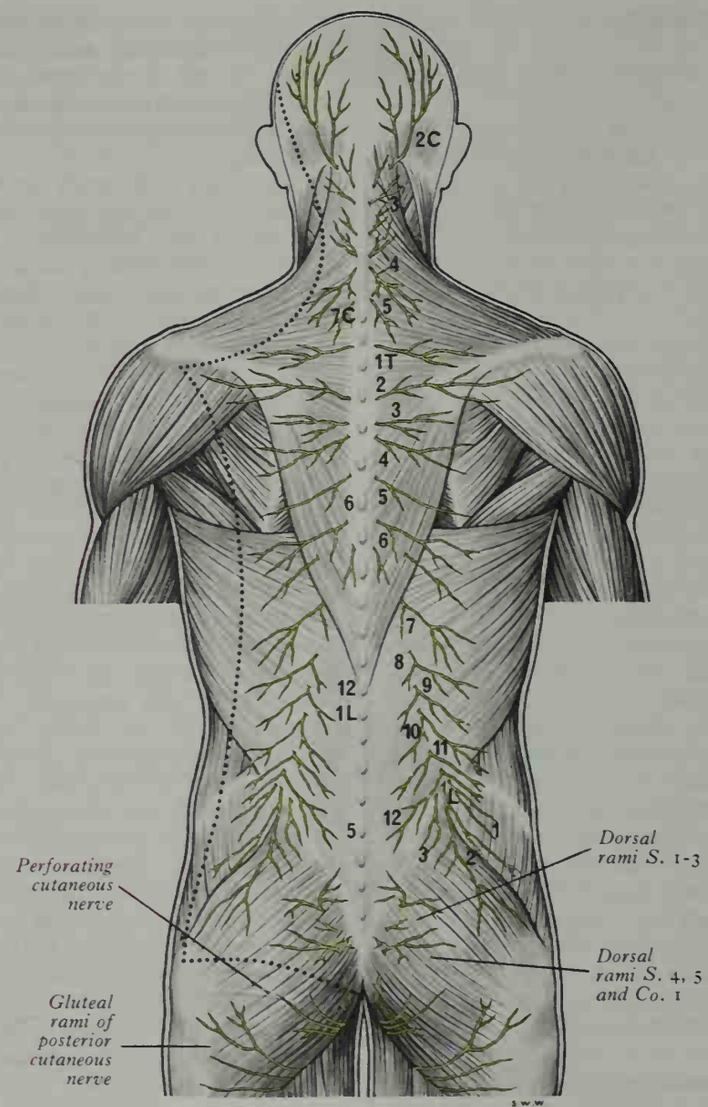
The ascending branches of the upper three cervical meningeal nerves are relatively large and they are distributed to the cerebral dura mater of the posterior cranial fossa (p. 1048).

These various meningeal nerves are of importance in relation to the referred pain which characterizes many spinal disorders and also in occipital headache.

DORSAL RAMI OF THE SPINAL NERVES

The dorsal (posterior primary) rami of the spinal nerves are as a rule smaller than the *ventral*. They are directed posteriorly, and, with the exception of those of the first cervical, the fourth and fifth sacral, and the coccygeal, divide into medial and lateral branches for the supply of muscles and skin (7.196) of the posterior regions of the neck and trunk.

CERVICAL DORSAL RAMI



The dorsal ramus of each cervical spinal nerve, with the exception of the first, divides into a medial and a lateral branch. All these branches innervate muscles but, in general, only the medial branches of the second, third, fourth and, usually, the fifth, supply cutaneous areas. Except for the first and second, each dorsal ramus passes backwards medial to the posterior intertransverse muscle and winds round the articular process into the interval between the semispinalis capitis and the semispinalis cervicis.

The first cervical dorsal ramus (sometimes termed the **suboccipital nerve**) (5.40) is larger than the ventral ramus, and emerges superior to the posterior arch of the atlas and inferior to the vertebral artery. It enters the suboccipital triangle and supplies the muscles which bound this region—the rectus capitis posterior major, and the superior and inferior oblique; it gives branches also to the rectus capitis posterior minor and the semispinalis capitis. A filament from the branch to the inferior oblique joins the dorsal ramus of the second cervical nerve (5.40). The nerve occasionally gives off a cutaneous branch which accompanies the occipital artery to the scalp, and communicates with the greater and lesser occipital nerves.

The second cervical dorsal ramus is slightly larger than the ventral and all the other cervical dorsal rami. It emerges between the posterior arch of the atlas and the lamina of the axis, below the inferior oblique. It supplies a twig to this muscle, receives a communicating filament from the dorsal ramus of the first cervical, and then divides into a large medial and a small lateral branch. Its ganglion is said to be extradural in position.

The *medial* branch, called from its size and distribution the *greater occipital nerve* (7.196, 198), ascends obliquely between the inferior oblique and the semispinalis capitis, and pierces the latter muscle and the trapezius near their attachments to the occipital bone. It is then joined by a filament from the medial branch of the dorsal ramus of the third cervical, and, ascending in the occipital area with the occipital artery, divides into branches which communicate with the lesser occipital nerve and supply the skin of the scalp as far forward as the vertex of the skull. It gives muscular branches to the semispinalis capitis, and occasionally a twig to the back of the auricle. The *lateral* branch supplies filaments to the splenius, longissimus capitis and semispinalis capitis, and is often joined by the corresponding branch of the third cervical.

The third cervical dorsal ramus is intermediate in size between those of the second and fourth. It courses backwards round the articular pillar of the third cervical vertebra, passing medial to the posterior intertransverse muscle, and divides into medial and lateral branches. Its *medial* branch runs between the spinalis capitis and semispinalis cervicis, and, piercing the

7.196 The cutaneous distribution of the dorsal rami of the spinal nerves. The nerves are shown lying on the superficial muscles; on the left side the limit of the skin area supplied by these nerves is indicated by the dotted line. The nerves are numbered on the right side and the spines of the seventh cervical, sixth and twelfth thoracic and first and fifth lumbar vertebrae are labelled on the left side.

splenius and trapezius, ends in the skin. While deep to the trapezius it gives a branch, called the *third occipital nerve*, which pierces the trapezius and ends in the skin of the lower part of the occipital region (7.196). It is medial to the greater occipital nerve, and communicates with it. The *lateral* branch often joins that of the second cervical dorsal ramus.

The dorsal ramus of the suboccipital, and the medial branches of the dorsal rami of the second and third cervical nerves are sometimes joined by communicating loops to form the *posterior cervical plexus*.

The dorsal rami of the lower five cervical nerves curve backwards round the vertebral articular pillars and divide into medial and lateral branches. The *medial* branches of the fourth and fifth run between the semispinalis cervicis and semispinalis capitis, and, having reached the spines of the vertebrae, pierce the splenius and trapezius to end in the skin (7.196). Sometimes the medial branch of the fifth fails to reach the skin. The medial branches of the lowest three nerves are small, and end in the semispinalis cervicis, semispinalis capitis, multifidus and interspinales. The *lateral* branches of the lower five nerves supply the iliocostalis cervicis, longissimus cervicis and longissimus capitis.

THORACIC DORSAL RAMI

The dorsal rami of the thoracic spinal nerves pass backwards close to the joints between the articular processes of the vertebrae and divide into medial and lateral branches. The medial branch emerges between the joint and the medial edge of the superior costotransverse ligament and the intertransverse muscle, but the lateral branch runs laterally in the interval between the ligament and the muscle before inclining posteriorly on the medial side of the levator costae.

The *medial* branches of the *upper six* thoracic dorsal rami run between semispinalis thoracis and multifidus, which they supply; they then pierce the rhomboids and trapezius, and reach the skin by the sides of the vertebral spines (7.196). The medial branches of the *lower six* thoracic dorsal rami are distributed chiefly to the multifidus and longissimus thoracis; occasionally they give filaments to the skin near the median plane.

The *lateral* branches increase in size from above downwards. They run through or deep to the longissimus thoracis to the interval between it and the iliocostalis cervicis, and supply these muscles and the levatores costarum; the lower five or six also give off cutaneous branches, which pierce the serratus posterior inferior and latissimus dorsi in a line with the angles of the ribs (7.196). The lateral branches of a variable number of the upper thoracic rami also give filaments to the skin. The lateral branch of the twelfth thoracic, after sending a filament medially along the iliac crest, passes downwards to the skin of the anterior part of the gluteal region.

The medial cutaneous branches of the dorsal rami of the thoracic spinal nerves descend for some distance close to the vertebral spines before reaching the skin, while the lateral branches travel downwards for a considerable distance—it may be as much as the breadth of four ribs—before they become

superficial; the branch from the twelfth thoracic, for instance, reaches the skin only a little way above the iliac crest.

LUMBAR DORSAL RAMI

The dorsal rami of the lumbar spinal nerves pass back medial to the medial intertransverse muscles and at once divide into medial and lateral branches.

The *medial* branches run close to the articular processes of the vertebrae and end in the multifidus. (These nerves are related to bone between the accessory and mamillary processes. They may groove the bone, traverse a distinct notch or even a foramen.)

The *lateral* branches supply the erector spinae (sacrospinalis). In addition the upper three give off cutaneous nerves which pierce the aponeurosis of the latissimus dorsi at the lateral border of the erector spinae and cross the posterior part of the iliac crest to reach the skin of the gluteal region (7.196), some reaching as far as the level of the greater trochanter.

SACRAL DORSAL RAMI

The dorsal rami of the sacral spinal nerves are small, and diminish in size from above downwards; with the exception of the fifth, they emerge through the dorsal sacral foramina. The *upper three* are covered at their points of exit by the multifidus, and divide into medial and lateral branches.

The *medial* branches are small, and end in the multifidus.

The *lateral* branches join with one another and with the lateral branches of the dorsal rami of the last lumbar and fourth sacral to form loops on the dorsal surface of the sacrum. From these loops branches run to the dorsal surface of the sacrotuberous ligament and form a second series of loops under the gluteus maximus. From this second series of loops the *gluteal branches*, two or three in number, arise and at once pierce the gluteus maximus along a line drawn from the posterior superior iliac spine to the apex of the coccyx; they supply the skin over the posterior gluteal area (7.196).

The dorsal rami of the *lower two* sacral nerves are small and lie below the multifidus. They do not divide into medial and lateral branches, but unite with each other and with the dorsal ramus of the coccygeal nerve to form loops on the back of the sacrum; filaments from these loops supply the skin over the coccyx. Berthold and Carlstedt (1977) have recorded a highly detailed study of the first sacral nerve of the cat at its junction with the spinal cord.

COCCYGEAL DORSAL RAMUS

The dorsal ramus of the coccygeal spinal nerve does not divide into a medial and a lateral branch, but receives, as already stated, a communicating branch from the last sacral; it is distributed to the skin over the back of the coccyx.

VENTRAL RAMI OF THE SPINAL NERVES

The ventral rami of the spinal nerves supply the limbs and the anterolateral aspects of the trunk; they are for the most part larger than the dorsal rami. In the thoracic region they run independently of one another, retaining, like all the dorsal rami, a more or less segmental distribution. In the cervical, lumbar and sacral regions, however, they unite near their origins to form plexuses. It is to be noted that the dorsal rami of the spinal nerves do not enter into the formation of these plexuses; their distribution has already been described (*vide supra*).

CERVICAL VENTRAL RAMI

The ventral rami of the cervical nerves, with the exception of the first, appear between the corresponding anterior and posterior intertransverse muscles. The ventral rami of the *upper four* nerves unite to form the *cervical plexus*; those of the *lower four*, together with the greater part of the ventral ramus of the first thoracic nerve, join to form the *brachial plexus*.

Each nerve receives at least one grey ramus communicans, the upper four from the superior cervical ganglion, the fifth and sixth from the middle cervical ganglion, and the seventh and eighth from the cervicothoracic ganglion of the sympathetic trunk (*see* p. 1127).

The ventral ramus of the *first cervical nerve* (sometimes termed the *suboccipital nerve*) appears above the posterior arch of the atlas vertebra, and passes forwards lateral to its lateral mass, and medial to the vertebral artery. It supplies a branch to the rectus lateralis, and, emerging on the medial side of that muscle, descends in front of the transverse process of the atlas and behind the internal jugular vein, and joins with the ascending branch of the second nerve.

The ventral ramus of the *second cervical nerve* issues between the vertebral arches of the atlas and axis and runs forwards between the transverse processes of these two vertebrae; passing in front of the first posterior intertransverse muscle and on the lateral side of the vertebral artery it emerges between the longus capitis and levator scapulae, but when the scalenus medius takes origin from the transverse process of the atlas, it intervenes between the nerve and the levator scapulae. It divides into an ascending branch which joins with the first cervical nerve, and a descending branch which unites with the ascending branch of the third cervical nerve.

The ventral ramus of the *third cervical nerve* appears between the longus capitis and scalenus medius. The ventral rami of the remaining cervical nerves emerge between the scalenus anterior and scalenus medius.

The Cervical Plexus

The cervical plexus (7.197) is formed by the ventral rami of the upper four cervical nerves; it distributes branches to some of the muscles of the neck, the diaphragm, and to parts of the integument of the head, neck and chest (7.182). It is at the level of the first four vertebrae, deep to the internal jugular vein and the sternocleidomastoid, in front of the scalenus medius and levator scapulae. The disposition of the nerves in the plexus is as follows: each nerve, except the first, divides into an ascending and a descending part; these are united in communicating loops with the contiguous nerves. From the union of the second and third nerves superficial branches are supplied to the head and neck, and from the junction of the third with the fourth arise some of the cutaneous nerves of the shoulder and chest. Muscular and communicating branches spring from the same nerves.

The branches of the plexus may be divided into two sets—a superficial and deep, the superficial consisting of those which perforate the cervical fascia and supply the integument, the deep comprising branches which are distributed for the most part to the muscles. The superficial nerves may be subdivided into ascending and descending, the deep nerves into a medial and a lateral series.

SUPERFICIAL ASCENDING BRANCHES

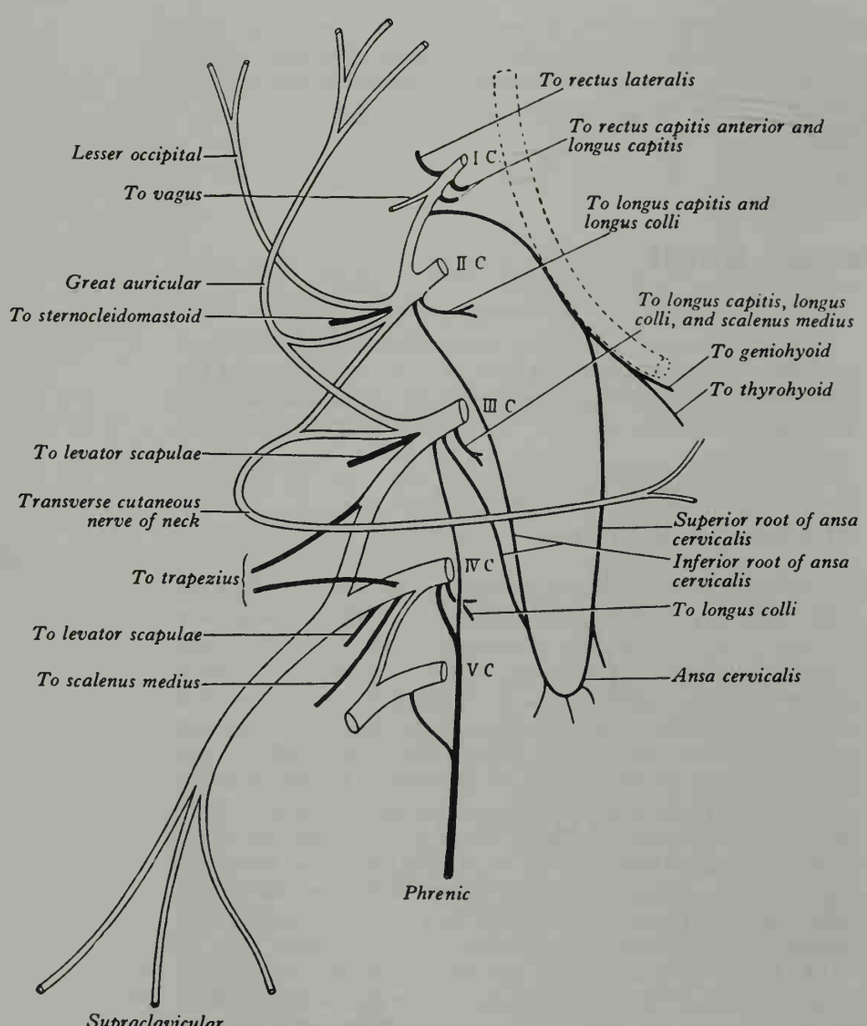
The superficial ascending branches of the cervical plexus (7.197–199) include:

Lesser occipital	2 C.
Greater auricular	2, 3 C.
Transverse (anterior) cutaneous	2, 3 C.

The lesser occipital nerve (7.197, 198) arises from the second cervical nerve, sometimes also from the third; it curves around the accessory nerve and ascends along the posterior border of the sternocleidomastoid. Near the cranium it perforates the deep fascia, and is continued upwards on the side of the head behind the auricle, supplying the skin and communicating with the great auricular and greater occipital nerves, and with the posterior auricular branch of the facial nerve. The lesser occipital nerve varies in size, and is sometimes duplicated.

It sends off an *auricular branch* which supplies the skin of the upper third of the cranial surface of the auricle, and communicates with the posterior branch of the great auricular nerve. The auricular branch is occasionally derived from the greater occipital nerve.

The great auricular nerve (7.197, 198) is the largest of the ascending branches. It arises from the second and third cervical nerves, encircles the posterior border of the sternocleidomastoid, and, after perforating the deep fascia, ascends upon that muscle beneath the platysma in company with the external jugular vein. It passes on to the parotid gland, where it divides into an anterior and a posterior branch.



The *anterior branch* is distributed to the skin of the face over the parotid gland, and communicates in the substance of the gland with the facial nerve.

The *posterior branch* supplies the skin over the mastoid process and on the back of the auricle, except at its upper part; a filament pierces the auricle to reach its lateral surface, where it is distributed to the lobule and the concha. The posterior branch communicates with the lesser occipital nerve, the auricular branch of the vagus nerve, and the posterior auricular branch of the facial nerve.

The transverse (anterior) cutaneous nerve of the neck (7.197, 198) arises from the second and third cervical nerves, turns round the posterior border of the sternocleidomastoid about its middle, and runs obliquely forwards, deep to the external jugular vein, to the anterior border of the muscle. It perforates the deep cervical fascia, and divides beneath the platysma into ascending and descending branches, which are distributed to the anterolateral parts of the neck.

The *ascending branches* pass upwards to the submandibular region, and form a plexus with the cervical branch of the facial nerve, beneath the platysma; others pierce that muscle, and are distributed to the skin of the upper and front parts of the neck.

The *descending branches* pierce the platysma, and are distributed to the skin of the side and front of the neck, as low as the sternum.

7.197 A plan of the cervical plexus. The hypoglossal nerve is shown by interrupted lines and the muscular branches by solid black lines. The roman numerals and letters I C to V C indicate the *ventral rami* of these cervical spinal nerves.

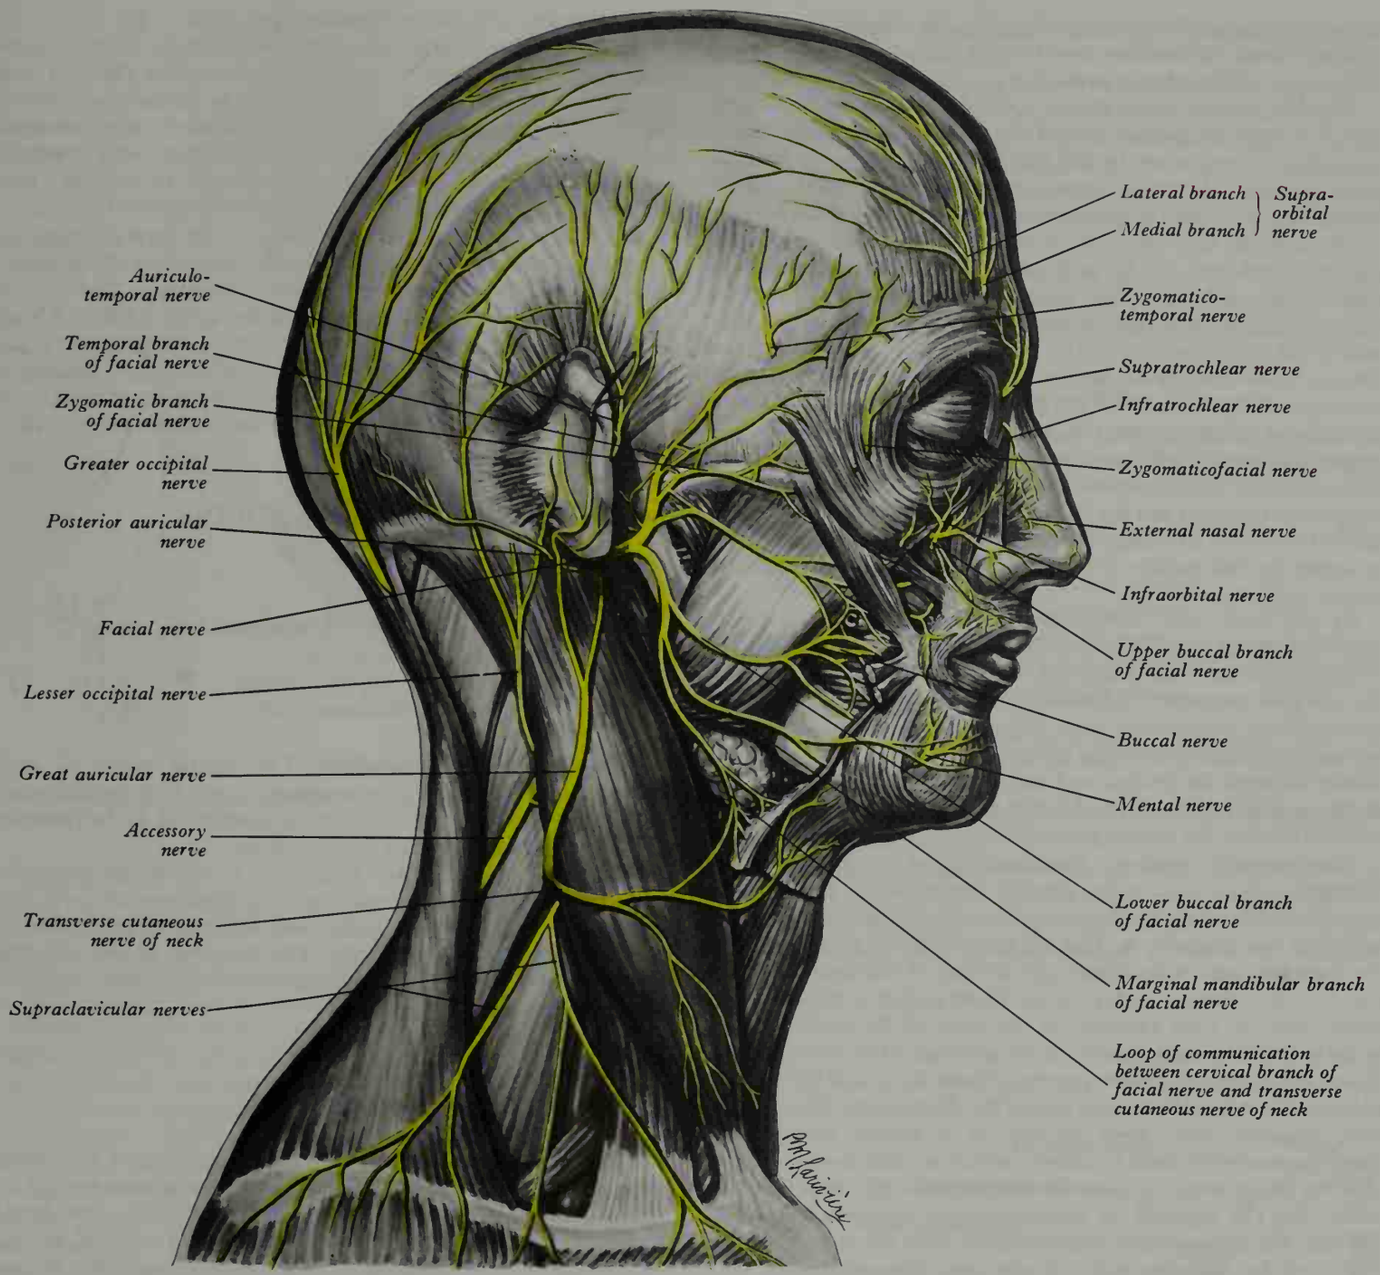
SUPERFICIAL DESCENDING BRANCHES

These are: Supraclavicular (3, 4 C.)—medial, intermediate and lateral.

The supraclavicular nerves (7.197, 198) arise by a common trunk derived from the third and fourth cervical nerves. This trunk emerges from beneath the posterior border of the sternocleidomastoid, descends under cover of the platysma and deep cervical fascia, and divides into medial, intermediate and lateral (posterior) branches, which diverge from one another and pierce the deep fascia a little above the level of the clavicle.

The *medial supraclavicular nerves* run obliquely downwards and medially, crossing the external jugular vein and the clavicular and sternal heads of the sternocleidomastoid, to supply the skin as far as the median plane and as low down as the second rib. They furnish one or two filaments to the sternoclavicular joint.

The *intermediate supraclavicular nerves* cross the clavicle, and supply the skin over the pectoralis major and deltoid as low down as the level of the second rib, immediately adjoining the area supplied by the second thoracic nerve (7.221). The amount of overlapping in this situation is minimal.



The *lateral (posterior) supraclavicular nerves* descend obliquely across the superficial surface of the trapezius and the acromion, and supply the skin of the upper and posterior parts of the shoulder.

DEEP BRANCHES—MEDIAL SERIES

These include the following communicating and muscular branches:

Communicating branches with	Hypoglossal	1, 2 C.
	Vagus	1, 2 C.
	Sympathetic	1, 2, 3, 4 C.
Muscular branches to	Rectus capitis lateralis	1 C.
	Rectus capitis anterior	1, 2 C.
	Longus capitis	1, 2, 3 C.
	Longus colli	2, 3, 4 C.
	Inferior root of ansa cervicalis	2, 3 C.
	Phrenic	3, 4, 5 C.

The communicating branches consist of several filaments which pass from the loop between the first and second cervical nerves to the vagus, hypoglossal and sympathetic. The branch to the hypoglossal ultimately leaves that nerve as a series of branches, viz. the meningeal, the *superior root of the ansa cervicalis*, the nerve to the thyrohyoid and, probably, the nerve to the geniohyoid (p. 1182). A communicating branch also passes from the fourth to the fifth cervical nerve, while each of the first

7.198 The nerves of the right side of the scalp, face and side of neck.

four cervical nerves receives a grey ramus communicans from the superior cervical ganglion of the sympathetic trunk.

Muscular branches supply the rectus capitis lateralis, rectus capitis anterior, longus capitis and longus colli.

The inferior root of the ansa cervicalis (nervus descendens cervicalis) (**7**.197) is formed usually by the union of two branches, one derived from the second cervical nerve and the other from the third. It passes downwards on the lateral side of the internal jugular vein, crosses in front of this vein a little below the middle of the neck, and continues forwards to join the superior root in front of the common carotid artery, so forming the *ansa cervicalis* (*ansa hypoglossi*). Not infrequently it passes forwards between the internal jugular vein and the common carotid artery to reach the ansa cervicalis (**6**.46), from which all the infrahyoid muscles, with the exception of the thyrohyoid, are supplied. In a series of 160 dissections of the ansa cervicalis, the inferior root was from the second and third cervical anterior primary rami in 74 per cent, from the second, third and fourth in 14 per cent, from the third alone in 5 per cent, from the second alone in 4 per cent and from the first, second and third in 2 per cent (Poriraer and Chernikov 1965).

The phrenic nerve is the sole motor nerve supply to the diaphragm, but it also contains sensory fibres which have a widespread distribution. It arises chiefly from the fourth cervical nerve but also receives contributions from the third and fifth cervical nerves (**7**.197). Formed at the upper part of the lateral border of the scalenus anterior, the nerve passes downwards almost vertically across the front of that muscle, *behind the prevertebral fascia* covering the anterior surface of the muscle. The phrenic nerve descends through the neck deep to sterno-cleidomastoid, the inferior belly of the omohyoid (near the intermediate tendon of that muscle), the internal jugular vein, the transverse cervical and surprascapular arteries (**6**.45) and, on the left side, the thoracic duct. It then runs in front of the subclavian artery and behind the subclavian vein, to enter the thorax by crossing from the lateral to the medial side, and in front of the internal thoracic artery (**6**.67). In the thorax, it descends in front of the root of the lung, between the fibrous pericardium and the mediastinal pleura, to the diaphragm, being accompanied by the pericardiacophrenic vessels. The right and left phrenic nerves differ in their intrathoracic relations.

The *right phrenic nerve*, slightly shorter and more vertical than the left, is separated at the root of the neck from the second part of the right subclavian artery by the scalenus anterior. It then lies

lateral to the right brachiocephalic vein, the superior vena cava, and the fibrous pericardium covering the right surface of the right atrium and of the inferior vena cava.

The *left phrenic nerve*, at the root of the neck, is commonly stated to leave the medial edge of the scalenus anterior to pass in front of the *first* part of the left subclavian artery and behind the thoracic duct. However, Quist (1977) claims to have demonstrated that right and left nerves are *symmetrical* in their cervical course and that at the thoracic inlet the left nerve crosses anterior to the *second* part of the left subclavian artery, separated by scalenus anterior. Thereafter the left phrenic crosses the anterior aspect of the left internal thoracic artery obliquely, descending across the medial aspect of the apical part of the left lung and pleura; it now reaches the first part of the subclavian artery which it crosses obliquely to reach the groove between the left common carotid and subclavian arteries, and passes medially and forwards superficially to the left vagus nerve just above the aortic arch and behind the left brachiocephalic vein. It then passes superficially to the arch of the aorta and the left superior intercostal vein, anterior to the root of the left lung, to lie between the fibrous pericardium covering the left surface of the left ventricle and the mediastinal pleura (*see* also p. 692).

In the neck each nerve receives variable and inconstant communicating filaments from the cervical sympathetic ganglia or their branches. The phrenic nerve may also communicate with the internal mammary sympathetic plexus (Pearson and Sauter 1971); these connexions may represent a devious course of sympathetic fibres to join this plexus (see also p. 1129). During its course through the thorax, each nerve supplies sensory branches to the mediastinal pleura and to the fibrous pericardium and the parietal layer of the serous pericardium.

Diaphragmatic relations (Merendino *et al.* 1956; Perera and Edwards 1957). The right phrenic nerve passes through the central tendon of the diaphragm, either through the inferior caval orifice or just lateral to it. The left phrenic nerve passes through the muscular part of the diaphragm in front of the central tendon, just lateral to the left surface of the heart and on a more anterior plane than the right phrenic. At the level of the diaphragm, or slightly above it, each phrenic nerve gives off a few fine branches which are distributed to the parietal pleura above and the parietal peritoneum below the central part of the diaphragm. The trunk of each phrenic nerve then divides as it passes through the diaphragm into its main branches, which are commonly three in number and arranged in the following way, though variations may occur. (*a*) The anterior (or sternal) branch runs anteromedially towards the sternum and communicates with the corresponding nerve of the opposite side; (*b*) the anterolateral branch runs laterally just in front of the lateral leaflet of the central tendon; (*c*) the posterior branch is short and divides into a posterolateral branch which courses just behind the lateral leaflet of the central tendon, and a posterior (crural) branch that passes to the crural part of the diaphragm. The posterolateral and crural branches may arise separately from the phrenic nerve. These branches are often submerged in the muscular substance of the diaphragm, but may lie to some extent below it, and in addition to supplying motor fibres to the diaphragm they give off sensory fibres to the peritoneum and pleura related to the central part of the diaphragm. The branches also contain proprioceptive sensory fibres from the musculature of the diaphragm. The position of these main branches is of surgical importance in planning incisions through the diaphragm without damage to large branches of the phrenic nerve. The right crus of the diaphragm splits to enclose the oesophagus (p. 549). The right phrenic nerve supplies the part of the right crus that lies to the right of the oesophagus, while the left phrenic nerve supplies the left crus and the part of the right crus that lies to the left of the oesophagus (*see* Collis *et al.* 1954; Thornton and Sehewcisthal 1969).

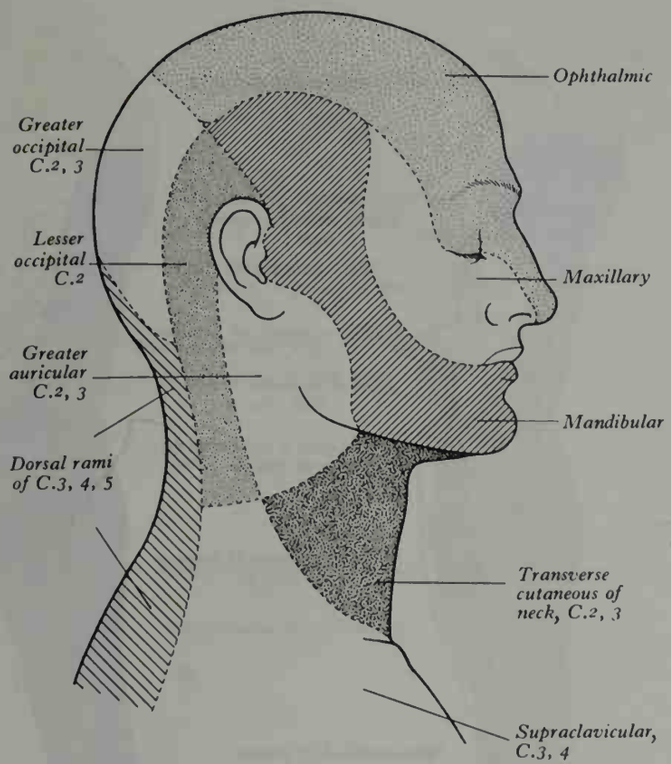
On the inferior surface of the diaphragm, rami of the phrenic nerves communicate with phrenic branches of the coeliac plexus (p. 1134); on the right side, at the junction of the plexuses there is a small *phrenic ganglion*. From these plexuses branches are distributed to the suprarenal glands and, on the right side, to the falciform and coronary ligaments of the liver and the inferior vena cava, and, possibly, through communications with the coeliac and hepatic plexuses, to the gall bladder (pp. 1134, 1137).

Accessory phrenic nerve. The contribution to the phrenic nerve from the fifth cervical nerve is frequently derived as a branch from the nerve to the subclavius. This is known as the *accessory phrenic nerve*. It lies lateral to the main phrenic nerve and descends behind, or sometimes in front of, the subclavian vein; it usually joins the main nerve about the level of the first rib, though it may not do so until the level of the root of the lung or even lower in the thorax. An accessory phrenic nerve may be derived from the fourth or sixth cervical nerve, or from the ansa cervicalis (p. 1083).

Applied Anatomy. The phrenic nerve is the sole motor nerve supply to the diaphragm and section of the nerve in the neck leads to complete paralysis and atrophy of the corresponding half of the diaphragm. If an accessory phrenic nerve is present, section or crushing of the main nerve alone as it lies on the scalenus anterior will not produce complete paralysis of the corresponding half of the diaphragm.

DEEP BRANCHES—LATERAL SERIES

These include:



Communicating—Accessory		2, 3, 4 C.
Muscular branches	Sternocleidomastoid	2, (3) C.
	Trapezius	3, 4 C.
	Levator scapulae	3, 4 C.
	Sealenus medius	3, 4 C.

Communicating branches. The lateral series of deep branches of the cervical plexus communicate with the accessory nerve in the substance of the sternocleidomastoid, in the posterior triangle and under cover of the trapezius.

Muscular branches are distributed to the sternocleidomastoid from the second and occasionally the third cervical nerve, and to the trapezius, levator scapulae and scalenus medius from the third and fourth cervical nerves. The branches to the trapezius cross the posterior triangle obliquely at a lower level than the accessory nerve.

The Brachial Plexus

The brachial plexus (7.200) is formed by the union of the ventral rami of the lower four cervical nerves and the greater part of the ventral ramus of the first thoracic nerve (p. 1103); the fourth cervical nerve usually gives a branch to the fifth cervical, and the first thoracic nerve frequently receives one from the second thoracic. The contributions made to the plexus by C. 4 and T. 2 are subject to frequent variation. When the branch from C. 4 is large, the branch from T. 2 is frequently absent and the branch from T. 1 is reduced in size. This constitutes the *prefixed type* of plexus. On the other hand the branch from C. 4 may be very small or entirely absent. In that event the contribution of C. 5 is reduced in size but that of T. 1 is larger and the branch from T. 2 is always present. This arrangement constitutes the *postfixed type* of plexus. These nerves constitute the *roots* of the plexus. The roots are nearly equal in size, but the way in which they form the plexus is subject to some variation. The following is, however, the most constant arrangement. The fifth and sixth cervical nerves unite at the lateral border of the scalenus medius to form the *upper trunk* of the plexus. The eighth cervical and first thoracic nerves unite behind the scalenus anterior to form the *lower trunk* of the plexus, while the seventh cervical nerve itself constitutes the *middle trunk*. These three trunks run downwards and laterally and just above or behind the clavicle, each splits into an *anterior* and a *posterior division*. The anterior divisions of the upper and middle trunks unite to form a cord, which is situated on the lateral side of the axillary artery, and is called the *lateral cord* of the plexus. The anterior division of the lower trunk passes down at first behind and then on the medial side of the axillary artery, and forms the *medial cord* of the brachial plexus; this cord frequently receives fibres from the seventh cervical nerve. The posterior divisions of all three trunks unite to form the *posterior cord* of the plexus, which is situated at first above and then behind the axillary artery.

7.199 A diagram showing the cutaneous nerve supply of the face, scalp and neck.

The posterior division of the lower trunk is very much smaller than the others, and contains few fibres, if any, from the first thoracic nerve. It is frequently derived from the eighth cervical nerve before the trunk is formed.

Morphologically the brachial plexus still shows, despite much adaptation to the evolutionary changes in the upper-limb musculature, a clear reflexion of the original flexor-extensor organization of a primitive fin. The posterior cord represents the extensor nerve supply, the medial and lateral cords, the flexor supply. The migration of muscle masses has in some instances modified this basic pattern; for example, the brachialis and the anterior part of deltoid are both supplied (the former only in part) from 'extensor' nerves. For details of the comparative morphology of the plexus consult Harris (1939).

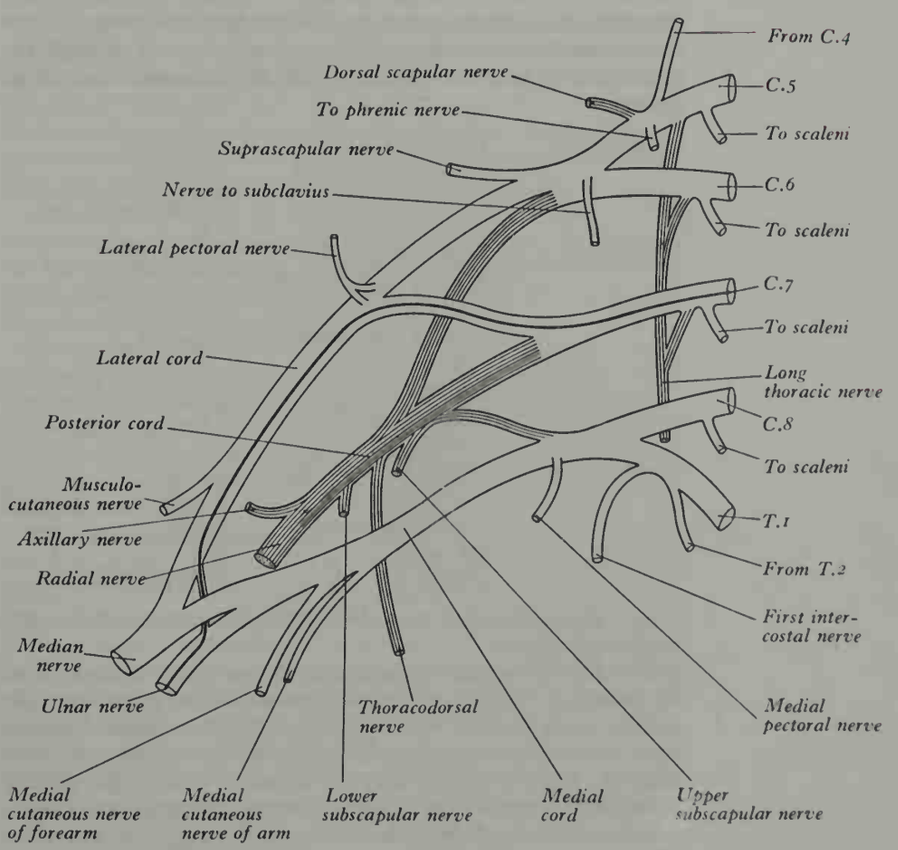
Relations of the Brachial Plexus

In the neck, the brachial plexus lies in the posterior triangle in the angle between the clavicle and the lower part of the posterior border of the sternocleidomastoid, being covered by the skin, platysma and deep fascia. When the arm is by the side, it can be felt in this situation as a bunch of tense cords. The plexus is crossed by the supraclavicular nerves, the nerve to the subclavius, the inferior belly of the omohyoid, the external jugular vein and the superficial ramus of the transverse cervical artery (**6**.64). It emerges between the scalenus anterior and scalenus medius; its proximal part is above the third part of the subclavian artery, while the lower trunk is posterior to the artery; the plexus next passes behind the anterior convexity of the medial two-thirds of the clavicle, the subclavius and the suprascapular vessels, and lies upon the first digitation of the serratus anterior and the subscapularis. *In the axilla* the lateral and posterior cords of the plexus are on the lateral side of the first part of the axillary artery, and the medial cord behind it. The cords surround the second part of the axillary artery on three sides, the medial cord lying on the medial side, the posterior cord behind, and the lateral cord on the lateral side of the artery. In the lower part of the axilla the cords split into the nerves for the upper limb. With the exception of the medial root of the median nerve, the branches of the three cords bear the same relationships to the third part of the axillary artery as the cords from which they spring bear to the second part, i.e. branches from the lateral cord are lateral, branches of the posterior cord are behind, and branches of the medial cord are medial to the artery.

Close to their exit from the intervertebral foramina the fifth and sixth cervical nerves receive grey rami communicantes from the middle cervical ganglion, and the seventh and eighth cervical similar rami from the cervicothoracic ganglion of the sympathetic trunk (p. 1129). The first thoracic nerve also receives a grey ramus from, and contributes a white ramus to, the cervicothoracic ganglion.

The branches of the brachial plexus are usually considered, for convenience, as two groups—those arising above the clavicle (*supraclavicular*) and those below it (*infraclavicular*).

SUPRACLAVICULAR BRANCHES



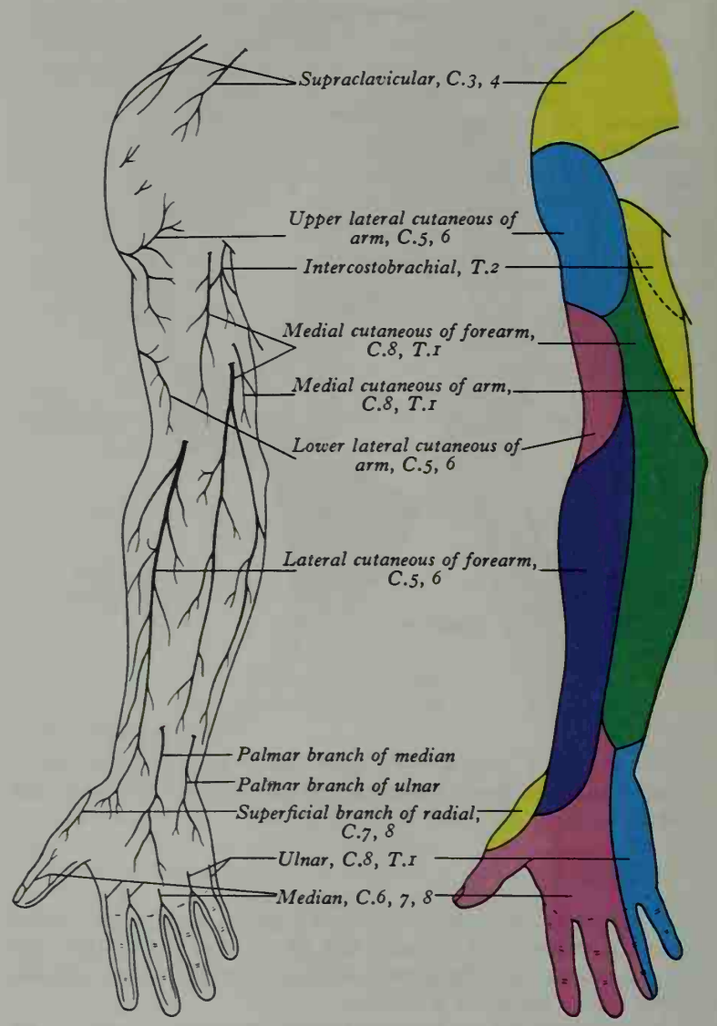
The supraclavicular branches may be grouped as follows: (*a*) those arising from the roots, and (*b*) those arising from the trunks of the plexus.

From the roots of the plexus	1. To scaleni and longus colli	5, 6, 7, 8 C.
	2. To join phrenic nerve	5 C.
	3. Dorsal scapular nerve	5 C.
	4. Long thoracic nerve	5, 6, 7 C.
From the trunks of the plexus	1. Nerve to subclavius	5, 6 C.
	2. Suprascapular nerve	5, 6 C.

The branches for the scaleni and longus colli muscles arise from the lower cervical nerves close to their points of exit from the intervertebral foramina.

On the scalenus anterior the phrenic nerve is joined by a branch from the fifth cervical nerve.

The dorsal scapular nerve arises from the fifth cervical nerve, pierces the scalenus medius, passes on to the deep surface of the levator scapulae, to which it occasionally gives a twig, and runs in company with the deep branch of the dorsal scapular



7.200 A plan of the brachial plexus. The posterior divisions of the trunks and their derivatives are shaded and the fibres from C. 7 which enter the ulnar nerve are shown as a heavy black line. Letters and numbers C. 4–C. 8 and T. 1–T. 2 indicate the *ventral rami* of these cervical and thoracic spinal nerves.

artery on the anterior surfaces of the rhomboids; it ends by supplying these muscles.

The long thoracic nerve (7.204) is usually formed by three roots from the fifth, sixth and seventh cervical nerves, but the root from the seventh nerve may be absent. (A study of seventy dissections of the nerve demonstrated all three roots in only 42 per cent of cases; *see* Alexandre *et al.* 1968.) The upper two roots pierce the scalenus medius obliquely, uniting either in the substance of the muscle or on its lateral surface, and the nerve so formed descends dorsal to the brachial plexus and the first part of the axillary artery. Having crossed the upper border of the serratus anterior to gain its outer surface, it is soon joined by the root from C. 7, which emerges from the interval between the scalenus anterior and the scalenus medius at a lower level and descends on the lateral surface of the latter muscle. The nerve is continued downwards to the lower border of the serratus anterior, supplying, in its course, filaments to each of its digitations.

The nerve to the subclavius is small and is derived near the point of junction of the fifth and sixth cervical nerves; it descends in front of the plexus and the third part of the subclavian artery, and is usually connected by a filament with the phrenic nerve. It then passes above the subclavian vein and reaches the subclavius, which it supplies.

The suprascapular nerve (6.64, 7.205) is a large branch from the superior trunk of the brachial plexus. It runs laterally deep to the trapezius and the omohyoid, and enters the supraspinous fossa through the suprascapular notch, inferior to the superior transverse scapular ligament; it then runs deep to the supraspinatus, and curves round the lateral border of the spine of the scapula in company with the suprascapular artery to gain the infraspinous fossa. In the supraspinous fossa it gives two branches to the supraspinatus and articular filaments to the shoulder joint and acromioclavicular joint; and in the infraspinous fossa it gives two branches to the infraspinatus, besides some filaments to the shoulder joint and scapula.

7.201 The cutaneous nerves of the right upper limb, their areas of distribution and segmental origins, viewed from the anterior aspect.

INFRACLAVICULAR BRANCHES

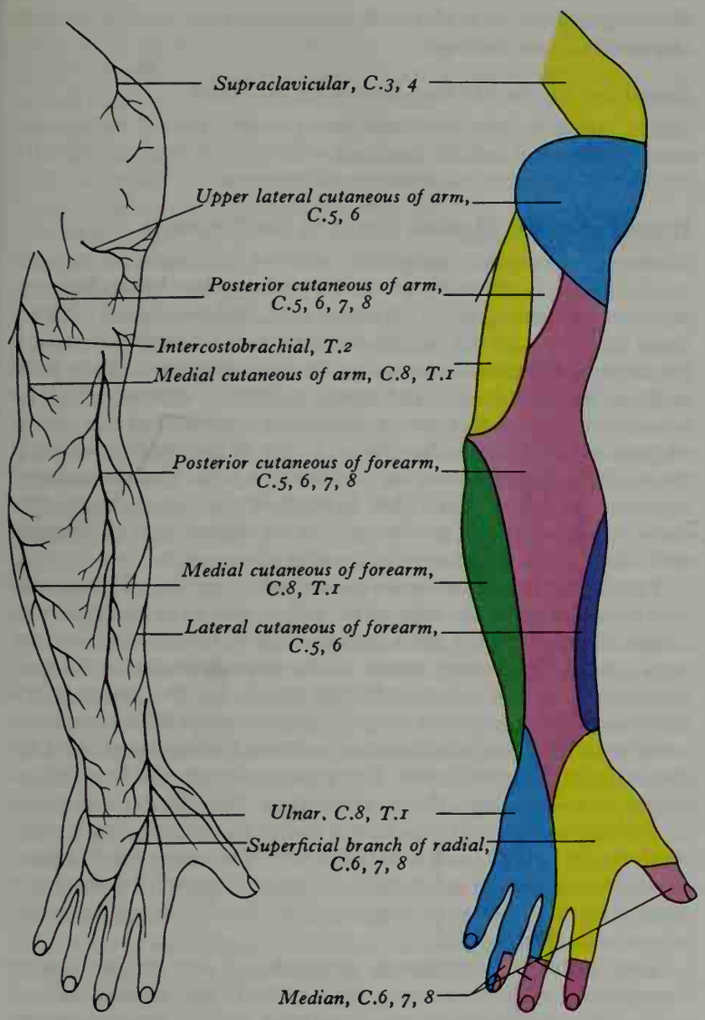
The infraclavicular branches are derived from the three cords of the brachial plexus, but their fibres may be traced through the plexus to the spinal nerves from which they originate. They are as follows:

Lateral cord	Lateral pectoral	5, 6, 7 C.
	Musculocutaneous	5, 6, 7 C.
	Lateral root of median	(5), 6, 7 C.
Medial cord	Medial pectoral	8 C., 1 T.
	Medial cutaneous of forearm	8 C., 1 T.
	Medial cutaneous of arm	8 C., 1 T.
	Ulnar	(7), 8 C., 1 T.
	Medial root of median	8 C., 1 T.
Posterior cord	Upper subscapular	5, 6 C.
	Thoracodorsal	6, 7, 8 C.
	Lower subscapular	5, 6 C.
	Axillary	5, 6 C.
	Radial	5, 6, 7, 8 C., (1 T).

The *pectoral nerves* (7.204) supply the pectoralis major and pectoralis minor.

The lateral pectoral nerve, the larger of the two, may arise by two roots from the anterior divisions of the upper and middle trunks, or by a single root from the point where these divisions unite to form the lateral cord of the plexus; it receives its fibres from the fifth, sixth and seventh nerves. It crosses the axillary artery and vein anteriorly, pierces the clavipectoral fascia, and is distributed to the deep surface of the pectoralis major. It sends a filament to join the medial pectoral nerve and forms with it a loop in front of the first part of the axillary artery (7.204); through this loop the lateral pectoral nerve distributes some fibres to the pectoralis minor.

The medial pectoral nerve receives its fibres from the eighth cervical and first thoracic nerves, and arises from the medial cord of the plexus while that cord is still posterior to the axillary artery. It curves forwards between the axillary artery and vein, and unites in front of the artery with a filament from the lateral pectoral nerve. It then enters the deep surface of the pectoralis minor and supplies that muscle. Two or three branches pierce the pectoralis minor, and others may pass round its inferior border, to end in the pectoralis major.



The subscapular nerves, two in number, spring from the posterior cord of the plexus, and through it from the fifth and sixth cervical nerves.

The superior subscapular nerve, the smaller, enters the subscapularis at a cranial level, and is frequently represented by two branches.

The inferior subscapular nerve supplies the caudal part of subscapularis, and ends in teres major; the latter muscle is sometimes supplied by a separate branch.

The thoracodorsal nerve, a branch of the posterior cord of the plexus, derives its fibres from the sixth, seventh and eighth cervical nerves; it arises between the upper and lower subscapular nerves and then accompanies the subscapular artery along the posterior wall of the axilla and supplies the latissimus dorsi, in which it may be traced as far as the lower border of the muscle.

The axillary (circumflex humeral) nerve (7.205) arises from the posterior cord of the brachial plexus, its fibres being derived from the fifth and sixth cervical nerves. It lies at first on the lateral side of the radial nerve and is placed behind the axillary artery, and in front of the subscapularis. At the lower border of that muscle it winds backwards in close relation to the lowest part of the articular capsule of the shoulder joint, and, in company with the posterior circumflex humeral vessels, passes through a quadrangular space bounded *above* by the subscapularis, in front,

7.202 The cutaneous nerves of the right upper limb, their areas of distribution and segmental origins, viewed from the posterior aspect.

and the teres minor, behind, *below* by the teres major, *medially* by the long head of the triceps, and *laterally* by the surgical neck of the humerus. The nerve ends by dividing into an anterior and a posterior branch.

The *anterior branch*, accompanied by the posterior circumflex humeral vessels, winds round the surgical neck of the humerus, deep to the deltoid, as far as the anterior border of the muscle, supplying it, and giving a few small cutaneous branches which pierce the muscle and ramify in the skin covering its lower part.

The *posterior branch* supplies the teres minor and the posterior part of the deltoid; upon the branch to the teres minor an oval enlargement (pseudoganglion) usually exists. The posterior branch pierces the deep fascia at the lower part of the posterior border of the deltoid and is continued as the *upper lateral cutaneous nerve of the arm*, which supplies the skin over the lower part of the deltoid and the skin covering the upper part of the long head of the triceps (7.201).

The trunk of the axillary nerve gives an articular filament which enters the shoulder joint below the subscapularis.

The musculocutaneous nerve (7.204) arises from the lateral cord of the brachial plexus, opposite the lower border of the pectoralis minor, its fibres being derived from the fifth, sixth and seventh cervical nerves. It pierces the coracobrachialis and runs downwards and laterally between the biceps and the brachialis to reach the lateral side of the arm; a little beyond the elbow it pierces the deep fascia on the lateral side of the tendon of the biceps and is continued into the forearm as the *lateral cutaneous nerve of the forearm*. A line drawn distally from the lateral side of the third part of the axillary artery, and laterally across the elevations produced by the coracobrachialis and the biceps, to the lateral side of the biceps tendon of insertion, indicates the position of the musculocutaneous nerve relative to the surface; but variation in the point of entry of the nerve into the coracobrachialis may modify considerably its surface marking (Latarjet *et al.* 1967). In its course through the arm it supplies the coracobrachialis, both heads of the biceps and the greater part of the brachialis. The branch to the coracobrachialis leaves the musculocutaneous before that nerve enters the muscle; it receives its fibres from the seventh cervical nerve, and in some instances arises directly from the lateral cord of the brachial plexus. The branches to the biceps and brachialis leave the musculocutaneous nerve after it has pierced the coracobrachialis; that supplying the brachialis gives a filament to the elbow joint. The nerve also sends a small branch to the humerus; this branch enters the bone with the nutrient artery.

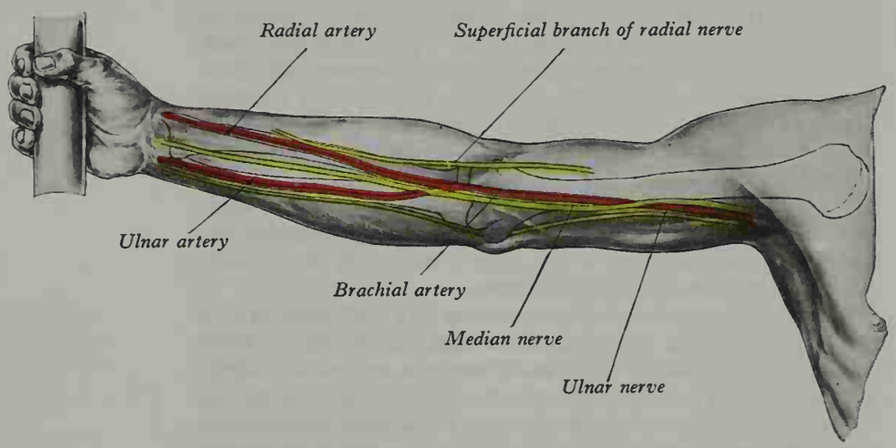
The lateral cutaneous nerve of the forearm (7.201) passes deep to the cephalic vein, and descends along the radial border of the forearm to the wrist. It supplies the skin over the lateral half of the anterior surface of the forearm and distributes branches which turn round the radial border of the forearm to communicate with the posterior cutaneous nerve of the forearm and the terminal branch of the radial nerve. At the wrist joint it is placed in front of the radial artery, and some filaments, piercing the deep fascia, accompany that vessel to the dorsal surface of the carpus. The nerve then passes downwards to the base of the thenar eminence, where it ends in cutaneous filaments. It communicates with the terminal branch of the radial nerve, and with the palmar cutaneous branch of the median nerve.

The musculocutaneous nerve presents frequent variations. It may run behind the coracobrachialis or it may adhere for some distance to the median nerve and then pass behind the biceps instead of through the coracobrachialis. Some of the fibres of the median nerve may run for some distance in the musculocutaneous nerve and then leave it to join their proper trunk; less frequently the reverse is the case, and the median nerve sends a branch to join the musculocutaneous nerve. Occasionally it gives a filament to the pronator teres and, sometimes, it may replace the branches of the radial nerve to the dorsal surface of the thumb.

The medial cutaneous nerve of the forearm (7.204) arises from the medial cord of the brachial plexus. It is derived from the eighth cervical and first thoracic nerves, and at its commencement is placed between the axillary artery and vein. Near the axilla it supplies a filament which pierces the fascia and is distributed to the skin covering the biceps, almost as far as the elbow. The nerve then runs down the arm on the medial side of the brachial artery, pierces the deep fascia with the basilic vein about the middle of the arm, and divides into an anterior and a posterior branch.

The *anterior branch*, the larger, usually passes in front of, but occasionally behind, the median cubital vein. It then descends on the front of the medial side of the forearm, distributing filaments to the skin as far as the wrist, and communicating with the palmar cutaneous branch of the ulnar nerve (7.201).

The *posterior branch* passes obliquely downwards on the medial side of the basilic vein, in front of the medial epicondyle of the humerus, winds round to the back of the forearm, and descends on its medial side as far as the wrist, distributing filaments to the skin. It communicates with the medial cutaneous nerve of the arm, the posterior cutaneous nerve of the forearm, and the dorsal branch of the ulnar (7.202).



The medial cutaneous nerve of the arm is distributed to the skin on the medial side of the arm (7.201). It is the smallest branch of the brachial plexus, and, arising from the medial cord, receives its fibres from the eighth cervical and first thoracic nerves. It passes through the axilla and crosses in front of, or behind, the axillary vein. It then runs on the medial side of this vein, and communicates with the intercostobrachial nerve. It descends along the medial side of the brachial artery and basilic vein (7.204) to the middle of the upper arm, where it pierces the deep fascia, and is distributed to the skin of the medial side of the distal third of the arm, extending on to its anterior and posterior aspects; some filaments reach the skin in front of the medial epicondyle and others over the olecranon. It communicates with the posterior branch of the medial cutaneous nerve of the forearm.

In some subjects the medial cutaneous nerve of the arm and the intercostobrachial nerve are connected by two or three filaments, which form a plexus in the axilla. In others the intercostobrachial

nerve is large and may be reinforced by a part of the lateral cutaneous branch of the third intercostal nerve; it then takes the place of the medial brachial cutaneous nerve, receiving from the brachial plexus a communicating filament which represents the latter nerve; occasionally this filament is absent.

THE MEDIAN NERVE

The median nerve (7.204) arises by two roots, one from the lateral cord, C. (5), 6, 7, and the other from the medial cord, C. 8, T. 1, of the brachial plexus; the roots embrace the third part of the axillary artery, uniting either in front, or on the lateral side, of the artery. Often some of the fibres derived from C. 7 leave the lateral root in

7.203 The anterior aspect of the right upper limb, showing the position of the principal nerves and vessels projected on to the surface.

the lower part of the axilla and pass distally and medially behind the medial root and usually in front of the axillary artery to join the ulnar nerve (7.220). These fibres from C. 7 may arise from the lateral cord or even directly from the seventh cervical nerve root of the brachial plexus. On clinical grounds they are believed to be mainly motor fibres to the flexor carpi ulnaris. If the lateral root is small, the musculocutaneous nerve (C. 5, 6, 7) sends a communicating branch to the median nerve in the arm. The median nerve descends into the arm, lying at first lateral to the brachial artery; about the level of insertion of the coracobrachialis it crosses in front of (rarely behind) the artery and descends on its medial side to the cubital fossa, where it lies behind the bicipital aponeurosis and in front of the brachialis, which separates it from the elbow joint. The nerve usually enters the forearm between the two heads of the pronator teres, crossing from the medial to the lateral side of the ulnar artery, but separated from it by the deep head of the muscle. It then passes deep to the tendinous bridge that connects the humero-ulnar to the radial head of the flexor digitorum superficialis and descends through the forearm deep to, and adherent to, the flexor digitorum superficialis, lying on the flexor digitorum profundus. About 5 cm above the flexor retinaculum it emerges from behind the lateral edge of the flexor digitorum superficialis and, becoming more superficial just above the wrist, it lies between the tendons of the flexor digitorum superficialis and the flexor carpi radialis, projecting laterally from under cover of the tendon of the palmaris longus (if present). The nerve then passes deep to the flexor retinaculum to gain the palm of the hand. In the forearm it is accompanied by the median branch of the anterior interosseous artery and its course can be represented on the surface by a line running approximately along the midline of the front of the forearm from the medial side of the end of the brachial artery in the cubital fossa (7.203).

The relation of the median nerve when entering the forearm is variable. According to Anson (1963) the route described above occurred in 82·8 per cent of 1,000 dissections; 10·8 per cent showed the nerve posterior to the humeral part of the muscle, the ulnar slip being absent. Less frequently (4·6 per cent) the nerve passed posterior to both heads, and more rarely (1·8 per cent) *through* the humeral head.

Branches of the Median Nerve in the Arm

These comprise vascular branches to the brachial artery and usually a branch to the pronator teres which is given off at a variable distance proximal to the elbow joint.

Branches of the Median Nerve in the Forearm

These are muscular, articular, anterior interosseous, palmar cutaneous and communicating. The **muscular branches** are, with one exception, given off in the proximal part of the forearm (near the elbow) to the superficial flexor forearm muscles (except the flexor carpi ulnaris), namely, the pronator teres, flexor carpi radialis, palmaris longus and flexor digitorum superficialis. The branch of the median nerve supplying the part of the flexor digitorum superficialis that passes to the index finger arises near the middle of the forearm and it may be a branch of the anterior interosseous nerve. **Articular branches** arise from the median nerve at, or just distal to, the level of the elbow joint and supply this joint as well as the proximal radio-ulnar joint.

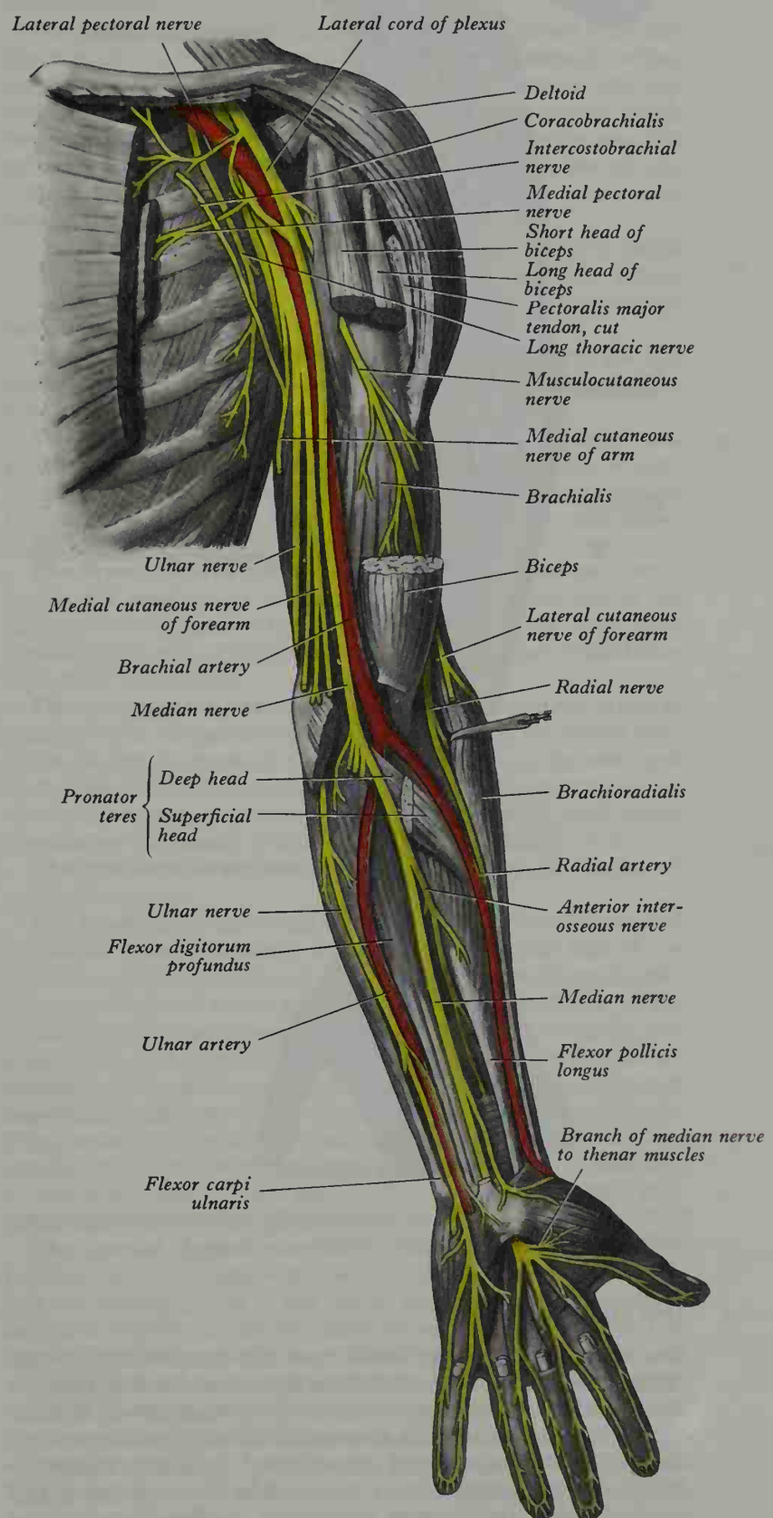
The anterior interosseous nerve is given off from the posterior surface of the median nerve as it passes between the two heads of the pronator teres and just distal to the origin of the branches of the median nerve to the superficial flexor forearm muscles described above. Accompanied by the anterior interosseous artery, it passes distally on the front of the interosseous membrane, between and deep to the flexor pollicis longus and the flexor digitorum profundus. It supplies a number of branches to these two muscles; those supplying the flexor digitorum profundus are limited to the lateral part of the muscle which sends tendons to the index and middle fingers. The nerve finally passes beneath the pronator quadratus, supplying a branch that enters its deep surface, and ends by supplying the distal radio-ulnar, radiocarpal and carpal joints.

The palmar cutaneous branch of the median nerve commences a short distance above the flexor retinaculum; it pierces the deep fascia or proximal edge of the retinaculum and divides into lateral branches which supply the skin over the thenar eminence and communicate with the lateral cutaneous nerve of the forearm, and medial branches which supply the skin of the central part of the palm and communicate with the palmar cutaneous branch of the ulnar nerve.

The communicating branch of the median nerve, which may take the form of a number of slender nerves, is frequently present. It arises from the median nerve (or sometimes its anterior interosseous branch) in the upper part of the forearm and passes distally and medially between the flexor digitorum superficialis and flexor digitorum profundus and behind the ulnar artery to join the ulnar nerve. This communication is of importance in relation to the anomalous nerve supply of certain hand muscles (p. 1101).

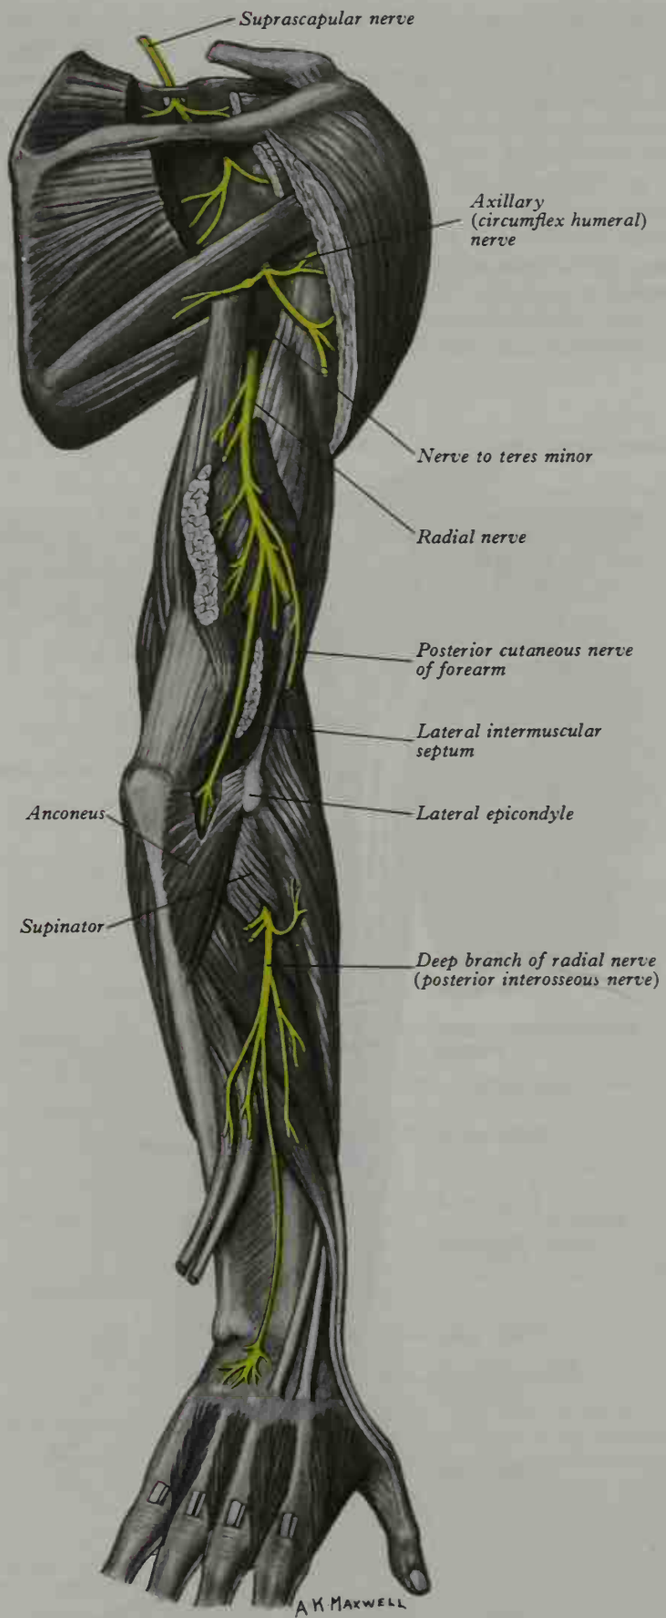
The Median Nerve in the Hand

Just proximal to the flexor retinaculum, the nerve is lateral to the tendons of the flexor digitorum superficialis, but dorsal to the retinaculum it lies immediately deep to the latter and on the anterior aspect of the tendons, in the limited space of the 'carpal tunnel' (*see* p. 583), i.e. the space bounded in front by the retinaculum and behind by the anterior surfaces of the carpal bones; in certain circumstances the nerve may be compressed in this situation. (*See* carpal tunnel syndrome, p. 1102.) Immediately distal to the flexor retinaculum the nerve becomes enlarged and flattened and usually divides into five or six branches, though the exact mode and level of division of the nerve are variable.



The muscular branch is a short stout nerve that arises from the lateral side of the median nerve; it may be the first branch of the median nerve in the palm or it may arise as a terminal branch at the same level as the digital branches. It runs laterally, just distal to the flexor retinaculum, with a slight recurrent curve proximally, lying beneath the lateral portion of the palmar aponeurosis covering the thenar muscles. It winds round the distal border of the flexor retinaculum and comes to lie on the superficial surface of the flexor pollicis brevis, usually giving a

branch to this surface of the muscle. It then continues on the superficial surface of the muscle, or it may pass through the muscle itself. It gives a branch to the abductor pollicis brevis, which enters the muscle at its medial edge, then passes deep to this muscle to supply the opponens pollicis, entering the muscle through its medial edge. Rarely, the terminal part of the nerve gives a branch to the first dorsal interosseous, which may be the sole or part nerve supply of this muscle.



The muscular branch may arise in the carpal tunnel and pierce the flexor retinaculum, a point of surgical importance (Papathanassion 1968).

The palmar digital branches (Throughout the following account of the cutaneous innervation of the digits of the hand, note should be taken of the distinction between the proximal, penultimate, as yet undivided rami termed *common palmar digital nerves* and their ultimate branches to individual digits, the *proper palmar digital nerves*. Corresponding terms for the foot are *common plantar digital nerves* and *proper plantar digital nerves*.) The median nerve divides into four or five digital branches, though it often at first divides into two divisions, a lateral which provides the digital branches to the thumb and radial side of the index finger, and a medial, which supplies the digital branches to the adjacent sides of the index, middle and ring fingers. Other variations in the mode of terminal branching of the nerve occur, as well as in the level in the hand at which the branching takes place (Poisel 1974). The arrangement of the digital nerves is commonly as follows. They pass distally, deep to the superficial palmar arch and its digital branches, lying at first in front of the long flexor tendons. Two proper palmar digital nerves, which may arise by a common stem, pass to the sides of the thumb, the one supplying its lateral side crossing in front of the tendon of the flexor pollicis longus. The proper palmar digital nerve to the lateral side of the index finger supplies a branch to the first lumbrical. Two common palmar digital nerves pass distally between the long flexor tendons, the lateral one dividing in the distal palm into two proper palmar digital nerves traversing the adjacent sides of the index and middle fingers, and the medial one dividing into two proper palmar digital nerves which supply the adjacent sides of the middle and ring fingers. The lateral common digital nerve gives a branch to the second lumbrical, and the medial one receives a communicating twig from the common palmar digital branch of the ulnar nerve and may supply the third lumbrical muscle. In the distal part of the palm, the digital arteries pass deeply between the divisions of the digital nerves, so that on the sides of the digits the nerves lie immediately in front of the arteries. In most cases the median nerve supplies palmar cutaneous digital branches to the lateral three and one-half digits (thumb, index, middle and lateral side of the ring finger); in some cases the lateral side of the ring finger is supplied by the ulnar nerve. The proper palmar digital nerves that run along the medial side of the index finger, both sides of the middle finger and the lateral side of the ring finger, enter the bases of these digits in the fat between the slips into which the central portion of the palmar aponeurosis divides (p. 585). They pass, with the lumbricals and palmar digital arteries, dorsal to the superficial transverse metacarpal ligament (p. 586) and ventral to the deep transverse metacarpal ligament (p. 472). In the digits, the nerves run distally on the sides of the long flexor tendons, outside their fibrous sheaths, on the plane of the anterior surfaces of the phalanges, and immediately in front of the accompanying digital arteries. Each nerve gives off several branches to the skin on the front and sides of the digit, many of which end in lamellated corpuscles (p. 855), and branches to the metacarpophalangeal and interphalangeal joints. Branches are also supplied to the fibrous sheaths of the long flexor tendons, to the digital arteries (vasomotor), and to the sweat glands (secretomotor). A little beyond the base of the distal phalanx, the digital nerve gives off a branch passing dorsally to supply the nail bed, while the main nerve divides into branches supplying the skin of the terminal part of the digit and the pulp. Just beyond the base of the proximal phalanx, each *palmar* digital nerve gives off a dorsal branch that runs obliquely, distally and dorsally, to supply branches to the skin over the back of the middle and distal phalanges (7.202). The proper palmar digital nerves to the thumb and lateral side of the index finger run from beneath the lateral edge of the central part of the palmar aponeurosis, in company with the long flexor tendons to these digits, and in the digits themselves have the same arrangements as described above, but in the case of the thumb small branches from the distal part of the palmar digital nerves are given off to supply the skin on the back of the distal phalanx only.

In addition to the branches of the median nerve described above, variable vasomotor branches pass to supply the radial and ulnar arteries and their branches. Some of the intercarpal, carpometacarpal and intermetacarpal joints are said to receive branches from the median nerve or its anterior interosseous branch, though the precise details of the origin and distribution of these branches are uncertain.

7.204 The nerves of the left upper limb dissected from the anterior aspect.

7.205 The suprascapular, axillary and radial nerves of the right upper limb, dissected from the posterior aspect.

THE ULNAR NERVE

The ulnar nerve (7.204) arises from the medial cord of the brachial plexus, C. 8, T. 1, though, as described above (p. 1094), it often receives fibres from the seventh cervical nerve. It runs distally through the axilla on the medial side of the axillary artery, intervening between it and the axillary vein, and continues distally on the medial side of the brachial artery as far as the middle of the arm. Here it pierces the medial intermuscular septum, and inclines medially, as it descends in front of the medial head of the triceps to the interval between the medial epicondyle and the olecranon, accompanied by the superior ulnar collateral artery. At the elbow it lies in a groove on the dorsum of the medial epicondyle, and as it enters the forearm between the two heads of the flexor carpi ulnaris, it lies on the posterior and oblique parts of the ulnar collateral ligament of the elbow joint. It descends along the medial side of the forearm, lying upon the flexor digitorum profundus; its upper half is covered by the flexor carpi ulnaris; its lower half lies on the lateral side of this muscle, and is covered by the skin and fasciae. In the upper one-third of the forearm, the ulnar nerve is separated from the ulnar artery by a considerable interval, but in the rest of its extent it lies close to the medial side of the vessel (7.204). About 5 cm above the wrist it gives off a dorsal branch, and it is then continued downwards into the hand, passing in front of the flexor retinaculum on the lateral side of the pisiform bone and lying medial to and somewhat behind the ulnar artery. In company with the artery the nerve passes behind the superficial part of the retinaculum and ends by dividing into a superficial and a deep terminal branch. Its relationship to the brachial artery in the arm and to the medial epicondyle at the elbow renders the nerve easy to map out in the upper part of its course; a line drawn from the medial epicondyle to the lateral edge of the pisiform bone represents its course through the forearm (7.203).

The branches of the ulnar nerve are: articular, muscular, palmar cutaneous, dorsal, superficial terminal and deep terminal.

The articular branches to the elbow joint are several small filaments which issue from the nerve as it lies between the medial epicondyle and olecranon. Other articular branches are described below.

The muscular branches, two in number, begin near the elbow; one supplies the flexor carpi ulnaris (*see* p. 1098), the other, the medial half of the flexor digitorum profundus.

The palmar cutaneous branch arises about the middle of the forearm, and descends on the ulnar artery (7.204), giving some filaments to the vessel. It perforates the deep fascia and ends in the skin of the palm, after communicating with the palmar branch of the median nerve. It sometimes supplies the palmaris brevis.

The dorsal branch arises about 5 cm above the wrist; it passes distally and backwards deep to the flexor carpi ulnaris, perforates the deep fascia, and, running along the medial side of the back of the wrist and hand, divides into two, frequently three, dorsal digital nerves: one supplies the medial side of the little finger; the second the adjacent sides of the little and ring fingers. The third, when present, supplies the adjoining sides of the ring and middle fingers, but it may be replaced, wholly or partially, by a branch of the radial nerve, with which it always communicates on the dorsum of the hand (7.202). In the little finger the dorsal digital nerves extend only as far as the base of the distal phalanx, and in the ring finger as far as the base of the middle phalanx; the more distal parts of these digits are supplied by dorsal branches derived from the proper digital branches of the ulnar and—on the lateral side of the ring finger—median nerves.

The superficial terminal branch supplies the palmaris brevis and the skin on the medial side of the hand, and divides into two palmar digital nerves, which can be compressed against the hook of the hamate bone (p. 371). One of these palmar digital nerves supplies the medial side of the little finger; the other (a common palmar digital nerve) sends a twig to join the median nerve and then divides into two proper digital nerves for the adjoining sides of the little and ring fingers (7.204). The proper digital branches are distributed to the fingers in the same manner as those of the median nerve. Murakami (1969) has described articular branchlets from the superficial terminal branch of the ulnar nerve.

The deep terminal branch, accompanied by the deep branch of the ulnar artery, passes between the abductor digiti minimi and flexor digiti minimi; it then perforates the opponens digiti minimi and follows the course of the deep palmar arch behind the flexor tendons. At its origin it supplies the three short muscles of the little finger. As it crosses the hand, it gives branches to the interossei and to the third and fourth lumbricals; it ends by supplying the adductor pollicis, the first palmar interosseous and, in most cases (p. 587), the flexor pollicis brevis. It also sends articular filaments to the wrist joint.

It has been pointed out that the medial part of the flexor digitorum profundus is supplied by the ulnar nerve; the third and fourth lumbricals which are connected with the tendons of this part of the muscle, are supplied by the same nerve. In like manner the lateral part of the flexor digitorum profundus and the first and second lumbricals are supplied by the median nerve. The third lumbrical frequently receives an additional twig from the median nerve.

The deep terminal branch of the ulnar nerve is said to give branches to some of the intercarpal, carpometacarpal and intermetacarpal joints, though, as in the case of the median nerve, the precise details of the origin and distribution of these branches are uncertain. Vascular (vasomotor) branches are given off from the ulnar nerve in the forearm and hand to supply the ulnar artery and the palmar arteries.

Anomalous Nerve Supply of Hand Muscles

The nerve supply to the short thenar muscles (flexor pollicis brevis, abductor pollicis brevis and opponens pollicis) is subject to considerable variation. From a study of the results of lesions of the median and ulnar nerves in the forearm (Rowntree 1949; Day and Napier 1961) the following variations have been deduced, expressed here in percentages of 226 hands examined, relating to the innervation of these thenar muscles by the median nerve, the ulnar nerve or both nerves: flexor pollicis brevis—median 36, ulnar 48, both nerves 17; abductor pollicis brevis—median 95, ulnar 2·5, both nerves 2; opponens pollicis—median 83, ulnar 9, both nerves 7·5. The usual description of the nerve supply to these muscles is that they are all supplied by the median nerve; the results of the investigations cited are possibly to be explained, in many cases, by the variable connexions between the median and ulnar nerves in the axilla, arm or forearm, whereby truly median nerve fibres are aberrantly conveyed distally in the ulnar nerve to these muscles.

An arcuate connecting loop has long been known to occur between the median and ulnar nerves in the substance of the flexor pollicis brevis (Cannieu 1886), either part of which, superficial or deep, may be supplied by fibres from both nerves. In a more recent survey (Harness and Sekeles 1971) of the considerable literature on this topic, results of dissections of 35 hands showed a loop in 77 per cent of individuals, indicating that it should be a feature of 'normal' description.

Clinically these variations are important in that even with a complete lesion of the median nerve some of these muscles may not be paralysed, and this may lead to the erroneous conclusion that the median nerve has not suffered a complete lesion. Clinical evidence reveals that the short muscles of the thumb, whether apparently supplied by the median or ulnar nerves, receive their segmental supply from the eighth cervical and first thoracic segments of the spinal cord.

THE RADIAL NERVE

The radial nerve (7.205) arises from the posterior cord of the brachial plexus, C. 5, 6, 7, 8; (T. 1). It is the largest branch of the brachial plexus, and it descends behind the third part of the axillary artery and the upper part of the brachial artery, and in front of the subscapularis and the tendons of the latissimus dorsi and teres major. Accompanied by the arteria profunda brachii and, later, its radial collateral branch, it inclines dorsally between the long and medial heads of the triceps. From here it passes obliquely across the back of the humerus, first between the lateral and medial heads of the triceps and then in a shallow groove deep to the lateral head of the triceps muscle. On reaching the lateral side of the humerus it pierces the lateral intermuscular septum and enters the anterior compartment of the arm. It then descends, lying deeply in the intermuscular furrow, which is bounded on the medial side by the brachialis and on the lateral side by the brachioradialis, above, and the extensor carpi radialis longus, below. On reaching the front of the lateral epicondyle, it divides into terminal rami, *superficial* and *deep*.

In the arm the radial nerve is indicated by a line drawn from the commencement of the brachial artery and carried distally and laterally across the elevations produced by the long and the lateral heads of the triceps to the junction of the upper and middle thirds of a line joining the lateral epicondyle to the deltoid tuberosity. The line of the nerve is then continued on the anterior aspect of the arm to the level of the lateral epicondyle, where it lies 1 cm or less to the lateral side of the biceps tendon.

The branches of the radial nerve are: muscular, cutaneous, articular and superficial and deep terminal branches.

The muscular branches of the radial nerve supply the triceps, anconeus, brachioradialis, extensor carpi radialis longus and brachialis, and are grouped as *medial*, *posterior* and *lateral*.

The *medial* muscular branches arise from the radial nerve on the medial side of the arm and supply the medial and long heads of the triceps; the branch to the medial head is a long, slender filament, which lies close to the ulnar nerve as far as the distal third of the arm, and is therefore frequently named the *ulnar collateral nerve*.

The *posterior* muscular branch, of large size, arises from the nerve as it lies in the groove. It divides into filaments which supply the medial and lateral heads of the triceps and the anconeus. The branch for the latter muscle is a long nerve which descends in the substance of the medial head of the triceps, and gives numerous branches to it. It is accompanied by the middle collateral branch of the arteria profunda brachii, and passes behind the elbow joint to end in the anconeus.

The *lateral* muscular branches arise from the nerve as it lies in front of the lateral intermuscular septum; they supply the lateral part of the brachialis, the brachioradialis, and the extensor carpi radialis longus.

The cutaneous branches of the radial nerve are the posterior cutaneous and the lower lateral cutaneous nerves of the arm and the posterior cutaneous nerve of the forearm.

The posterior cutaneous nerve of the arm, of small size, arises in the axilla and passes to the medial side of the arm to supply the skin on its dorsal surface nearly as far as the olecranon. It crosses posterior to, and communicates with, the intercostobrachial nerve.

The lower lateral cutaneous nerve of the arm perforates the lateral head of the triceps just below the insertion of the deltoid. It then passes to the front of the elbow, lying close to the cephalic vein, and supplies the skin of the lateral part of the lower half of the arm (7.201).

The posterior cutaneous nerve of the forearm arises in common with the preceding branch. Perforating the lateral head of the triceps, it descends along the lateral side of the arm, and then along the dorsum of the forearm to the wrist, supplying the skin in its course, and joining, near its termination, with dorsal branches of the lateral cutaneous nerve of the forearm (7.201).

The articular branches of the radial nerve are distributed to the elbow joint.

The superficial terminal branch descends from the front of the lateral epicondyle along the front of the lateral side of the upper two-thirds of the forearm, lying at first upon the supinator, lateral to the radial artery and behind the brachioradialis. In the middle third of the forearm it lies behind the brachioradialis, but is now close to the lateral side of the artery. Here it lies first on the pronator teres, next on the radial head of the flexor digitorum superficialis and then on the flexor pollicis longus. It quits the artery about 7 cm above the wrist, passes deep to the tendon of the brachioradialis and, winding round the lateral side of the radius as it descends, pierces the deep fascia and divides into five, sometimes four, dorsal digital nerves.

The dorsal digital nerves are small and four or five in number. The first supplies the skin of the radial side of the thumb and the adjoining part of the thenar eminence, communicating with branches of the lateral cutaneous nerve of the forearm; the second supplies the medial side of the thumb; the third, the lateral side of the index finger; the fourth, the adjoining sides of the index and middle fingers; the fifth communicates with a filament from the dorsal branch of the ulnar nerve and supplies the adjoining sides of the middle and ring fingers, but it is frequently replaced by the dorsal branch of the ulnar nerve. On the dorsum of the hand the superficial branch of the radial nerve usually communicates with the posterior and lateral cutaneous nerves of the forearm. The digital nerves to the thumb reach only as far as

the root of the nail; those to the index finger as far as the middle of the middle phalanx and those to the middle and ring fingers not farther than the proximal interphalangeal joints. The remaining distal areas of skin on the dorsal surface of these digits are supplied by the palmar digital branches of the median and ulnar nerves (7.202). The superficial radial nerve may supply the whole of the dorsum of the hand; for this and other variations consult Sayfi (1967).

The deep terminal branch (posterior interosseous nerve) (7.205) winds to the back of the forearm round the lateral side of the radius between the two planes of fibres of the supinator. It gives a branch to the extensor carpi radialis brevis, and another to the supinator before it enters the latter muscle, and as it traverses its substance it supplies additional branches to it. The branch to the extensor carpi radialis brevis may spring from the commencement of the superficial branch of the radial nerve. As soon as it emerges from the supinator on the back of the forearm the deep branch of the radial nerve gives off three short branches—to the extensor digitorum, extensor digiti minimi and extensor carpi ulnaris—and two long branches—a *medial* to the extensor pollicis longus and the extensor indicis, and a *lateral*, which supplies the abductor pollicis longus and ends in the extensor pollicis brevis. The nerve lies at first between the superficial and the deep muscles of the back of the forearm, but, at the distal border of the extensor pollicis brevis, it passes deep to the extensor pollicis longus and, diminished to a fine thread, runs down on the dorsal aspect of the interosseous membrane of the forearm. Finally it reaches the dorsum of the carpus, where it presents a flattened and somewhat expanded termination ('pseudoganglion') from which filaments are distributed to the ligaments and articulations of the carpus (7.205).

Articular branches from the deep branch of the radial nerve are distributed to the carpal and distal radio-ulnar joints and to some of the intercarpal and intermetacarpal joints, while the digital branches of the radial nerve supply branches to the metacarpophalangeal and proximal interphalangeal joints of the appropriate digits.

Applied Anatomy. The brachial plexus may be injured by falls from a height on to the side of the head and shoulder, the nerves of the plexus being violently stretched; the upper trunk of the plexus sustains the greatest injury, and the subsequent paralysis may be confined to the muscles supplied by the fifth nerve—the deltoid, biceps, brachialis and brachioradialis, with sometimes the supraspinatus, infraspinatus and supinator. The position of the limb, under such conditions, is characteristic: the arm hangs by the side and is rotated medially; the forearm is extended and pronated. The arm cannot be raised from the side; all power of flexion of the elbow is lost, as is also supination of the forearm. This is known as *Erb's paralysis*, and a very similar condition is occasionally met with in newborn children, either from injury to the upper trunk from the pressure of the forceps used in effecting delivery, or from traction of the head in breech presentations. A second variety of partial palsy of the brachial plexus is known as *Klumpke's paralysis*. In this it is the eighth cervical and first thoracic nerves that are injured, either before or after they have joined to form the lower trunk. The subsequent paralysis affects, principally, the intrinsic muscles of the hand and the flexors of the wrist and fingers.

The brachial plexus may also be injured by direct violence or gunshot wounds, by violent traction on the arm, or by efforts at reducing a dislocation of the shoulder joint; the amount of paralysis will depend upon the amount of injury to the constituent nerves. When the entire plexus is involved, the whole of the upper extremity will be paralysed and anaesthetic. In some cases the injury appears to be rather a tearing away of the roots of the nerves from the spinal cord than a rupture of the nerves themselves, and where this involves the first thoracic nerve the pupil on the same side may be constricted, on account of damage to the preganglionic fibres emerging in it to supply the dilatator pupillae. The brachial plexus in the axilla is often damaged from the pressure of a crutch, producing the condition known as '*crutch paralysis*'. In these cases the radial is the nerve most frequently implicated; the ulnar nerve suffers next in frequency. The median and radial nerves often suffer from '*sleep palsies*', paralysis from pressure coming on while the patient is profoundly asleep under the influence of alcohol or some narcotic.

Paralysis of the long thoracic nerve throws the serratus anterior out of action, and may occur in porters who have to carry heavy weights on the shoulder, for the nerve is exposed to injury as it lies in the posterior triangle of the neck. The inferior angle of the scapula is drawn towards the median plane, by the unopposed action of the rhomboids and levator scapulae, and tends to project backwards ('winging' of the scapula) when the arm is held horizontally forwards or when forward pushing movements are attempted against resistance. The arm cannot be raised above the horizontal unless the inferior angle of the scapula is pushed anterolaterally for the patient.

The *axillary (circumflex humeral) nerve*, on account of its course round the surgical neck of the humerus, is liable to be injured in fractures of this part of the bone, and in dislocations of the shoulder joint; paralysis of the deltoid, and anaesthesia of the skin over the lower part of that muscle, result. Paralysis of the deltoid renders effective abduction of the arm impossible. The associated paralysis of the teres minor is not easily demonstrated.

The *median nerve* is liable to injury in wounds of the forearm. When it is completely divided proximal to its muscular and anterior interosseous branches, there is loss of flexion of the second phalanges of all the fingers, and of the terminal phalanges of the index and middle fingers. Flexion of the terminal phalanges of the ring and little fingers is effected by the section of the flexor digitorum profundus which is supplied by the ulnar nerve. There is power to flex the proximal phalanges through the interossei. The thumb cannot be opposed or abducted, nor can it be flexed at the interphalangeal joint (*see* p. 1099), and it is maintained in a position of extension and adduction. There is loss in the power of pronating the forearm; the brachioradialis has the power of bringing the forearm into a position of mid-pronation, but beyond this no further pronation can be effected. The wrist can be flexed by the flexor carpi ulnaris, but flexion is combined with adduction of the hand. There is loss or impairment of sensation on the palmar surfaces of the thumb, index, middle, and radial half of the ring fingers, and on the dorsal surfaces of the same fingers over the last two phalanges, except in the thumb, where the loss of sensation is limited to the back of the distal phalanx. Owing to the paralysis of the short muscles of the thumb and the unopposed action of the extensor pollicis longus, an '*ape-like*' hand is produced. Injury of the nerve just above the middle of the forearm may result only in weakness of flexion of the index finger ('*pointing*' index finger), since the branch to the part of the flexor digitorum superficialis distributed to that finger arises at about the middle of the forearm (p. 1098). More commonly, however, the nerve is injured proximal to the flexor retinaculum, when the power of flexion of the fingers and pronation of the forearm remains intact, unless the flexor tendons are also divided. The chief effect of lesions here is usually inability to oppose the thumb, though the intact abductor pollicis longus and adductor pollicis may combine to imitate this action. As it lies deep to the flexor retinaculum, the median nerve is situated in the restricted space (carpal tunnel or carpal canal) between the retinaculum and the carpal bones. Any pathological condition which diminishes the size of this tunnel (e.g. carpal dislocation or arthritis, tenosynovitis of the long flexor tendons, etc.) will cause pressure on the nerve with resultant pain and slight sensory impairment in the digits supplied by the nerve and sometimes slight wasting of the thenar muscles, these clinical features constituting the '*carpal tunnel syndrome*'. Most commonly there is no apparent cause for this syndrome and, in any case, complete division of the retinaculum is curative.

The *ulnar nerve* is also liable to be injured in wounds of the forearm. The commonest cause of complete or partial ulnar nerve lesion is injury to the nerve as it lies behind the medial humeral epicondyle. Such injury leads to impaired power of adduction, and, upon an attempt being made to flex the wrist, the hand is drawn to the radial side by the flexor carpi radialis; there is inability to spread out the fingers owing to paralysis of the dorsal interossei, and for the same reason the fingers, especially the ring and little fingers, cannot be flexed at the metacarpophalangeal

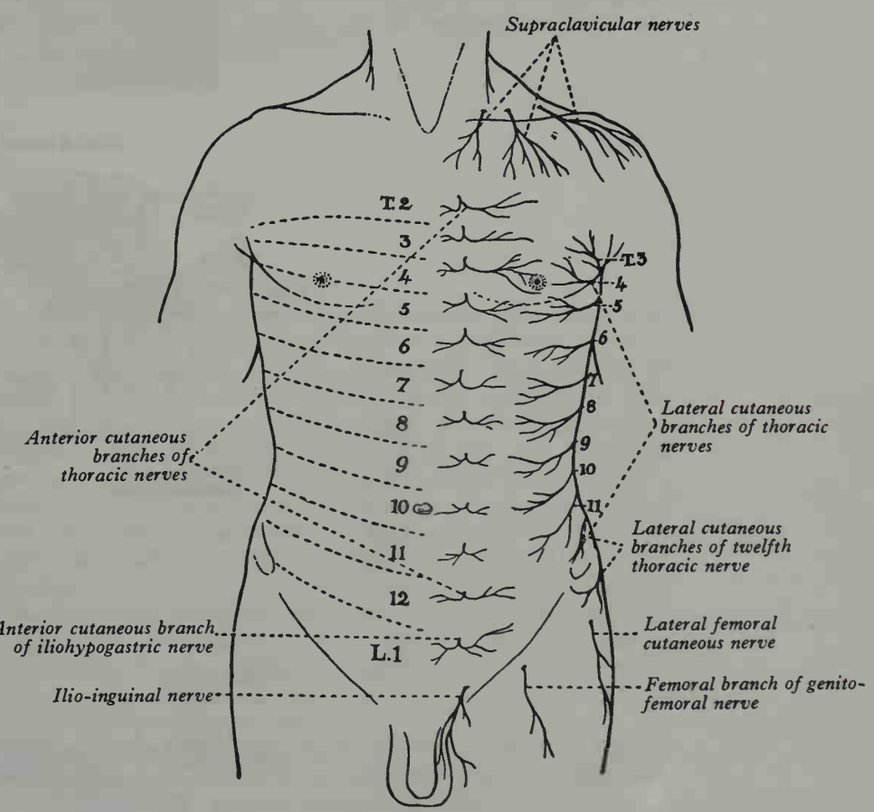
joints or extended at the interphalangeal joints, and the hand assumes a claw shape from the action of the opposing muscles; there is loss in the power of flexion in the fourth and fifth digits and inability to adduct the thumb. The muscles of the hypothenar eminence become wasted. Sensation is lost, or impaired, in the skin supplied by the nerve.

The *radial nerve* also is frequently injured. In consequence of its close relationship to the humerus, it may be injured, but is seldom torn, in fractures of this bone. Callus formation in repair of the fracture seldom interferes with the function of the nerve. In fractures of the middle part of the humerus, the triceps is not paralysed, since its supplying nerves arise from the radial nerve more proximally. It is also liable to be contused against the bone by kicks or blows, or to be divided in wounds of the arm. When paralysed, the hand is flexed at the wrist and lies flaccid. This is known as *wrist drop*. The fingers are also flexed, and when an attempt is made to extend them, the last two phalanges only will be extended, through the action of the lumbrical and interosseous muscles; the first phalanges remain flexed. Extension of the wrist is impossible. Supination is completely lost when the forearm is extended on the arm, but is possible to a certain extent if the forearm be flexed to allow effective action of the biceps. The power of extension of the forearm is lost on account of paralysis of the triceps, if the injury to the nerve has taken place near its origin. As the radial nerve has only a very small area of exclusive supply, the extent of the anaesthesia associated with even severe injuries to it is surprisingly small and is confined to a limited region on the lateral part of the dorsum of the hand.

Dislocations and epiphyseal separations of the elbow and supracondylar fractures of the humerus in children frequently lead to ulnar, median or posterior interosseous injury.

THORACIC VENTRAL RAMI

The ventral rami of the thoracic nerves (7.206, 207) are twelve in number on each side. The upper eleven lie between the ribs (*intercostal nerves*), while the twelfth lies below the last rib (*subcostal nerve*). Each nerve is connected with the adjoining ganglion of the sympathetic trunk by grey and white rami communicantes: the grey ramus joins the nerve proximal to the point at which the white ramus leaves it. The intercostal nerves are distributed chiefly to the thoracic and abdominal walls. The first two nerves supply fibres to the upper limb in addition to their thoracic branches; the next four are limited in their distribution to the thoracic wall; the lower five supply the thoracic and abdominal walls (p. 1104); the subcostal nerve is distributed to the abdominal wall and the gluteal skin. Communicating branches link the intercostal nerves in the posterior parts of the intercostal spaces and, in addition, the lower five communicate freely as they traverse the abdominal wall (Davies *et al.* 1932).



Each intercostal nerve gives off a collateral and a lateral cutaneous branch before it reaches the angle of adjoining ribs. The *collateral branch* follows the caudal border of the space in the same intermuscular interval as the main trunk, which it may rejoin before it is distributed as an additional anterior cutaneous nerve. The *lateral cutaneous branch* accompanies the main trunk for a time and then pierces the intercostal muscles obliquely. With the exception of the lateral cutaneous branches of the first and second intercostal nerves, each divides into anterior and posterior branches, which subsequently pierce the serratus anterior. The *anterior branches* run forwards over the border of the pectoralis major and supply twigs to the overlying skin; those of the fifth and sixth nerves supply twigs to a variable number of the upper digitations of the obliquus abdominis externus. The *posterior branches* run backwards, and supply the skin over the scapula and latissimus dorsi.

The 1st to 6th Thoracic Nerves

The ventral ramus of the first thoracic nerve divides into a large and a small branch. The large branch ascends in front of the neck of the first rib on the lateral side of the superior intercostal artery, and enters the brachial plexus (p. 1094). The small branch is the *first intercostal nerve*; it runs along the first intercostal space, and ends on the front of the chest as the first anterior cutaneous nerve of the thorax. It furnishes a lateral cutaneous branch which pierces the chest wall in front of the serratus anterior and supplies the skin of the axilla; it may communicate with the intercostobrachial nerve and sometimes joins the medial cutaneous nerve of the arm (Cave 1929). The first thoracic nerve frequently receives a connecting ramus from the second; this twig ascends in front of the neck of the second rib.

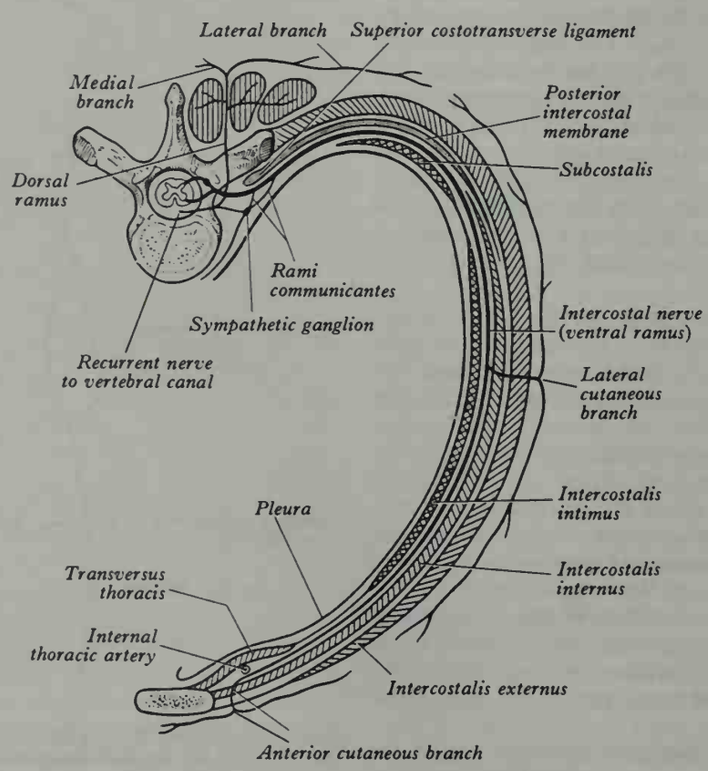
The ventral rami of the second, third, fourth, fifth and sixth thoracic spinal nerves pass forwards (7.201) in the intercostal spaces below the intercostal vessels. At the back of the chest they lie between the pleura and the posterior intercostal membranes, but in most of their course they run between the internal intercostals and the subcostales and intercostales intimi (7.207). Near the sternum, they cross in front of the internal thoracic artery and transversus thoracis, pierce the internal intercostals, the external intercostal membranes, and the pectoralis major, and their terminal branches form the **anterior cutaneous nerves of the thorax**; they supply the skin of the front of the thorax; the anterior cutaneous branch of the second nerve may be connected to the medial supraclavicular nerves of the cervical plexus. Twigs from the anterior cutaneous branch of the sixth intercostal nerve supply the abdominal skin in the upper part of the infrasternal angle.

Branches. Numerous slender muscular filaments supply the intercostals, the serratus posterior superior, and the transversus thoracis. At the front of the thorax some of these branches cross the costal cartilages from one intercostal space to another.

7.206 A diagram showing the approximate segmental distribution of the cutaneous nerves on the front of the trunk. The contribution from the first thoracic spinal nerve is not shown, and the considerable overlap which occurs between adjacent segments is not indicated. For the latter see 7.221.

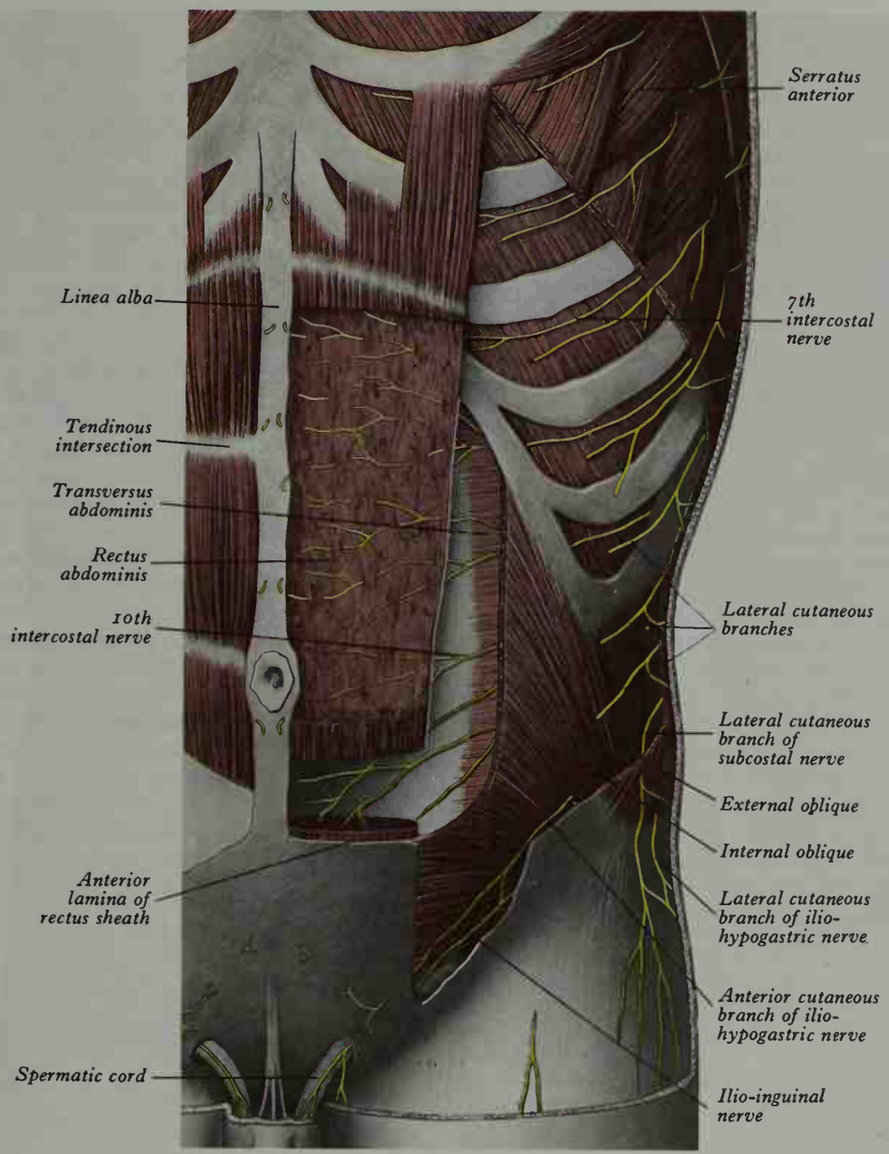
The lateral cutaneous branch of the second intercostal nerve is named the *intercostobrachial nerve* (7.204). It crosses the axilla to gain the medial side of the arm, and joins with a filament from the medial cutaneous nerve of the arm. It then pierces the deep fascia of the arm, and supplies the skin of the upper half of the medial and posterior parts of the arm, communicating with the posterior brachial cutaneous branch of the radial nerve. The size of the intercostobrachial nerve is in inverse proportion to that of the medial brachial cutaneous nerve. A second intercostobrachial nerve is frequently given off from the anterior part of the lateral cutaneous branch of the third intercostal nerve; it supplies filaments to the axilla and to the medial side of the arm.

The 7th to 12th Thoracic Nerves



The ventral rami of the seventh, eighth, ninth, tenth and eleventh thoracic nerves are continued anteriorly from the intercostal spaces into the abdominal wall.

As they approach the anterior ends of the spaces in which they lie, the seventh and eighth nerves curve *upwards* and medially across the deep surface of the costal margin, insinuating themselves between the digitations of the transversus abdominis to gain the deep aspect of the posterior lamella of the aponeurosis of the internal oblique. Having pierced this layer, they lie behind the rectus abdominis and continue upwards and medially (7.208) for a short distance parallel with the costal margin. Both supply the rectus abdominis and, having passed through the muscle near its lateral edge, pierce the anterior wall of its sheath, to reach and supply the skin. It will be observed that both the seventh and the eighth intercostal nerves cross the costal margin medial to the lateral border of the rectus abdominis and therefore enter its sheath by piercing its posterior wall.



The ninth, tenth and eleventh intercostal nerves pass between the digitations of the diaphragm and transversus abdominis to gain the interval between the latter muscle and the internal oblique. In this intermuscular interval the ninth nerve runs almost *horizontally*, but the tenth and eleventh nerves are inclined caudally and medially. When they reach the lateral edge of the rectus abdominis, they pierce the posterior lamella of the internal oblique aponeurosis and pass behind the muscle. They end like the terminal branches of the seventh and eighth intercostal nerves. The tenth nerve supplies the band of skin which includes the umbilicus (7.206, 221).

The lower intercostal nerves supply the intercostal, the subcostal and the abdominal muscles, and the last three send branches to the serratus posterior inferior. They also supply sensory fibres to the costal part of the diaphragm and the related parietal pleura and peritoneum. Like the upper intercostal nerves the lower intercostal nerves give off *collateral* and *lateral cutaneous branches* before they reach the angles of the ribs. The collateral branch may rejoin the main trunk, but, if it does so, it leaves it again near the lateral border of the rectus abdominis and runs forwards below it (7.208). It pierces the muscle and the anterior wall of its sheath near the linea alba and supplies the skin. The lateral cutaneous branches pierce the intercostals and the external oblique, in the same line as the lateral cutaneous branches of the upper thoracic nerves, and divide into anterior and posterior branches, which are distributed to the skin of the abdomen and back respectively; the anterior branches also supply twigs to the digitations of the external oblique, and extend downwards and forwards nearly as far as the margin of the rectus abdominis; the posterior branches pass backwards to supply the skin over the latissimus dorsi. Each lateral cutaneous branch descends as it pierces the external oblique and the superficial fascia so that it reaches the skin on a level with the corresponding anterior cutaneous branch and the cutaneous branch of the corresponding dorsal ramus (p. 1090 and 7.196).

The ventral ramus of the **twelfth thoracic nerve** (subcostal nerve) is larger than the others, and gives a communicating branch to the first lumbar nerve (sometimes termed the *dorsolumbar nerve*). Like the intercostal nerves it soon gives off a collateral branch. It accompanies the subcostal artery along the lower border of the twelfth rib and passes behind the lateral arcuate ligament. It then runs behind the kidney (8.148), and in front of the upper part of the quadratus lumborum, perforates the aponeurosis of origin of the transversus and passes forwards between that muscle and the obliquus internus, to be distributed in the same manner as the lower intercostal nerves. It communicates with the iliohypogastric nerve of the lumbar plexus, and gives a branch to the pyramidalis. The *lateral cutaneous branch* of the twelfth thoracic nerve pierces the internal

7.207 A diagram of the course of a typical intercostal nerve. The muscular and the collateral branches are not shown.

7.208 Diagram to illustrate the course of the lower intercostal and the cutaneous branches of some lumbar nerves. Portions of the muscles of the anterior abdominal wall have been removed, including most of the anterior layer of the rectus sheath and parts of the rectus abdominis.

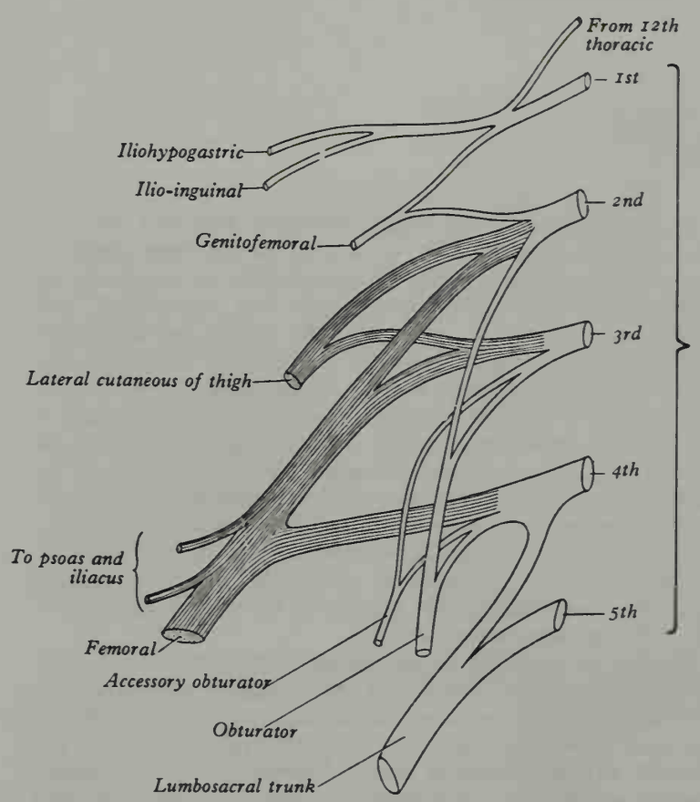
and external oblique muscles, gives a twig to the lowest slip of the latter, descends over the iliac crest about 5 cm behind the anterior superior iliac spine (7.215), and is distributed to the skin of the front part of the gluteal region, some filaments reaching as low as the greater trochanter of the femur.

Applied Anatomy. In many diseases affecting the nerve trunks at or near their origins, the pain is referred to their peripheral terminations. Thus, in tuberculosis of thoracic vertebrae, patients often suffer from pain in the abdominal wall. When confined to a single pair of nerves the sensation complained of is often a feeling of constriction, as if a cord were tied round the abdomen, and in these cases the situation of the sense of constriction may serve to localize the disease in the vertebral column. Where the bone disease is more extensive and two or more nerves are involved, a more general, diffused pain in the abdomen is felt.

Occasionally subluxation of an interchondral joint between the lower costal cartilages may trap an intercostal nerve with consequently referred abdominal pain; for a review of the literature of this 'interchondral subluxation' or 'clicking rib syndrome' *see* Abrahams (1976).

Again, it must be borne in mind that the nerves which supply the skin of the abdomen supply also the planes of muscle which constitute the greater part of the abdominal wall, and this is of importance in protecting the abdominal viscera from injury. A blow on the abdomen, even of considerable force, will do no injury to the viscera if the muscles are in a condition of firm contraction; whereas in cases where the subject has been taken unawares, and the blow has been struck with the abdominal muscles relatively relaxed, an injury insufficient to produce any lesion of the abdominal wall may be accompanied by rupture of some of the abdominal contents. The importance, therefore, of immediate reflex contraction upon the receipt of, or in anticipation of, an injury cannot be overestimated, and the origin of the cutaneous and motor fibres from the same segments of the spinal cord results in a much more rapid response on the part of the muscles to any peripheral stimulation of the cutaneous filaments than would be the case if the two sets of fibres were derived from independent sources.

The nerves supplying the abdominal muscles and skin, derived from the lower intercostal nerves, are intimately connected with the sympathetic nerves supplying the abdominal viscera through the lower thoracic ganglia, from which the splanchnic nerves are derived. In consequence of this, in laceration of the abdominal viscera, and in acute peritonitis, the muscles of the belly wall become firmly contracted, and thus as far as possible preserve the abdominal contents in a condition of rest.



LUMBAR VENTRAL RAMI

The ventral rami of the lumbar nerves increase in size from the first to the last. They are joined, near their origins, by grey rami communicantes from the four lumbar ganglia of the sympathetic trunk. These rami consist of long, slender branches which accompany the lumbar arteries round the sides of the vertebral bodies, under cover of the psoas major. Their arrangement is somewhat irregular: one ganglion may give rami to two lumbar nerves, or one lumbar nerve may receive rami from two ganglia: not infrequently the rami leave the sympathetic trunk between two ganglia. The first and second, and sometimes the third, lumbar nerves are each connected with the lumbar part of the sympathetic trunk by a *white ramus communicans*.

The ventral rami of the lumbar nerves pass downwards and laterally into the psoas major. The first three nerves and the greater part of the fourth form the *lumbar plexus*. The smaller part of the fourth nerve joins with the fifth to form the *lumbosacral trunk*, which assists in the formation of the *sacral* plexus. The fourth nerve is often termed the *nervus furcalis*, from the fact that it is subdivided between the two plexuses. In many cases the fourth lumbar is the nervus furcalis but this arrangement is frequently departed from. The third is occasionally the lowest nerve which enters the lumbar plexus giving at the same time some fibres to the sacral plexus, and thus forming the nervus furcalis; or both the third and fourth may be furcal nerves. When this occurs, the plexus is termed *high* or *prefixed*. More frequently the fifth nerve is divided between the lumbar and sacral plexuses, and constitutes the nervus furcalis; and when this takes place, the plexus is distinguished as a *low* or *postfixed* plexus. These variations necessarily produce corresponding modifications in the sacral plexus. (For further information on variation in primates, including man, consult Piasecka-Kacperska and Gladyskowska-Rzeczycka 1972.)

The Lumbar Plexus

The lumbar plexus (7.209, 210) lies within the posterior part of the psoas major, in front of the transverse processes of the lumbar vertebrae; it is formed by the ventral rami of the first three lumbar nerves and the greater part of the ventral ramus of the fourth; the first lumbar nerve receives a branch from the last thoracic nerve. (It may be noted that the *paravertebral* part of the psoas major muscle is in two planes, a *posterior* mass arising from transverse processes, and an *anterior* mass arising from the lips of vertebral bodies, intervertebral discs and tendinous arches (p. 593); the lumbar plexus is deployed between these planes, and their relationship to the intervertebral foramina should be appreciated.)

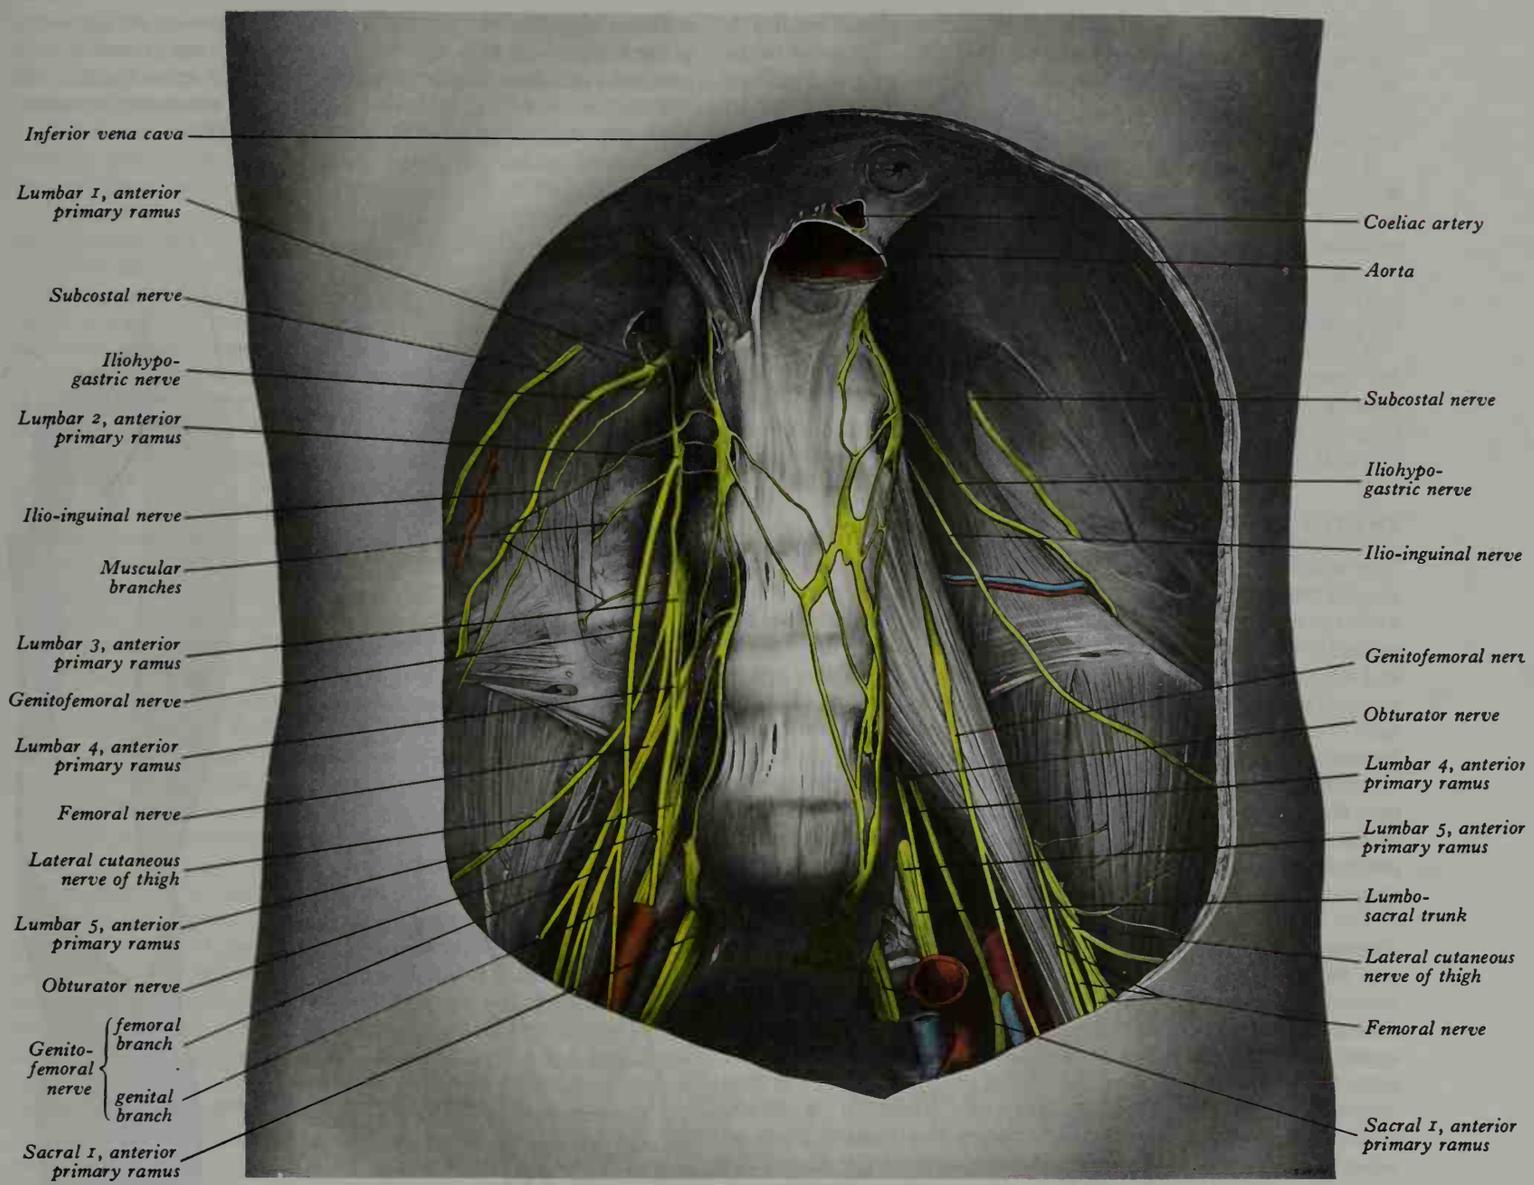
7.209 A plan of the lumbar plexus. The *dorsal divisions* of the second, third and fourth lumbar nerves are shaded.

Its arrangement varies in different subjects, but the usual condition is the following. The first lumbar nerve, supplemented by a twig from the last thoracic, splits into an upper and a lower branch; the upper, larger branch divides into the iliohypogastric and ilio-inguinal nerves; the lower, smaller branch unites with a branch of the second lumbar to form the genitofemoral nerve. The remainder of the second nerve, the third nerve, and the part of the fourth nerve which joins the plexus, divide into ventral and dorsal branches. The ventral branch of the second unites with the ventral branches of the third and fourth nerves to form the obturator nerve. The dorsal branches of the second and third nerves each divide into a smaller and larger part; the smaller parts unite to form the lateral femoral cutaneous nerve, and the larger parts join with the dorsal branch of the fourth nerve to form the femoral nerve. The accessory obturator, when it exists, arises from the ventral branches of the third and fourth nerves. For details of the blood supply of the lumbar plexus see Day (1964).

The branches of the lumbar plexus may therefore be particularized as follows:

Muscular	T. 12, L. 1, 2, 3, 4.
Iliohypogastric	L. 1.
Ilio-inguinal	L. 1.
Genitofemoral	L. 1, 2.
	Dorsal divisions
Lateral cutaneous, of thigh	L. 2, 3.
Femoral	L. 2, 3, 4.
	Ventral divisions
Obturator	L. 2, 3, 4.
Accessory obturator	L. 3, 4.

Muscular branches are distributed to the quadratus lumborum from the twelfth thoracic and first three or four lumbar nerves; to the psoas minor from the first, to the psoas major from the second, third and, sometimes, from the fourth, and to the iliacus from the second and third lumbar nerves.



The iliohypogastric nerve arises from the first lumbar nerve (7.209). It emerges from the upper part of the lateral border of the psoas major, and crosses obliquely behind the lower part of the kidney, and in front of the quadratus lumborum (7.210; 8.148). Just above the iliac crest it perforates the posterior part of the transversus abdominis, and divides between that muscle and the internal oblique into a lateral and an anterior cutaneous branch; it supplies both.

The *lateral cutaneous branch* pierces the internal and external oblique muscles immediately above the iliac crest at a point a little behind the iliac branch of the twelfth thoracic nerve; it is distributed to the skin of the posterolateral gluteal region.

The *anterior cutaneous branch* (7.206) runs between the internal oblique and transversus, supplying twigs to both muscles. It then pierces the internal oblique at a point about 2 cm on the medial side of the anterior superior iliac spine, perforates the aponeurosis of the external oblique about 3 cm above the superficial inguinal ring, and is distributed to the skin of the abdomen above the pubis.

The iliohypogastric nerve communicates with the subcostal and ilio-inguinal nerves.

The ilio-inguinal nerve, smaller than the iliohypogastric, arises with it from the first lumbar nerve (7.209). It emerges from the lateral border of the psoas major, with or just caudal to the iliohypogastric nerve, and, passing obliquely across the quadratus lumborum and the upper part of the iliacus, perforates the

7.210 A dissection of the posterior abdominal wall to show the lumbar plexus and sympathetic trunks. The right psoas major has been removed.

transversus abdominis, near the anterior part of the iliac crest, and sometimes communicates with the iliohypogastric nerve. It then pierces the internal oblique, distributing filaments to it, lies below the spermatic cord in the inguinal canal and accompanies it through the superficial inguinal ring. It is distributed to the skin of the superomedial area of the thigh, to the skin over the root of the penis and upper part of the scrotum in the male (7.206), and to the skin covering the mons pubis and adjoining part of the labium majus in the female.

The size of the ilio-inguinal nerve is in inverse proportion to that of the iliohypogastric. Occasionally it is very small, and ends by joining the iliohypogastric nerve; in such cases, a branch from the iliohypogastric takes the place of the ilio-inguinal, or the latter nerve may at times be altogether absent. On the analogy of the intercostal nerves the ilio-inguinal nerve may be regarded as the collateral branch of the first lumbar nerve (Davies 1935), and the iliohypogastric as the main trunk, which gives off the lateral cutaneous branch.

The genitofemoral nerve arises from the first and second lumbar nerves (7.209). It passes obliquely forwards and downwards through the substance of the psoas major, and emerges on the abdominal surface of the muscle near its medial border, opposite the third or fourth lumbar vertebra; it then descends on the surface of the psoas major, under cover of the peritoneum, and, crossing obliquely behind the ureter, divides at a variable distance above the inguinal ligament into the genital and femoral branches. The genitofemoral nerve frequently divides close to its origin, and its two branches then emerge separately through the psoas major.

The *genital branch* crosses the lower end of the external iliac artery, and enters the inguinal canal through the deep inguinal ring; it supplies the cremaster, and gives a few filaments to the skin of the scrotum. In the female, it accompanies the round ligament of the uterus and ends in the skin of the mons pubis and labium majus.

The *femoral branch* descends on the lateral side of the external iliac artery, and sends a few filaments round it; it then crosses the deep circumflex iliac artery, and passing behind the inguinal ligament, enters the femoral sheath, lying lateral to the femoral artery. It pierces the anterior layer of the femoral sheath and the fascia lata, and supplies the skin over the upper part of the femoral triangle (7.211). It communicates with the intermediate cutaneous nerve of the thigh, and gives a few twigs to the femoral artery.

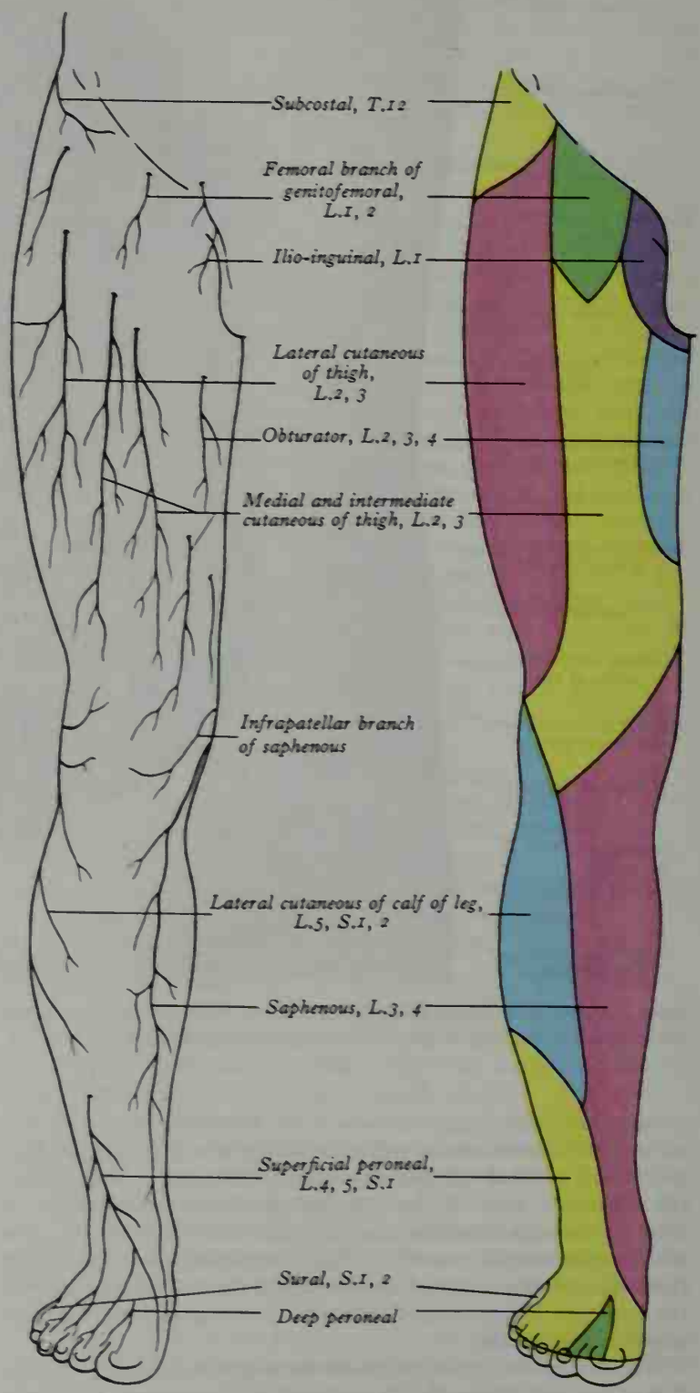
The lateral cutaneous nerve of the thigh arises from the dorsal branches of the ventral rami of the second and third lumbar nerves (7.209). It emerges from the lateral border of the psoas major, and crosses the iliacus obliquely, running towards the anterior superior iliac spine. It supplies branches to the parietal peritoneum of the iliac fossa. On the right side the nerve passes behind and lateral to the caecum, from which it is separated by the fascia iliaca and the peritoneum; on the left side, it passes behind

the lower part of the descending colon. It then passes behind or through the inguinal ligament, at a variable distance medial to the anterior superior iliac spine (commonly about 1 cm), and in front of or through the sartorius into the thigh, where it divides into an anterior and a posterior branch (7.211).

The *anterior branch* becomes superficial about 10 cm below the anterior superior iliac spine, and is distributed to the skin of the anterior and lateral parts of the thigh, as far as the knee. Its terminal filaments communicate with the cutaneous branches of the anterior division of the femoral nerve and with the infrapatellar branch of the saphenous nerve, forming with them the *patellar plexus*.

The *posterior branch* pierces the fascia lata at a higher level than the anterior branch, and subdivides into filaments which pass backwards to supply the skin on the lateral surface of the limb, from the level of the greater trochanter to about the middle of the thigh. It may also supply twigs to the skin of the gluteal region.

THE OBTURATOR NERVE



The obturator nerve arises from the ventral branches of the ventral rami of the second, third and fourth lumbar nerves (7.209, 210); the branch from the third is the largest, while that from the second is often very small. It descends through the psoas major, and emerges from its medial border at the brim of the pelvis, where it passes behind the common iliac vessels, and on the lateral side of the internal iliac vessels. It then runs downwards and forwards along the lateral wall of the lesser pelvis lying on the obturator internus, above and in front of the obturator vessels, to gain the upper part of the obturator foramen, through which it enters the thigh. Near the foramen it divides into an anterior and a posterior branch, which are separated at first by a few fibres of the obturator externus, and lower down by the adductor brevis.

The *anterior branch* (7.212) leaves the pelvis anterior to the obturator externus and descends in front of the adductor brevis, and behind the pectineus and adductor longus; at the lower border of the latter muscle it communicates with the medial cutaneous and saphenous branches of the femoral nerve, forming a plexus (termed the *subsartorial plexus*) from which branches are given off to the skin on the medial side of the thigh (7.211). It then descends upon the femoral artery, to which it is finally distributed. Near the obturator foramen this branch gives an articular twig to the hip joint. Behind the pectineus, it distributes branches to the adductor longus, gracilis, usually to the adductor brevis, and often to the pectineus; it receives a filament from the accessory obturator nerve when that nerve is present.

Occasionally the communicating branch to the medial cutaneous and saphenous branches of the femoral nerve is continued down, as a cutaneous branch, to the thigh and leg. When this is so, it emerges from behind the lower border of the adductor longus, descends along the posterior margin of the sartorius to the medial side of the knee, where it pierces the deep fascia, communicates with saphenous nerve, and is distributed to the skin halfway down the medial side of the leg.

The *posterior branch* pierces the anterior part of the obturator externus, and supplies this muscle; it then passes behind the adductor brevis on the front of the adductor magnus, and divides into branches which are distributed to the adductor magnus, and to the adductor brevis when this muscle does not receive a branch from the anterior division of the nerve. It generally gives a slender *articular branch* to the knee joint; this branch perforates the lower part of the adductor magnus or passes through the opening which transmits the femoral artery, and enters the popliteal fossa. Here it descends upon the popliteal artery, to the back of the knee joint, where it pierces the oblique posterior ligament of the knee, and is distributed to the articular capsule. It gives filaments to the popliteal artery.

The accessory obturator nerve (7.209) is occasionally present. It is of small size, and arises from the ventral branches of the ventral rami of the third and fourth lumbar nerves. It descends along the medial border of the psoas major, crosses the superior ramus of the pubis behind the pectineus, and divides into branches. One branch enters the deep surface of the pectineus; another goes to the hip joint; a third communicates with the anterior branch of the obturator nerve. On occasion the accessory obturator nerve is very small and supplies only the pectineus. Any of these rami may be absent, and occasionally others occur, one sometimes supplying adductor longus. An accessory obturator nerve was present in 69 of 800 instances (p. 599).

7.211 The cutaneous nerves of the right lower limb, their areas of distribution and segmental origins, viewed from the anterior aspect.

THE FEMORAL NERVE

The femoral nerve (7.209, 210), the largest branch of the lumbar plexus, arises from the dorsal branches of the ventral rami of the second, third and fourth lumbar nerves. It descends through the substance of psoas major, emerging from the muscle at the lower part of its lateral border, and passes down between it and the iliacus, deep to the iliac fascia; it then passes behind the inguinal ligament to enter the thigh, and splits into an anterior and a posterior division. Behind the inguinal ligament it is separated from the femoral artery by part of the psoas major.

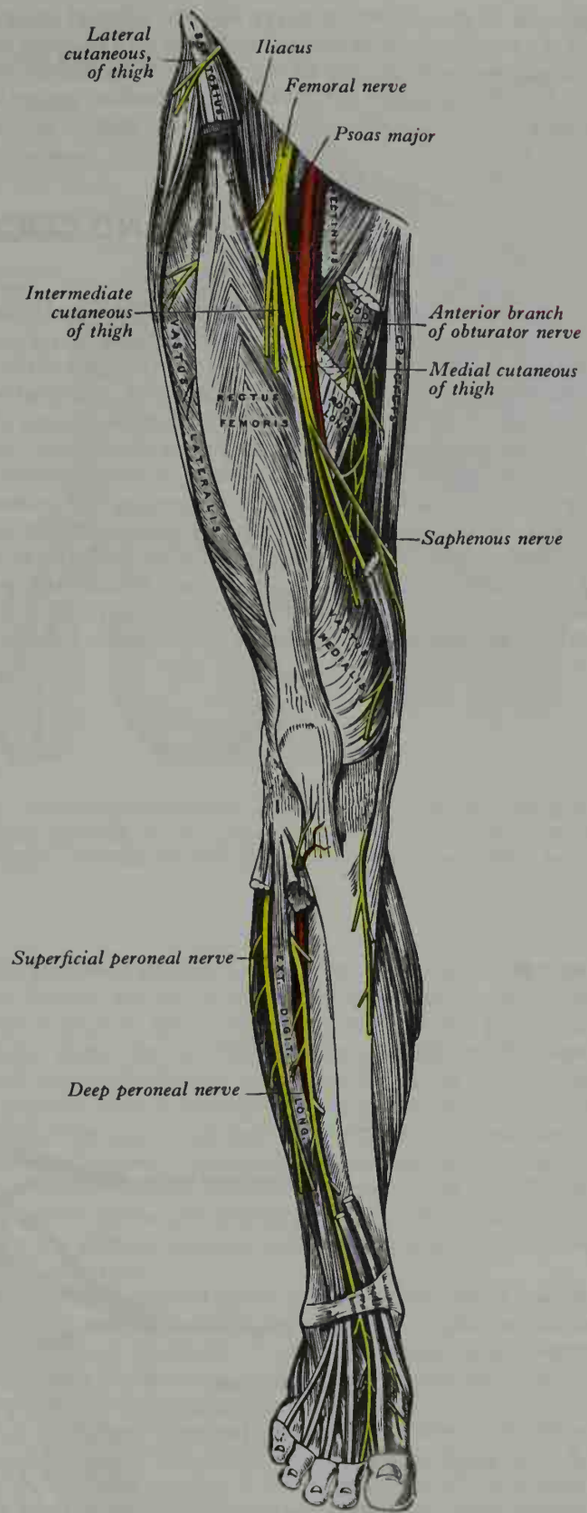
Within the abdomen the femoral nerve gives off small branches to the iliacus, the nerve to the pectineus, and a branch which is distributed upon the upper part of the femoral artery; the latter branch may arise in the thigh.

The nerve to the pectineus arises from the medial side of the femoral nerve near the inguinal ligament, passes behind the femoral sheath and enters the anterior surface of the muscle.

The anterior division of the femoral nerve gives off the intermediate and medial cutaneous nerves of the thigh (7.211, 212), and muscular branches to the sartorius.

The intermediate cutaneous nerve of the thigh pierces the fascia lata about 8 cm below the inguinal ligament, either as two branches, or as a single trunk which quickly divides into two branches; these branches descend vertically on the front of the thigh, and supply the skin as low as the knee. They end in the patellar plexus (p. 1108). The lateral branch of the intermediate cutaneous communicates with the femoral branch of the genitofemoral nerve, and frequently pierces the sartorius, to which it may give a branch of supply.

The medial cutaneous nerve of the thigh lies at first on the lateral side of the femoral artery, but at the apex of the femoral triangle it crosses ventral to the artery and divides into an anterior and a posterior branch. Before dividing, the nerve gives off a few filaments which pierce the fascia lata to supply the skin of the medial side of the thigh, in the neighbourhood of the long saphenous vein; one of these filaments emerges through the saphenous opening, and a second becomes subcutaneous about the middle of the thigh. The *anterior branch* runs downwards on the sartorius, perforates the fascia lata at the junction of the middle with the lower one-third of the thigh, and divides into two branches: one supplies the skin as low as the medial side of the knee; the other crosses to the lateral side of the patella, communicating in its course with the infrapatellar branch of the saphenous nerve. The *posterior branch* descends along the posterior border of the sartorius to the knee, where it pierces the fascia lata, communicates with the saphenous nerve, and gives off several cutaneous branches. It then descends to supply the skin of the medial side of the leg. Beneath the fascia lata, at the lower border of the adductor longus, it joins to form a plexiform network (*subsartorial plexus*) with branches of the saphenous and obturator nerves. When the communicating branch from the obturator nerve is large and continued to the skin of the leg, the posterior branch of the medial cutaneous is small, and terminates in the plexus, occasionally giving off a few cutaneous filaments.



The nerve to the sartorius arises in common with the intermediate cutaneous nerve of the thigh.

The posterior division of the femoral nerve gives off the saphenous nerve, and supplies muscular branches to the quadriceps femoris, and articular branches to the knee joint.

The saphenous nerve (7.212) is the largest cutaneous branch of the femoral nerve. It descends on the lateral side of the femoral artery and enters the adductor canal (p. 725) where it crosses in front of the artery obliquely from its lateral to its medial side. At the lower end of the canal it quits the artery, and emerges through the aponeurotic covering of the canal, accompanied by the saphenous branch of the descending genicular artery. It descends vertically along the medial side of the knee behind the sartorius, pierces the fascia lata between the tendons of the sartorius and gracilis, and becomes subcutaneous. It then passes down the medial side of the leg accompanied by the long saphenous vein, descends along the medial border of the tibia, and, at the lower third of the leg, divides into two branches: one continues its course along the medial border of the tibia, and ends at the ankle; the other passes in front of the ankle, and is distributed to the skin on the medial side of the foot, often reaching as far as the metatarsophalangeal joint of the great toe and communicating with the medial branch of the superficial peroneal nerve.

About the mid level of the thigh, the saphenous nerve gives a branch to join the subsartorial plexus.

After leaving the adductor canal it gives off an *infrapatellar branch* (7.211), which pierces the sartorius and fascia lata, and is distributed to the skin in front of the patella. Proximal to the knee it unites with the medial and intermediate cutaneous nerves of the thigh; below the knee, with other branches of the saphenous nerve; on the lateral side of the joint, with branches of the lateral cutaneous nerve of the thigh, forming a *patellar plexus*.

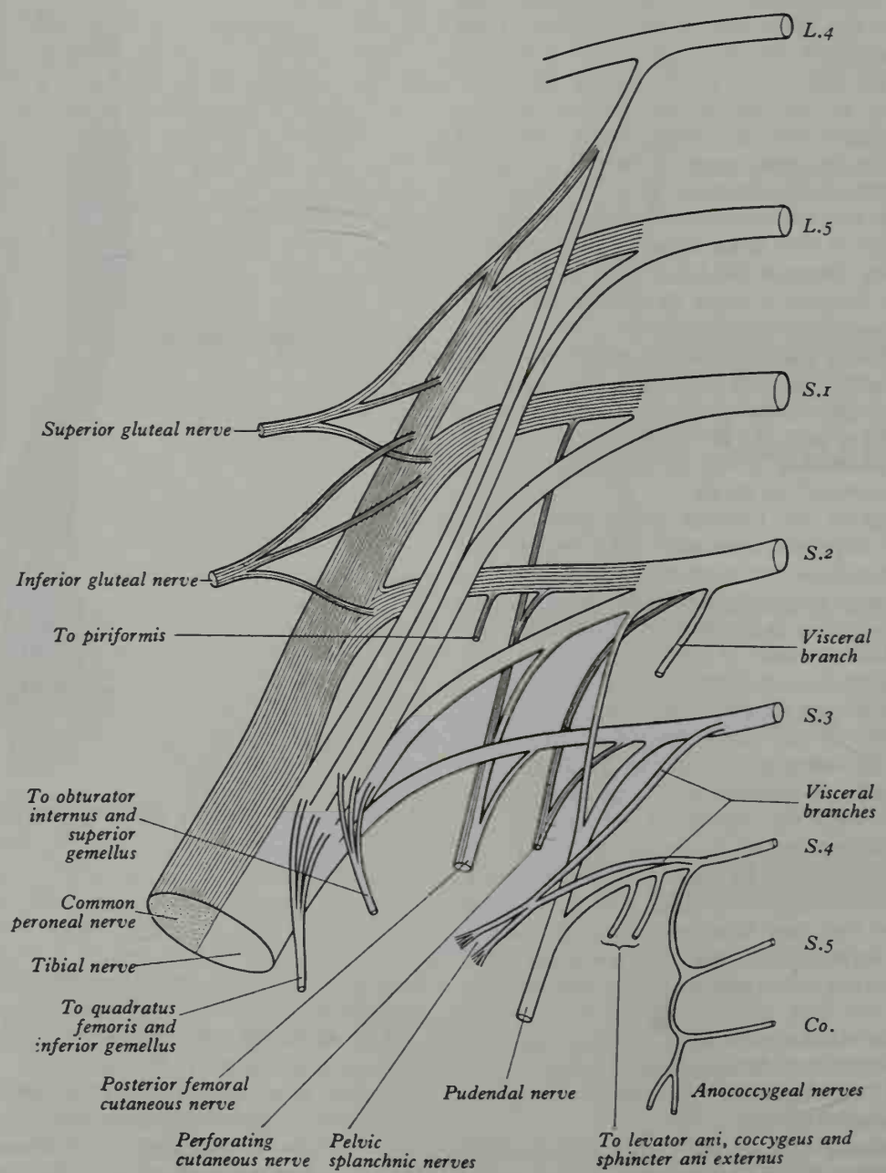
7.212 The nerves of the right lower limb displayed from the anterior aspect.

The muscular branches of the posterior division of the femoral nerve supply the quadriceps femoris. The branch to the rectus femoris enters the upper part of the deep surface of the muscle, and supplies a filament to the hip joint. The larger branch to the vastus lateralis forms a prominent neurovascular bundle with the descending branch of the lateral circumflex femoral artery to the lower part of the muscle, and sends an articular filament to the knee joint. The branch to the vastus medialis descends through the upper part of the adductor canal, on the

lateral side of the saphenous nerve and the femoral vessels. It enters the muscle about its middle, and gives off a filament which can usually be traced distally on the surface of the muscle to the knee joint. The branches to the vastus intermedius, two or three in number, enter the anterior surface of the muscle about the middle of the thigh; a filament from one of these descends through the muscle to the articularis genus and the knee joint.

Vascular branches are given off from the femoral nerve to the femoral artery and its branches (p. 1131).

SACRAL AND COCCYGEAL VENTRAL RAMI



The ventral rami of the sacral and coccygeal nerves form the sacral and coccygeal plexuses. Those of the upper four sacral nerves enter the pelvis through the pelvic sacral foramina, that of the fifth between the sacrum and coccyx, while that of the coccygeal nerve curves forwards below the rudimentary transverse process of the first piece of the coccyx. The first and second sacral spinal nerves are large; the third, fourth and fifth diminish progressively; the coccygeal nerve is the smallest. Each of these nerves receives a *grey ramus communicans* from the corresponding ganglion of the sympathetic trunk. *Visceral efferent rami* arise from the second, third and fourth sacral nerves; they are named the *pelvic splanchnic nerves* (7.231), and consist of parasympathetic fibres which pass directly to minute ganglia on the walls of the pelvic viscera (p. 1123).

The Sacral Plexus

The sacral plexus (7.213) is formed by the lumbosacral trunk, the ventral rami of the first, second and third sacral nerves, and part of the ventral ramus of the fourth sacral nerve, the remainder of which joins the coccygeal plexus.

The lumbosacral trunk comprises a part of the ventral ramus of the fourth lumbar nerve, and the whole ventral ramus of the fifth lumbar nerve; it appears at the medial margin of the psoas major and descends over the pelvic brim anterior to the sacro-iliac joint to join the first sacral nerve.

The nerves entering into the sacral plexus converge towards the greater sciatic foramen and unite without much interlacement to form an upper large and a lower small band. The upper band is

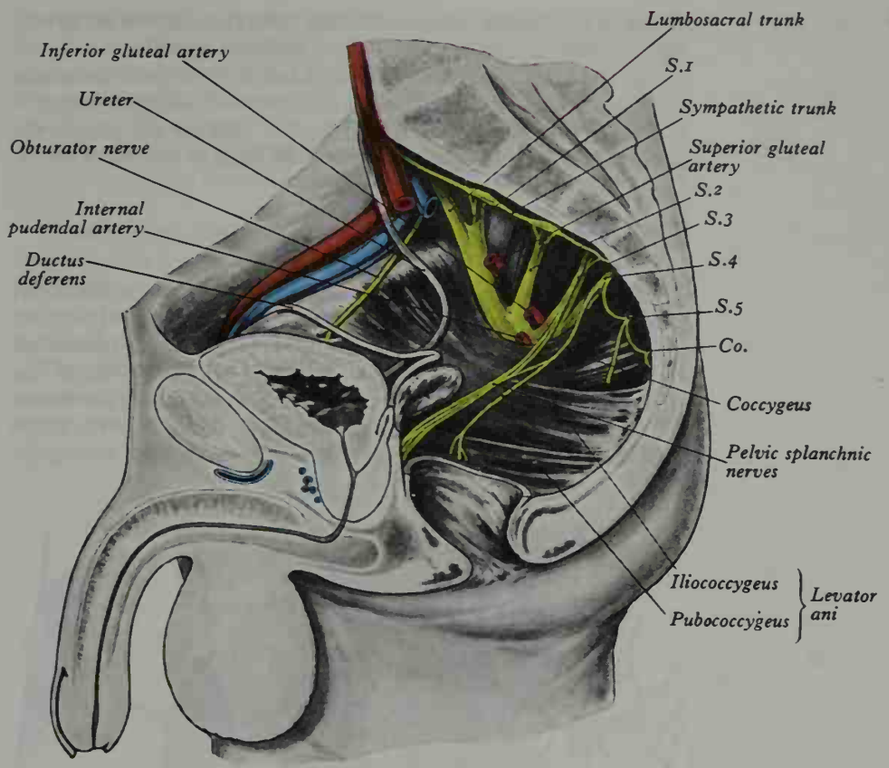
7.213 A plan of the sacral and coccygeal plexuses. L.4–5, S.1–5 and Co., indicate the *ventral rami* of these lumbar, sacral and coccygeal spinal nerves. The *ventral divisions* of these rami are unshaded, the *dorsal divisions*, and nerves derived from them, are shaded. The contribution from S.2 to the pelvic splanchnic nerves is shown before joining those from 3 and 4.

formed by the union of the lumbosacral trunk with the first, second and the greater part of the third sacral nerves and is continued into the sciatic nerve. The lower band, which has a more plexiform arrangement, results mainly from the junction of the smaller part of the third sacral nerve with the portion of the fourth nerve belonging to the plexus, and is prolonged into the pudendal nerve; it also receives a small contribution from the second sacral nerve. The sciatic nerve is composed of tibial and common peroneal nerves which usually become distinct in the thigh. Above this level, however, these two nerves can be separated to their roots of origin. It is then found that the tibial nerve is formed by the union of ventral divisions of the lumbosacral trunk and first three sacral nerves, while the common peroneal receives the dorsal divisions of the lumbosacral trunk and first two sacral nerves. The component nerves of the sciatic may, however, diverge anywhere along its course from the pelvis. When the division occurs at the plexus the common peroneal usually pierces the piriformis in the greater sciatic foramen. (For details of the blood supply of the sacral plexus *see* Day 1964.)

Relations of the Sacral Plexus

The sacral plexus lies on the posterior wall of the pelvic cavity in front of the piriformis (7.214), and behind the internal iliac vessels, the ureter and the sigmoid colon, on the left side, and the terminal coils of the ileum, on the right side. The superior gluteal vessels run between the lumbosacral trunk and the first sacral nerve, or between the first and second sacral nerves, and the inferior gluteal vessels between the ventral rami of the first and second, or second and third, sacral nerves.

The Branches of the Sacral Plexus



These may be summarized as follows:

	Ventral divisions	Dorsal divisions
To quadratus femoris and gemellus inferior	L. 4, 5, S. 1	
To obturator internus and gemellus superior	L. 5, S. 1, 2	
To piriformis		S. (1) 2
Superior gluteal		L. 4, 5, S. 1
Inferior gluteal		L. 5, S. 1, 2
Posterior femoral cutaneous	S. 2, 3	S. 1, 2
Sciatic—tibial	L. 4, 5, S. 1, 2, 3	
—common peroneal		L. 4, 5
		S. 1, 2
Perforating cutaneous		S. 2, 3
Pudendal	S. 2, 3, 4	
To levator ani, coccygeus and sphincter ani externus	S. 4	
Pelvic splanchnic	S. 2, 3, (4)	

The nerve to the quadratus femoris and gemellus inferior arises from the ventral branches of the ventral rami of the fourth and fifth lumbar and first sacral nerves (7.213); it leaves the pelvis through the greater sciatic foramen below the piriformis and descends on the ischium deep to the sciatic nerve, the gemelli and the tendon of the obturator internus. It supplies the gemellus inferior, and enters the anterior surface of the quadratus femoris; it also supplies the hip joint.

The nerve to the obturator internus and gemellus superior arises from the ventral branches of the ventral rami of the fifth lumbar and first and second sacral nerves (7.213). It leaves the pelvis through the greater sciatic foramen below the piriformis and gives a branch which enters the upper part of the posterior surface of the gemellus superior. It then crosses the ischial spine lateral to the internal pudendal vessels, re-enters the pelvis through the lesser sciatic foramen, and pierces the pelvic surface of the obturator internus.

The nerve to the piriformis arises usually from the dorsal branches of the ventral rami of the first and second sacral nerves, the contribution from the first sacral sometimes being absent; it enters the anterior surface of the muscle.

7.214 A dissection of the side wall of the pelvis, showing the sacral and coccygeal plexuses. S.1–5 indicate the anterior rami of the sacral spinal nerves; Co. indicates the ventral ramus of the coccygeal spinal nerve.

The superior gluteal nerve arises from the dorsal branches of the ventral rami of the fourth and fifth lumbar and first sacral nerves (7.213): it leaves the pelvis through the greater sciatic foramen above the piriformis, accompanied by the superior gluteal vessels, and divides into a superior and an inferior branch. The *superior* branch accompanies the upper branch of the deep division of the superior gluteal artery and supplies branches to the gluteus medius and occasionally also to the gluteus minimus. The *inferior* branch runs with the lower branch of the deep division of the superior gluteal artery across the gluteus minimus; it gives twigs to the gluteus medius and gluteus minimus, and ends in the tensor fasciae latae.

The inferior gluteal nerve arises from the dorsal branches of the ventral rami of the fifth lumbar and first and second sacral nerves: it leaves the pelvis through the greater sciatic foramen, below the piriformis, and divides into branches which enter the deep surface of the gluteus maximus.

The posterior femoral cutaneous nerve arises from the dorsal branches of the ventral rami of the first and second, and from the ventral branches of the ventral rami of the second and third, sacral nerves (7.213), and issues from the pelvis through the greater sciatic foramen distal to piriformis. It then descends under cover of the gluteus maximus with the inferior gluteal artery, lying posterior or medial to the sciatic nerve. It descends the back of the thigh superficial to the long head of the biceps femoris, and deep to the fascia lata: at the back of the knee it pierces the deep fascia and accompanies the short saphenous vein as far as the middle of the calf of the leg, its terminal twigs communicating with the sural nerve.

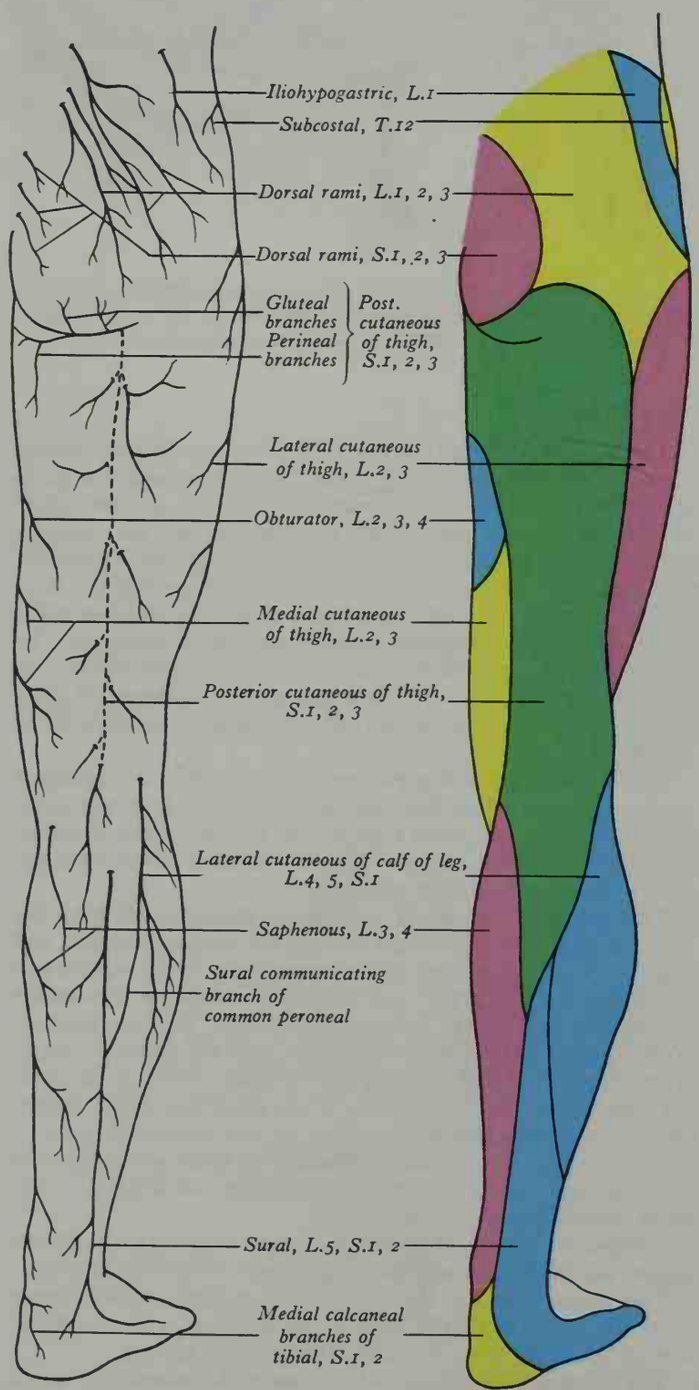
Its branches are all cutaneous, and are distributed to the gluteal region, the perineum, and the flexor aspect of the thigh and leg.

The *gluteal branches*, three or four in number, turn upwards round the lower border of the gluteus maximus, and supply the skin covering the lower and lateral part of that muscle.

The *perineal branch* distributes twigs to the skin at the upper and medial side of the thigh, and then curves forwards across the origin of the hamstrings, below the ischial tuberosity; it pierces the fascia lata, and runs beneath the superficial fascia of the perineum to the skin of the scrotum in the male, and of the labium

majus in the female, communicating with the inferior rectal and the posterior scrotal branches of the perineal nerve.

The *branches to the back of the thigh and leg* consist of numerous filaments derived from both sides of the nerve, and distributed to the skin covering the back and medial side of the thigh, the popliteal fossa and the upper part of the back of the leg (7.215).



The Sciatic Nerve

The sciatic nerve (7.213, 216), the largest in diameter in the body, measures at its commencement 2 cm in breadth. It is the continuation of the upper band of the sacral plexus. It passes out of the pelvis through the greater sciatic foramen, below the piriformis, descends between the greater trochanter of the femur and the tuberosity of the ischium, and along the back of the thigh to about its lower one-third, where it divides into two large branches, named the tibial and common peroneal nerves. The nerve also gives off articular and muscular branches.

In the upper part of its course the nerve is situated deep to the gluteus maximus, and rests first upon the posterior surface of the ischium, the nerve to the quadratus femoris intervening; it then crosses the obturator internus and gemelli, and passes on to the quadratus femoris, by which it is separated from the obturator externus and the hip joint; it is accompanied on its medial side by the posterior cutaneous nerve of the thigh and the inferior gluteal artery. More distally it lies upon the adductor magnus, and is crossed obliquely by the long head of the biceps femoris. It can be represented on the back of the thigh by a broad line drawn distally to the apex of the popliteal fossa from just medial to the midpoint of the line joining the ischial tuberosity to the apex of the greater trochanter.

The *articular branches* of the sciatic nerve arise from the upper part of the nerve, and supply the hip joint by perforating the posterior part of its capsule; they are sometimes derived directly from the sacral plexus.

The *muscular branches* of the sciatic nerve are distributed to the biceps femoris, semitendinosus, semimembranosus and to the ischial head of the adductor magnus (p. 599); the branches to the latter two arise by a common trunk. The nerve to the short head of the biceps femoris comes from the common peroneal division, the other muscular branches from the tibial division of the sciatic nerve.

7.215 The cutaneous nerves of the right lower limb and their areas of distribution and segmental origins, viewed from the posterior aspect. The major part of the trunk of the posterior cutaneous nerve of the thigh lies deep to the deep fascia and is therefore shown by an interrupted line.

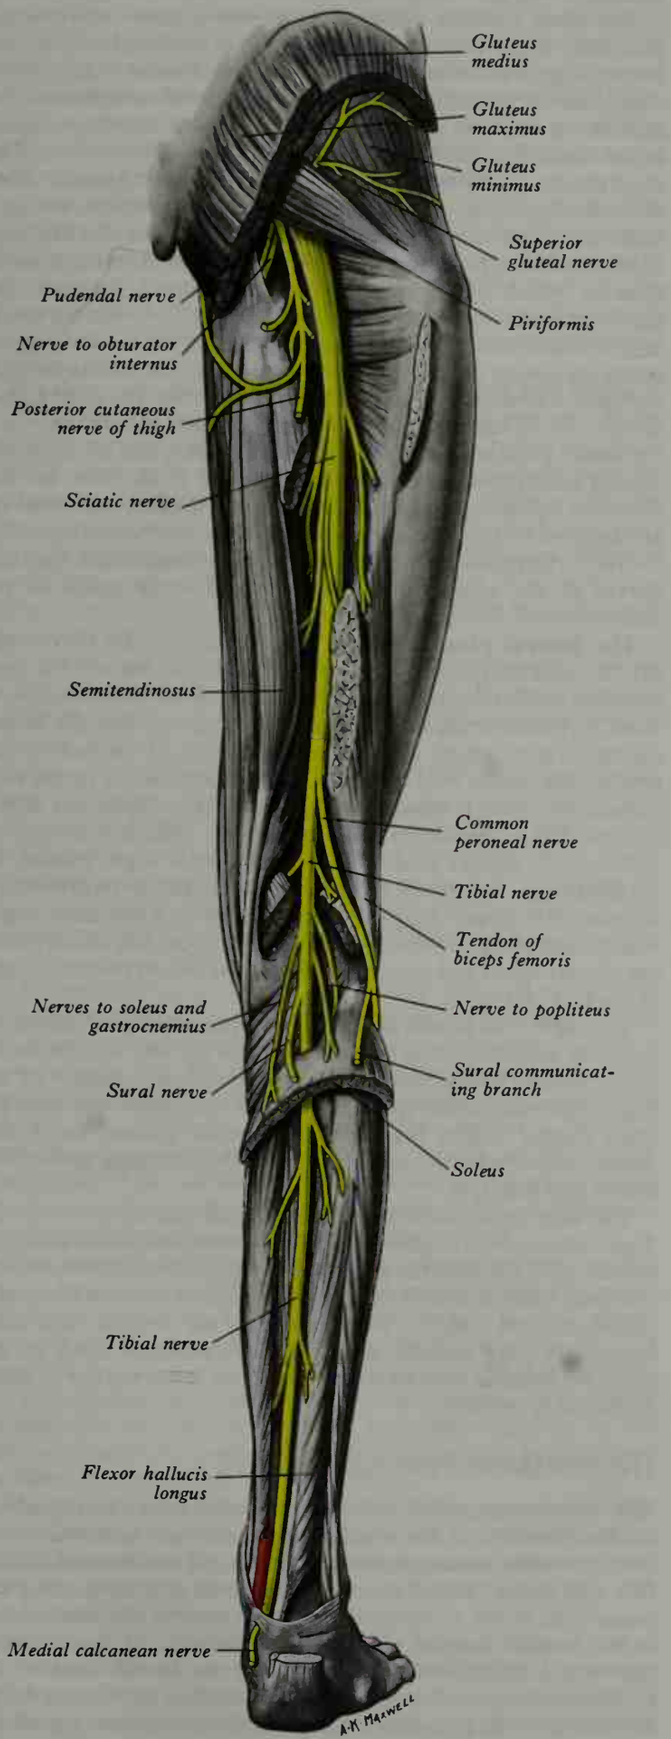
THE TIBIAL NERVE

The tibial (medial popliteal) nerve (7.216), the larger terminal division of the sciatic, arises from the ventral branches of the ventral rami of the fourth and fifth lumbar and first, second and third sacral nerves. It descends along the back of the thigh and through the middle of the popliteal fossa, to the distal border of the popliteus, where it passes with the popliteal artery deep to the arch of the soleus. Thereafter it is continued into the leg. In the thigh it is overlapped by the hamstring muscles above, but it becomes more superficial in the popliteal fossa, where it lies lateral to, and some distance from, the popliteal vessels; it is superficial to these vessels opposite the knee joint and then crosses to the medial side of the popliteal artery (7.217). In the lower part of the popliteal fossa, the nerve is covered by the contiguous margins of the two heads of the gastrocnemius. It can be represented by a line drawn downwards in the midline of the limb from the apex of the popliteal fossa to the level of the neck of the fibula. Continued downwards to a point midway between the medial malleolus and the tendo calcaneus, the line maps out the whole course of the tibial nerve.

In the leg it descends with the posterior tibial vessels to the interval between heel and medial malleolus, ending under the flexor retinaculum by dividing into the medial and lateral plantar nerves. Proximally it is deep to the soleus and gastrocnemius, but in the distal third of the leg it is covered only by skin and fasciae, although it is overlapped sometimes by the medial edge of the flexor hallucis longus. Proximally it is medial to the posterior tibial vessels, but it soon crosses behind them and descends lateral to them until it bifurcates. In most of its course it lies on the tibialis posterior, but in the lower part of the leg it comes into relation with the posterior surface of the tibia.

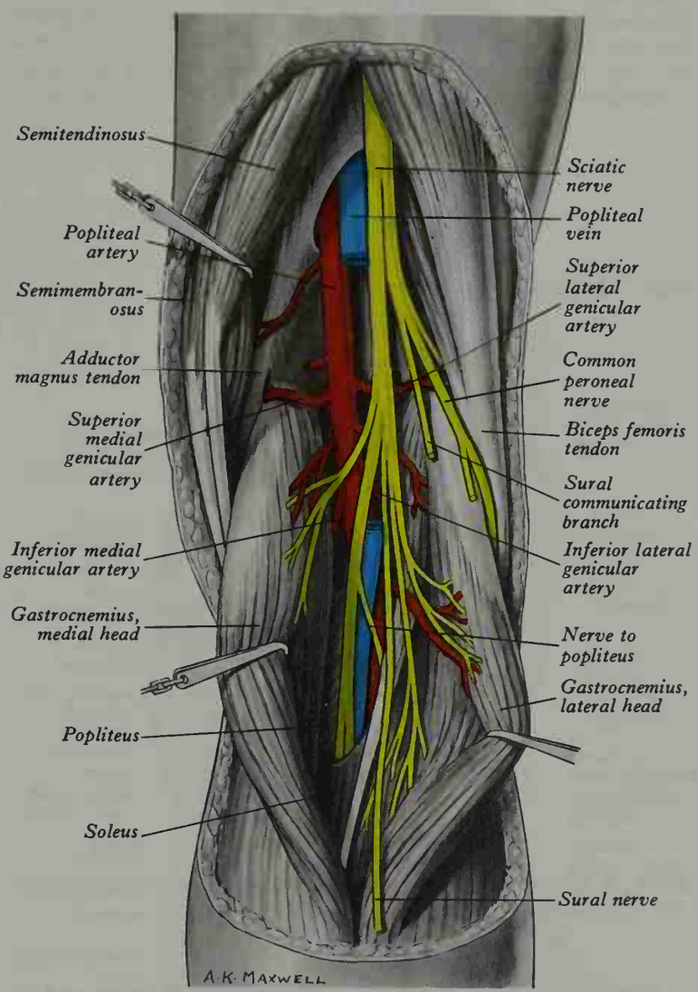
The branches of this nerve are articular, muscular, sural, medial calcanean and medial and lateral plantar.

Articular branches, usually three, supply the knee joint; one accompanies the superior, and another the inferior medial genicular artery; the third runs with the middle genicular artery. These branches form a plexus with the articular branch of the obturator nerve, and from the plexus branches are distributed to the oblique posterior ligament of the joint and those accompanying the superior and inferior medial genicular arteries supply the medial parts of the capsular ligament. Another articular branch arises from the nerve just above its terminal bifurcation, and supplies the ankle joint. For further details of this nerve supply consult Champetier and Déscours (1968). Gardner and Lenn (1977) have assessed the ratios of myelinated to non-myelinated fibres in genual articular nerves of the monkey as approximately



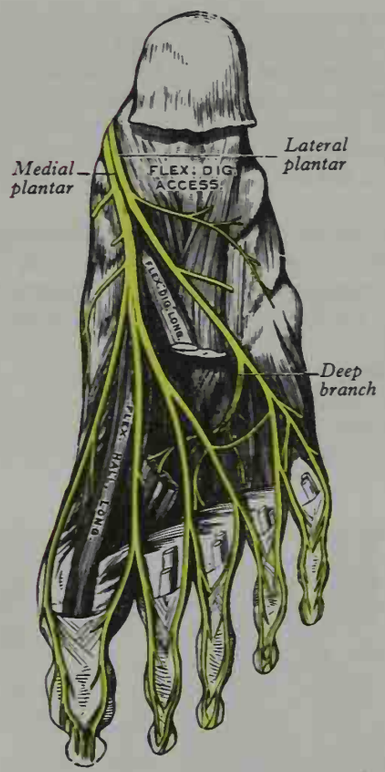
4:1; they suggest that most of the fibres subserve pain sensation.

The muscular branches arise from the nerve as it lies between the two heads of the gastrocnemius; they supply that muscle, as well as the plantaris, soleus and popliteus. The nerve to the soleus enters the superficial surface of the muscle. The branch for the popliteus descends, crossing the popliteal vessels obliquely, and turns round the distal border of the muscle to be distributed to its deep surface; it supplies small branches to the tibialis posterior, an articular twig to the upper tibiofibular joint, a medullary branch to the tibia, and an interosseous branch, which descends close to the fibula and reaches the inferior tibiofibular joint.

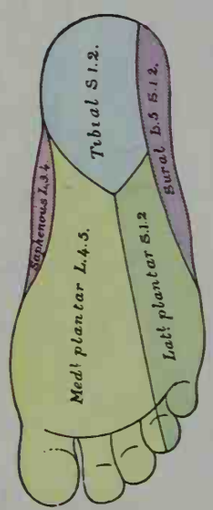


In the leg, the muscular branches arise either independently or by a common trunk. They supply the soleus (on its deep surface), the tibialis posterior, the flexor digitorum longus and the flexor hallucis longus; the branch to the last muscle accompanies the peroneal vessels.

The sural nerve descends between the two heads of the gastrocnemius, and, piercing the deep fascia in the middle or upper part of the back of the leg, is joined by the sural communicating branch of the common peroneal nerve (7.215). It then passes downwards near the lateral margin of the tendo calcaneus, and close to the small saphenous vein, to the interval between the lateral malleolus and the calcaneus; it supplies the skin of the lateral and posterior part of the lower one-third of the leg. It runs forwards below the lateral malleolus, and is continued along the lateral side of the foot and little toe, communicating on the dorsum of the foot with the superficial peroneal nerve. In the leg, its branches communicate with those of the posterior cutaneous nerve of the thigh. For a study of the fibre spectrum and ultrastructure of the fetal sural nerve consult Ochoa (1971).



The *medial calcanean branches* perforate the flexor retinaculum, and supply the skin of the heel and medial side of the sole of the foot.



7.216 The nerves of the right lower limb. Posterior aspect. In this figure the gluteus maximus, the gluteus medius and the superficial muscles of the calf of the leg have been removed and the middle part of the long head of the biceps femoris has been excised.

7.217 A dissection of the right popliteal fossa. The two heads of gastrocnemius and the semitendinosus and semimembranosus have been retracted in order to expose the contents of the fossa more fully.

7.218 The plantar nerves of the right foot.

7.219 A diagram showing the distribution of the cutaneous nerves in the sole of the right foot.

Vascular branches are supplied from the tibial nerve and its branches to the arteries which they accompany in the leg and foot (p. 1132).

The medial plantar nerve (7.218), the larger of the two terminal divisions of the tibial nerve, accompanies the medial plantar artery and lies on the lateral side of the vessel. From its origin under cover of the flexor retinaculum it passes deep to the abductor hallucis, and, appearing between this muscle and the flexor digitorum brevis, gives off a digital nerve to the medial side of the great toe and finally divides opposite the bases of the metatarsal bones into three plantar digital nerves.

Branches. Cutaneous branches pierce the plantar aponeurosis between the abductor hallucis and the flexor digitorum brevis and are distributed to the skin of the sole of the foot.

Muscular branches supply the abductor hallucis, the flexor digitorum brevis, the flexor hallucis brevis and the first lumbrical; those for the abductor hallucis and flexor digitorum brevis arise from the trunk of the nerve near its origin and enter the deep surfaces of the muscles; the branch for the flexor hallucis brevis springs from the digital nerve to the medial side of the great toe, and that for the first lumbrical from the first plantar digital nerve.

Articular branches supply the articulations of the tarsus and metatarsus.

The *proper digital nerve of the great toe* supplies the flexor hallucis brevis and the skin on the medial side of the great toe.

The *three common plantar digital nerves* pass between the divisions of the plantar aponeurosis, and each splits into two proper digital branches. Those of the first plantar digital nerve supply the adjacent sides of the great and second toes; those of the second, the adjacent sides of the second and third toes; and those of the third, the adjacent sides of the third and fourth toes. The third plantar digital nerve receives a communicating branch from the lateral plantar nerve; the first gives a twig to the first lumbrical. Each digital branch gives off cutaneous and articular filaments and opposite the distal phalanx sends upwards a dorsal branch, which supplies the structures around the nail, the continuation of the nerve being distributed to the ball of the toe. It will be observed that the digital branches of the medial plantar nerve *are similar in their distribution to those of the median nerve in the hand*. The muscles supplied by the two nerves also correspond closely. In the hand, the median nerve supplies the abductor and the flexor pollicis brevis, the opponens pollicis and the first and second lumbricals. The opponens is absent in the foot, but the abductor hallucis, flexor hallucis brevis and the first lumbrical are all supplied by the medial plantar nerve. As the flexor digitorum brevis corresponds to the flexor digitorum superficialis (median nerve) of the upper limb, the only difference exists in the innervation of the second lumbrical.

The lateral plantar nerve (7.218) supplies the skin of the fifth toe and lateral half of the fourth, as well as most of the deep muscles, *its distribution being similar to that of the ulnar nerve in the hand*. It passes obliquely forwards in company with the lateral plantar artery, which lies on the lateral side of the nerve, and reaches the lateral side of the foot near the tubercle of the fifth metatarsal bone. It passes between the flexor digitorum brevis and the flexor digitorum accessorius, and ends in the interval between the former muscle and the abductor digiti minimi by dividing into a superficial and a deep branch. Before its division, it supplies the flexor digitorum accessorius and abductor digiti minimi and gives off some small cutaneous branches which pierce the plantar fascia and supply the skin of the lateral part of the sole of the foot (7.219).

The *superficial branch* splits into two plantar digital nerves; of these the lateral supplies the lateral side of the fifth toe, the flexor digiti minimi brevis, and the two interosseous muscles of the fourth intermetatarsal space; the medial communicates with the third plantar digital branch of the medial plantar nerve and divides into two branches which supply the adjoining sides of the fourth and fifth toes.

The *deep branch* accompanies the lateral plantar artery on the deep surface of the tendons of the flexor muscles and the adductor hallucis, and supplies the second, third and fourth lumbricals, the adductor hallucis and all the interossei (except those of the fourth intermetatarsal space). The nerves to the second and third lumbricals pass distally deep to the transverse head of the adductor hallucis, and then pass round its distal border to reach the muscles (7.220).

THE COMMON PERONEAL NERVE

The common peroneal (lateral popliteal) nerve (7.217), about one-half the size of the tibial nerve, is derived from the dorsal branches of the ventral rami of the fourth and fifth lumbar and the first and second sacral nerves. It descends obliquely along the lateral side of the popliteal fossa to the head of the fibula, close to the medial margin of the biceps femoris. It lies between the tendon of the biceps femoris and the lateral head of the gastrocnemius, winds round the lateral surface of the neck of the fibula deep to the peroneus longus, and divides into the superficial and deep peroneal nerves. Its course can be indicated by a line drawn from the apex of the popliteal fossa distally and laterally, along the medial side of the biceps tendon, to the back of the head of the fibula, where the nerve can be rolled against the bone.

Previous to its division it gives off articular and cutaneous branches.

The *articular branches* are three in number; of these one accompanies the superior and another the inferior lateral genicular atery. Both may arise by a common trunk. The third, named the recurrent articular nerve, is given off at or near the point of division of the common peroneal nerve; it ascends with the anterior recurrent tibial artery through the tibialis anterior to supply the anterolateral part of the capsular ligament of the knee joint and also supplies branches to the superior tibiofibular joint.

The *cutaneous branches* (7.215), two in number, frequently spring from a common trunk; they are the lateral cutaneous nerve of the calf and the sural communicating branch.

The *lateral cutaneous nerve of the calf* supplies twigs to the skin on the anterior, posterior and lateral surfaces of the proximal part of the leg. The *sural communicating branch* arises near the head of the fibula, runs obliquely across the lateral head of the gastrocnemius to the middle of the leg, and joins with the sural nerve (p. 1113). It may, however, descend as a separate branch as far as the heel.

The deep peroneal (anterior tibial) nerve (7.212) begins at the bifurcation of the common peroneal nerve, between the fibula and the proximal part of the peroneus longus, passes obliquely forwards deep to the extensor digitorum longus to the front of the interosseous membrane, where it comes into relation with the anterior tibial artery in the proximal third of the leg; it then descends with the artery to the front of the ankle joint, where it divides into lateral and medial terminal branches. It lies at first on the lateral side of the anterior tibial artery, then in front of it, and again on its lateral side at the ankle joint.

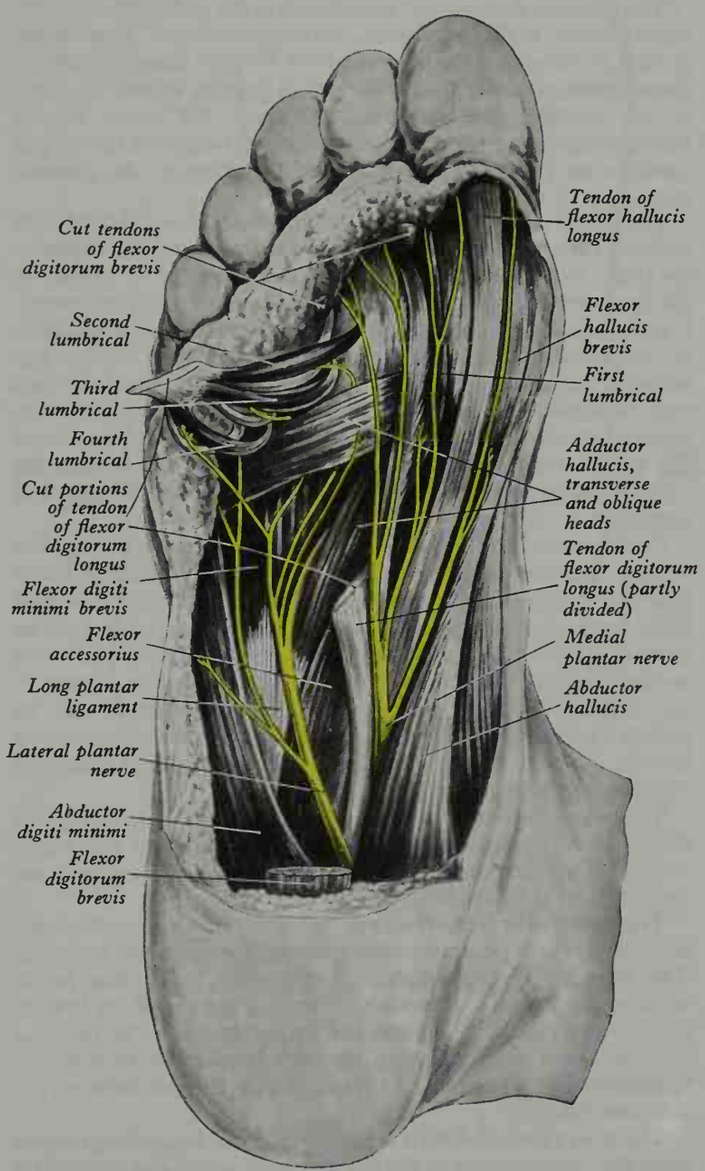
In the leg, the deep peroneal nerve supplies *muscular branches* to the tibialis anterior, extensor hallucis longus, extensor digitorum longus and peroneus tertius, and an *articular branch* to the ankle joint.

The *lateral terminal branch* of the deep peroneal nerve passes across the tarsus, deep to the extensor digitorum brevis and, becoming enlarged as a pseudoganglion (c.f. other sites pp. 1097) and then supplies the extensor digitorum brevis. From the enlargement three minute *interosseous branches* are given off which supply the tarsal and metatarsophalangeal joints of the second, third and fourth toes. The first of these sends a filament to the second dorsal interosseous muscle.

The *medial terminal branch* of the deep peroneal nerve runs forwards on the dorsum of the foot, and lies on the lateral side of the arteria dorsalis pedis. At the first interosseous space it communicates with the medial branch of the superficial peroneal nerve, and divides into two dorsal digital nerves which supply the adjacent sides of the great and second toes. Before it divides it gives off an *interosseous branch* which supplies the metatarsophalangeal joint of the hallux and sends a filament to the first dorsal interosseous. The deep peroneal nerve may end by dividing into *three* terminal branches (Geller and Barbato 1970).

The superficial peroneal (musculocutaneous) nerve (7.212) begins at the bifurcation of the common peroneal nerve and lies at first deep to the peroneus longus. It then passes forwards and downwards between the peronei and the extensor digitorum longus, pierces the deep fascia in the distal third of the leg, and divides into a medial and a lateral branch. In its course between the muscles, it gives off muscular branches to the peroneus longus and peroneus brevis, and filaments to the skin of the lower part of the leg.

The *medial branch* passes in front of the ankle joint, and divides into two dorsal digital nerves, one of which supplies the medial side of the great toe, the other, the adjacent sides of the second and third toes. It communicates with the saphenous nerve and with the deep peroneal nerve (7.211).



The *lateral branch*, the smaller, passes along the lateral part of the dorsum of the foot, and divides into dorsal digital branches, which supply the contiguous sides of the third and fourth, and of the fourth and fifth toes. It also supplies the skin of the lateral side of the ankle, and communicates with the sural nerve (7.211).

The branches of the superficial peroneal nerve supply the skin of the dorsal surfaces of all the toes excepting the lateral side of the little toe and the adjoining sides of the first and second toes, the former being supplied by the sural nerve, and the latter by the medial terminal branch of the deep peroneal nerve. Frequently some of the lateral branches of the superficial peroneal are absent, and their places are then taken by branches of the sural nerve.

The perforating cutaneous nerve usually arises from the posterior aspects of the second and third sacral nerves. It pierces the lower part of the sacrotuberous ligament, and, winding round the inferior border of the gluteus maximus, supplies the skin covering the medial and lower parts of that muscle.

The perforating cutaneous nerve may arise from the pudendal nerve or it may be absent; in the latter case its place may be taken by a branch from the posterior cutaneous nerve of the thigh or by a branch from the third and fourth, or fourth and fifth, sacral nerves.

The pudendal nerve (6.94) derives its fibres from the second, third and fourth sacral spinal nerves (7.213). It leaves the pelvis between piriformis and coccygeus through the lower part of the greater sciatic foramen and enters the gluteal region, crossing the sacrospinous ligament close to its attachment to the ischial spine, being situated on the medial side of the internal pudendal vessels which lie on the ischial spine itself. It accompanies the internal pudendal artery through the lesser sciatic foramen into the pudendal canal (p. 562) on the lateral wall of the ischiorectal fossa;

7.220 A dissection of the lateral and medial plantar nerves of the right foot. Most of the flexor digitorum brevis has been removed. The flexor digitorum longus has been partially divided and its distal end has been displaced together with the second, third and fourth lumbricals.

in the posterior part of this canal it gives off the inferior rectal nerve, and then divides into the perineal nerve and the dorsal nerve of the penis (or clitoris).

The *inferior rectal nerve* pierces the medial wall of the pudendal canal, crosses the ischiorectal fossa with the inferior rectal vessels, and is distributed to the sphincter ani externus, to the lining of the lower part of the anal canal and to the skin round the anus. Branches of this nerve communicate with the perineal branch of the posterior cutaneous nerve of the thigh and with the scrotal nerves. The inferior rectal nerve occasionally arises directly from the sacral plexus. It may traverse the sacrospinous ligament (in 8 out of 40 dissections according to Roberts and Taylor 1973) and it occasionally communicates with the pudendal nerve.

The *perineal nerve*, the inferior and larger terminal branch of the pudendal nerve, runs forwards below the internal pudendal artery. It accompanies the perineal artery and divides into posterior scrotal (or labial) and muscular branches.

The *posterior scrotal branches* number two, medial and lateral. They pierce, or pass superficial to, the inferior fascia of the urogenital diaphragm, and run forwards along the lateral part of the urethral triangle in company with the scrotal branches of the perineal artery; they are distributed to the skin of the scrotum, and communicate with the perineal branch of the posterior cutaneous nerve of the thigh and with the inferior rectal nerve. In the female the corresponding nerves (*posterior labial branches*) supply the labium majus.

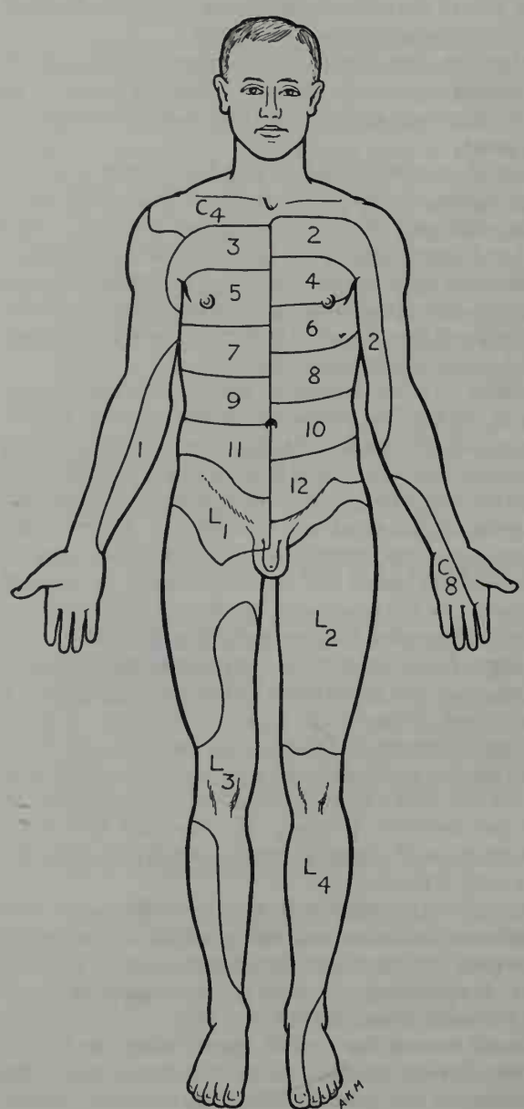
The *muscular branches* are distributed to the transversus perinei superficialis, bulbospongiosus, ischiocavernosus, transversus perinei profundus, sphincter urethrae and the anterior parts of the external sphincter and levator ani. A branch, termed the *nerve to the urethral bulb*, is given off from the nerve to the bulbospongiosus; it pierces this muscle, and supplies the corpus spongiosum penis, its terminal fibres ending in the mucous membrane of the urethra.

The *dorsal nerve of the penis* runs forwards above the internal pudendal artery along the ramus of the ischium, and accompanies the artery along the margin of the inferior ramus of the pubis, on the deep surface of the inferior fascia of the urogenital diaphragm. It gives a branch to the corpus cavernosum penis and, at the apex of the membrane, passes through the lateral part of the gap between the structure and the inferior pubic ligament. It then runs forwards, in company with the dorsal artery of the penis, between the layers of the suspensory ligament, to the dorsum of the penis, and ends in the glans penis. In the female the corresponding nerve (*dorsal nerve of the clitoris*) is very small, and supplies the clitoris.

Clinical evidence indicates that the pudendal nerve supplies sensory branches to the lower inch or so of the vagina, the fibres probably running in the inferior rectal nerve and in the posterior labial branches of the perineal nerve. The pudendal nerves can be infiltrated with a local anaesthetic ('pudendal nerve block') by a needle passed through the vaginal wall and guided by a finger to the ischial spine and sacrospinous ligament, which can be palpated *per vaginam*. For various vaginal operative procedures a general anaesthetic can thus usually be avoided (Huntingford 1959; Nakanishi 1967).

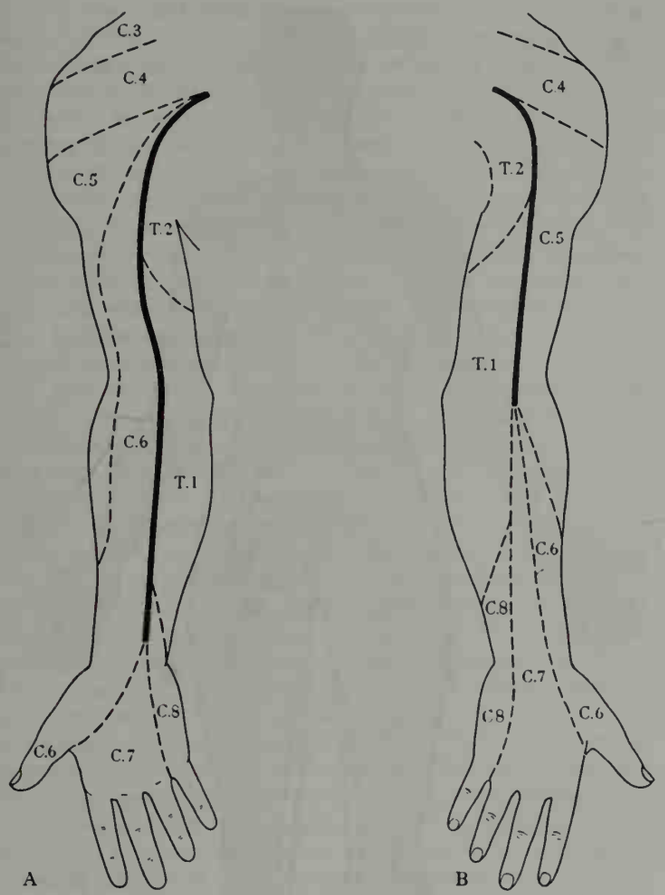
The visceral branches arise from the second, third and fourth sacral spinal nerves, and are distributed to the pelvic viscera. They are termed the *pelvic splanchnic nerves* and are described on p. 1123.

The muscular branches are derived from the fourth sacral, and supply the levator ani, coccygeus and sphincter ani externus. The branches to levator ani and coccygeus enter their pelvic surfaces; the ramus to the sphincter ani externus (perineal branch of fourth sacral nerve) reaches the ischiorectal fossa by piercing the coccygeus or by passing between it and the levator ani. Cutaneous filaments from this branch supply the skin between the anus and the coccyx.



The coccygeal plexus is formed by a small descending branch from the ventral ramus of the fourth sacral nerve, and the ventral rami of the fifth sacral and coccygeal nerves. The ventral ramus of the fifth sacral nerve emerges from the sacral hiatus and turns forwards round the lateral margin of the sacrum below the cornu. It pierces the coccygeus to gain its pelvic surface and is then joined by a descending filament from the fourth sacral nerve. The small trunk so formed descends on the pelvic surface of the coccygeus and unites with the minute ventral ramus of the coccygeal nerve, which descends from the sacral hiatus, turns round the lateral margin of the coccyx and pierces the coccygeus to gain the pelvis. This small trunk constitutes the *coccygeal plexus*. The *anococcygeal nerves* arise from the plexus, and consist of a few fine filaments which pierce the sacrotuberous ligament and supply the skin in the region of the coccyx.

Applied Anatomy. The *iliohypogastric nerve* may be cut, as it lies between the muscles inferiorly in the anterior abdominal wall (p. 1106), by an incision ('McBurney's gridiron') through which the vermiform appendix is sometimes approached; the consequent weakness of the muscles in the region of the inguinal canal may predispose to the development of a direct inguinal hernia.



The *lateral cutaneous nerve of the thigh* may be compressed and irritated as it passes through the inguinal ligament (p. 552) or as it pierces the dense fascia lata, and this is said to be one of the causes of a rare condition of pain on the lateral side of the thigh (*meralgia paraesthetica*).

The *femoral nerve* is occasionally injured by wounds in the groin or thigh; the result is paralysis of the quadriceps femoris and diminished cutaneous sensibility on the anterior and medial aspects of the thigh.

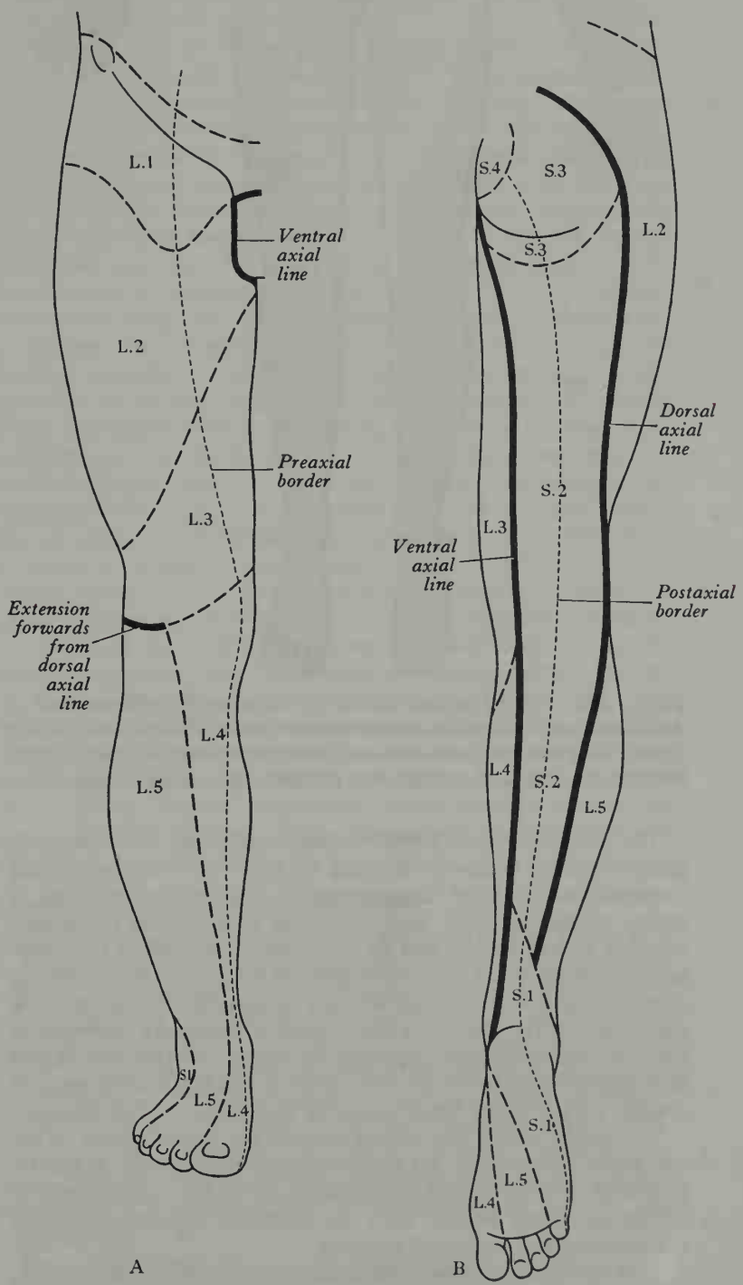
Surgical division of the *obturator nerve* is sometimes done for relief of spasm of the adductors of the thigh in certain cases of

7.221 The cutaneous areas supplied by the ventral rami of the thoracic and upper four lumbar nerves. (After Foerster 1933.) By comparing both sides the degree of overlapping and the area of exclusive supply of any individual nerve may be estimated. See text for the area supplied by T.1 on the trunk.

7.222 A *Left:* The arrangement of the dermatomes on the anterior aspect of the upper limb. The *heavy black line* represents the *ventral axial line* and the overlap across it is *minimal*. Across the interrupted lines, the overlap is considerable. *Right:* The arrangement of the dermatomes on the posterior aspect of the upper limb. The *heavy black line* represents the *dorsal axial line* and the overlap across it is *minimal*. Across the interrupted lines the overlap may be, and often is considerable.

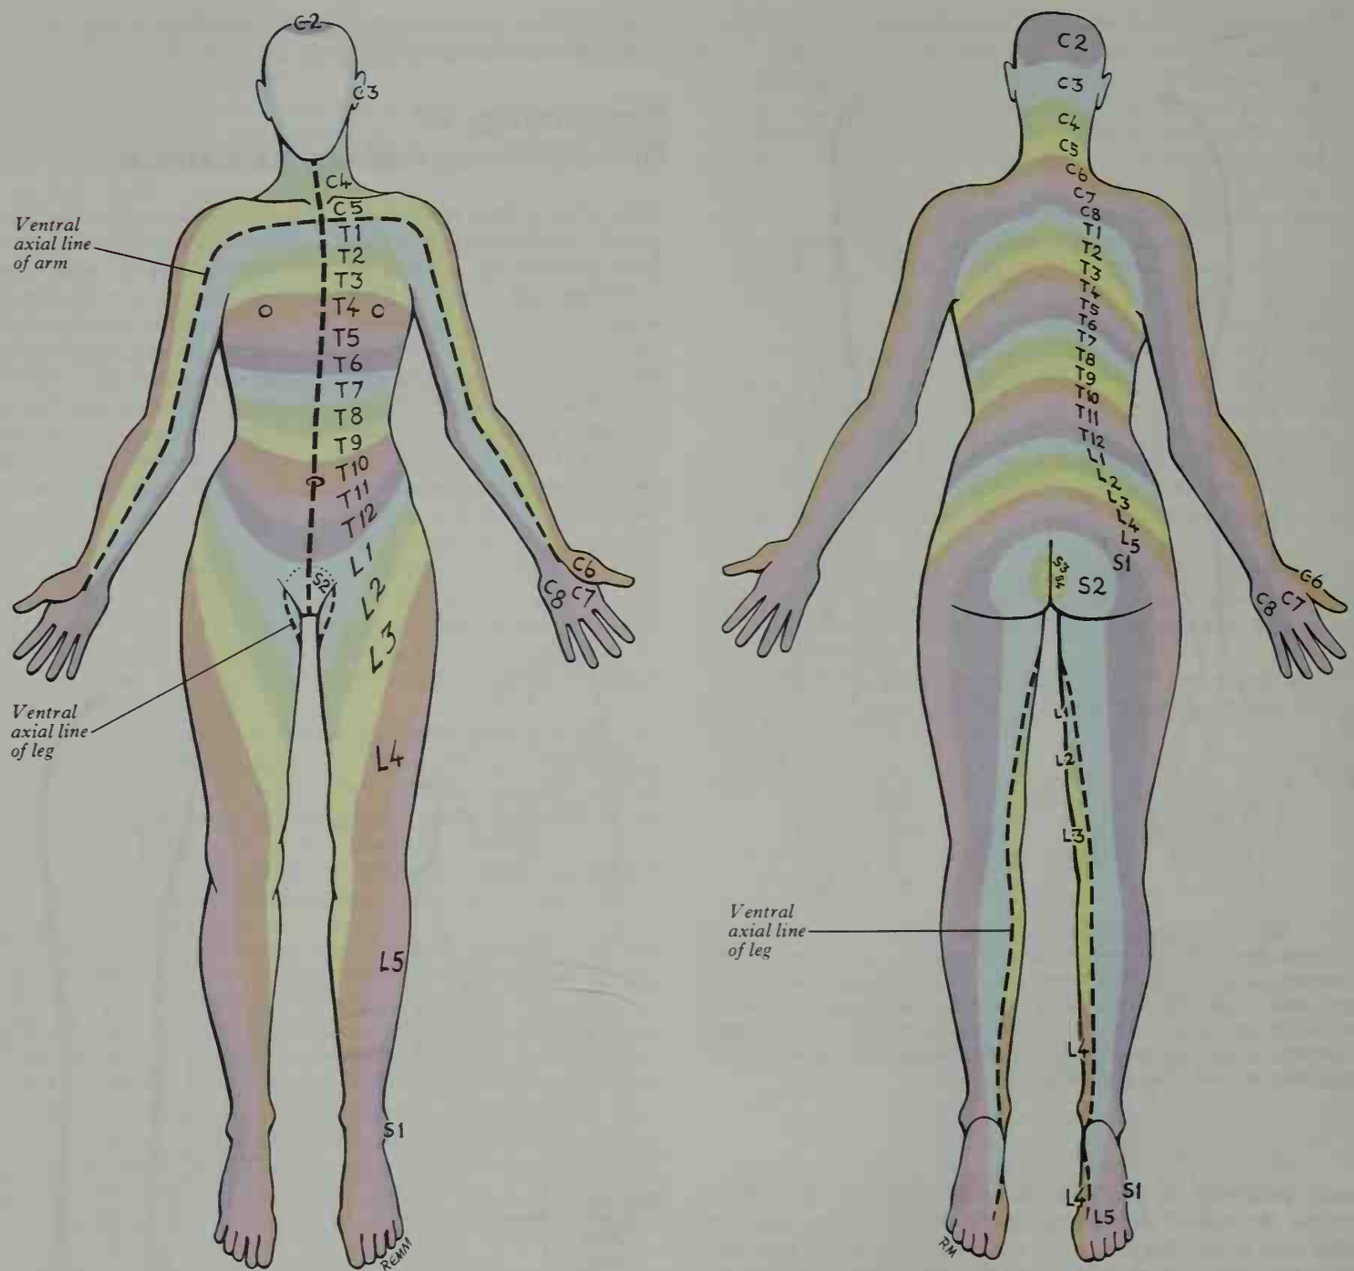
spastic paralysis in children, in paraplegia, or in multiple sclerosis. Because of its branches to the hip joint, knee joint and medial side of the thigh, in cases of disease of the hip joint pain may be referred to the medial side of the thigh or to the knee joint.

The *sacral plexus* and *lumbosacral trunk* may be compressed by pelvic tumours, or by the fetal head in pregnancy, and result in pain in the lower limbs which, in the case of malignant growths, may be extremely severe.



The *sciatic nerve* may be injured by posterior dislocations or fracture dislocations of the hip joint; if the lesion of the nerve is complete, which is rare, all muscles below the knee are paralysed and all cutaneous sensibility there is lost, except for the area supplied by the saphenous nerve. In traumatic lesions of the sciatic nerve in middle levels of the thigh, the flexor muscles generally escape because of the high origin of the nerves to these muscles. The surface marking of the sciatic nerve for purposes of injection is given on p. 1112.

The *common peroneal nerve* is the most commonly injured nerve in the lower limb, chiefly because of its exposed position as it winds round the neck of the fibula. Injury here will result in paralysis of all the dorsiflexor and evertor muscles of the foot (tibialis anterior, extensor hallucis longus, extensor digitorum longus, extensor digitorum brevis, peroneus longus and peroneus brevis) producing a '*drop foot*'. There is a variable loss of cutaneous sensibility on the anterolateral aspect of the leg and on the dorsum of the foot.



Owing to its deep and protected position, the tibial nerve is rarely injured. Wounds in the popliteal fossa or posterior dislocation of the knee joint may damage the tibial nerve and produce paralysis of the flexor muscles in the leg and the intrinsic muscles of the sole of the foot, resulting in considerable disability. Furthermore, loss of sensation in the sole of the foot renders its skin liable to 'pressure sores'.

Morphology of Spinal Nerves and Limb Plexuses

The spinal nerves which conform in their behaviour to the more primitive arrangement are the nerves of those segments which have retained to a large extent their *metameric* (segmental) characters, viz. T.2–L.1. These typical spinal nerves are distributed according to a definite plan. The dorsal epaxial ramus passes backwards and downwards lateral to the articular processes and divides into medial and lateral branches which penetrate the deep muscles of the back. Both branches innervate the muscles amongst which they lie, and either one or the other becomes superficial and supplies a band of skin extending from the posterior median line approximately to the scapular line (*see* below).

7.222 B *Left:* The segmental distribution of the nerves of the lumbar and sacral plexuses to the skin of the anterior aspect of the lower limb. *Right:* The segmental distribution of the nerves of the lumbar and sacral plexuses to the skin of the posterior aspect of the lower limb. For the significance of the markings see 7.222 caption.

7.233A & B Ventral (A) and dorsal (B) views of the distributions of dermatomic innervation, modified from the studies of Keegan and Garrett (1948). Diagrams of this kind can only be approximate and cannot clearly indicate the degree of overlap. For example, the overlap of the supraclavicular nerves (C_4 and 5) into the upper pectoral region is not shown, and it is possible that the pectoral area assigned to the first thoracic spinal nerve is here exaggerated.

The ventral hypaxial ramus is connected to the corresponding ganglion of the sympathetic trunk by both white and grey rami communicantes. After innervating the prevertebral muscles, it passes round the body wall supplying branches to the lateral muscles of the trunk, and in the neighbourhood of the mid-axillary line gives off a lateral branch which pierces the overlying muscles and divides into an anterior and a posterior division for the supply of the skin. The main trunk is continued forwards in the body wall and, after supplying the ventral muscles, distributes its terminal branches to the skin. (Both dorsal and ventral rami, of course, supply many other tissues in their zones of distribution.)

The behaviour of the ventral rami of the spinal nerves of the segments which have lost their obvious metamerism is greatly modified, and the initial modification is seen in the manner in which adjoining nerves unite to form the cervical, brachial, lumbosacral and coccygeal plexuses.

The cervical plexus. The cutaneous branches of this plexus are homologous with the anterior terminal and the lateral branches of the ventral rami of the typical spinal nerves. The transverse cutaneous nerve of the neck and the medial supraclavicular nerves represent the anterior terminal branches; the lesser occipital and the lateral supraclavicular represent the lateral branches, while the great auricular and the intermediate supraclavicular probably represent elements of both branches.

The brachial plexus. In the formation of the brachial and lumbosacral plexuses the division of the constituent nerves of the plexus into anterior (ventral or flexor) and posterior (dorsal or extensor) branches is characteristic. In the brachial plexus the division affects the three trunks of the plexus (p. 1094) and, to a remarkable extent, it conforms to the differentiation of the primitive musculature of the limb into a flexor (ventral) and extensor (dorsal) group. So far as the cutaneous innervation is concerned, branches of the ventral divisions of the trunks take a large part in the supply of the skin of the dorsal surface of the limb. This problem has been tentatively explained (Harris 1939) by assuming that each constituent root of the plexus originally divided into ventral and dorsal branches and that, in the evolution of the human type of plexus, inherently dorsal fibres enter the ventral branches of the trunks. As a result of this rearrangement, fibres of the median and ulnar nerves have a wide area of supply on the dorsal surface of the hand.

The position of the developing limb bud on the ventrolateral aspect of the trunk, and the behaviour of the first and second thoracic nerves, provide support for the view that the constituent

nerves of the great limb plexuses represent only the lateral branches of the ventral rami of the typical spinal nerves. The second thoracic nerve sends its lateral cutaneous branch into the upper limb as the intercostobrachial nerve, and the size of this nerve varies inversely with the size of the direct contribution which the second thoracic nerve makes to the brachial plexus. Otherwise the second thoracic behaves like a typical spinal nerve. The first thoracic nerve sends a large contribution to the brachial plexus, and this could be homologous with the lateral branch. The remainder of the nerve, despite its small size, behaves in a typical manner, although its fine anterior cutaneous branch is often absent, and, when present, only supplies a limited area of skin.

The lumbosacral plexus. The division of the constituent nerves of the lumbar and sacral plexuses into anterior (ventral or flexor) and posterior (dorsal or extensor) divisions is not so obvious as the corresponding pattern in the brachial plexus, but it can be demonstrated anatomically that the obturator and the tibial nerves arise from ventral and the femoral and peroneal nerves from dorsal divisions. The lateral branches of the twelfth thoracic and first lumbar spinal nerves are drawn over the iliac crest to assist in the innervation of the gluteal skin, but otherwise these nerves behave as typical spinal nerves. The second lumbar nerve behaves in a manner which renders its interpretation difficult, since it not only makes a substantial contribution to the lumbar plexus but also possesses both an anterior terminal branch, the genital branch of the genitofemoral nerve, and a lateral cutaneous branch, represented by the lateral cutaneous nerve of the thigh and the femoral branch of the genitofemoral nerve. The anterior terminal portions of the third, fourth and fifth lumbar and first sacral spinal nerves are suppressed, but the corresponding parts of the second and third sacral nerves supply the skin, etc., of the perineum. The posterior femoral cutaneous nerve provides an interesting example of the principles involved here: it is derived from anterior and posterior divisions and supplies 'flexor' skin in the thigh, but 'extensor' skin through its gluteal rami.

Segmental Innervation of the Skin

The area of skin supplied by any one spinal nerve, through both its rami, constitutes a **dermatome** and, typically, the dermatomes extend round the body from the posterior to the anterior median line (7.206, 221, 223). The dermatomes of *consecutive spinal nerves* overlap markedly, and this is seen most clearly in those segments of the body which have been least affected by the development of the limbs, i.e. second thoracic to first lumbar (7.221, 223).

In some situations, e.g. the upper part of the anterior thoracic wall, the cutaneous nerves supplying two adjoining areas are *not* derived from consecutive spinal nerves and the overlap between, above, and below, is minimal. When the second thoracic spinal nerve is severed, the line of anaesthesia is sharply demarcated, although there may be some overlap of the painful and thermal elements. Likewise the results found after section of a peripheral nerve (e.g. the ulnar nerve at the wrist) show that the area of tactile loss is always greater than the area of loss of painful and thermal sensibilities, for the degree of overlap of fibres conveying these types of sensibility is always more extensive than the overlap of fibres conveying tactile sensibility. As a result the area of total anaesthesia and analgesia following section of a peripheral nerve is considerably less than might be anticipated from a knowledge of its anatomical distribution (Foerster 1933; Wollard *et al.* 1940).

Cutaneous Innervation of the Neck and Upper Limb

The first cervical spinal nerve has no cutaneous branches. The second cervical usually supplies the skin of the head, from the vertex backwards to the neighbourhood of the superior nuchal line, the cranial surface and most, if not the whole, of the lateral surface of the auricle, the skin over the angle of the mandible and below the chin (7.182). The third cervical spinal nerve supplies a very oblique band of skin, commencing behind over the back of the scalp and the upper part of the back of the neck and passing forwards and downwards across the side of the neck. The area increases in extent as it is traced forwards, and in the ventral median line extends from the hyoid bone down to the level of the first rib. The fourth cervical spinal nerve supplies the upper half or more of the back of the neck, and the area widens as it is traced downwards and forwards round the side of the neck to the anterior aspect of the trunk. It supplies the skin over the clavicle and first intercostal space, as well as over the acromion and the upper part of the deltoid.

Each of these three areas is overlapped by the succeeding area, but the amount of overlapping is slight and is greater for the dorsal rami than for the ventral rami.

The cutaneous distribution of those spinal nerves which contribute to the brachial plexus becomes intelligible only when reference is made to an early stage in the development of the upper limb. In a human embryo of the fourth week the upper limb is represented by a small, somewhat flattened elevation on the ventrolateral aspect of the trunk opposite to the lower four cervical and the first thoracic segments. The ectoderm covering it is directly continuous with the ectoderm of the trunk and draws its nerve supply from the nerves of the corresponding segments. Similarly, its contained mesoderm is also continuous with the mesoderm of the same segments. The lower limb bud appears at a slightly later stage and always lags behind the upper limb bud in its development until after birth.

The limb buds possess ventral and dorsal surfaces and cranial or *preaxial*, and caudal or *postaxial* borders. In the upper limb the *fifth cervical* ventral ramus supplies a strip of skin on both ventral and dorsal surfaces along the preaxial border, and the *first thoracic nerve* has a similar distribution along the postaxial border. The intervening nerves supply approximately parallel strips of skin on both the ventral and dorsal surfaces. As the limb elongates the central nerves of the plexus (C. 6, 7 and 8) become buried proximally and reach the skin only in its more distal part, while the nerves of the adjoining segments (C.4 and T.2 and 3) become drawn in to supply the skin at the root of the limb. In the process of growth, the lengthening limb becomes rotated laterally through roughly 90° and adducted to the trunk (p. 350). Later, therefore, the *preaxial border* runs distally along the lateral aspect of the (supinated) limb to the thumb, which is the *preaxial digit*, while the *postaxial border* runs distally along the medial aspect to the little finger, which is the *postaxial digit*. Accordingly, the cutaneous nerve supply of the lateral aspect of the adult limb is derived from C. 4, which has been drawn in at the root of the limb, C. 5 and C. 6, and its medial aspect from T. 2, T. 1 and C. 8 (7.222). On the *front of the limb* the areas supplied by C. 5 and C. 6 adjoin the areas supplied by T. 2, T. 1 and C. 8 but at the dividing line between them, which is termed the *ventral axial line*, the overlap is minimal, for C. 7 is buried proximally and only reaches the skin a little proximal to the wrist (7.222A). On the *back of the limb* the condition is very similar, but C.7 (in the posterior cutaneous nerve of the forearm) reaches the skin at, or a little proximal to the elbow so that the *dorsal axial line* ends at a more proximal level (7.222A). (The reader must appreciate the effect of pronation of the forearm on the disposition of these lines—*see* p. 350.)

Cutaneous Innervation of the Trunk

The skin of the trunk is supplied by the spinal nerves T. 1 to L. 1 inclusive (7.206, 221, 223), by the sacral nerves, except the first, and by the coccygeal nerve. These nerves supply consecutive curved bands of skin, of which the upper are almost horizontal while the lower are disposed obliquely. The upper half of each band receives additional supply from the nerve above and the lower half from the nerve below, so that no appreciable loss of sensibility follows the section of any individual spinal nerve. It is convenient to remember that the band which includes the subcostal angle is supplied by the seventh thoracic nerve and that the umbilicus lies in the upper part of the band supplied by the tenth thoracic nerve.

The area supplied by the dorsal rami of these nerves are limited laterally by the dorsolateral line, which commences above on the back of the head and runs downwards and laterally to the medial end of the acromion. It is then continued downwards to the posterior aspect of the greater trochanter of the femur where it curves medially to the coccyx (7.222B). The cutaneous strips

supplied by the dorsal rami do not correspond exactly to the strips supplied by the ventral rami, for they differ both in their breadth and in their position.

On the upper part of the ventral aspect of the thorax the third and fourth cervical areas adjoin the first and second thoracic areas (7.206), owing to the fact that the muscles and skin areas supplied by intervening nerves have grown into the upper limb, and a similar but less extensive gap is found on the posterior aspect of the trunk.

A corresponding arrangement is found in the lower part of the trunk, but it is not so obvious owing to the approximation of the lower limbs to one another, but is still apparent in the gluteal region. The first lumbar area adjoins the second sacral area at the root of the penis and scrotum (*see* p. 1418), for the intervening nerves have been drawn away to supply the lower limb.

Cutaneous Innervation of the Lower Limb

The skin of the lower limb is innervated by the nerves of the segments from which it is derived, viz. T. 12–S. 3 (7.222B, 223). The arrangement originally is precisely similar to that in the upper limb, but its identification in the adult has been rendered difficult on account of the rotation of the lower limb in the early stages of its development (p. 153). Originally the *preaxial border* follows the cephalic border of the limb bud to the hallux, which is the *preaxial digit*, while the *postaxial border* follows its caudal margin to the little toe, which is the *postaxial digit*. As development proceeds, the limb undergoes rotation in a *medial* direction so that the hallux comes to lie on the medial side of the adult foot and the little toe on its lateral side. The tibia, although homologous with the radius, lies on the medial side of the leg. Since the torsion occurs at the hip joint, the gluteal region retains its dorsal (extensor) situation.

The preaxial border commences above on the middle of the front of the thigh and runs down to the knee. It then curves medially as it descends to the medial malleolus to gain the medial side of the foot and the hallux. The post-axial border commences above in the gluteal region and descends to the popliteal fossa. It then declines laterally as it descends to the lateral malleolus to gain the lateral side of the foot. The *ventral* and *dorsal axial lines* necessarily exhibit a corresponding obliquity. The ventral axial line commences proximally at the medial end of the inguinal ligament and descends the posteromedial side of the thigh and leg to end proximal to the heel. The dorsal axial line commences in the lateral part of the gluteal region and descends on the posterolateral aspect of the thigh to the knee. It then inclines medially and ends before it reaches the ankle (7.222B).

The segmental cutaneous distribution of the nerves to the lower limb is shown in 7.222B.

Our knowledge of the extent of the individual dermatomes, especially of the limbs, is necessarily based on clinical evidence, and different authorities have mapped out areas which are far from being identical for the same dermatomes. This is due partly to their failure to adopt a common method in the neurological examination of patients and partly to individual differences between patients suffering from similar lesions. There is more disagreement with regard to the dermatomes in the leg, perhaps in part due to the greater frequency of injuries to the brachial plexus, affording more numerous opportunities of correlation between the areas of cutaneous analgesia or anaesthesia and the exact site of damage to the nerve. The figures of the limb dermatomes here inserted in 7.222 A, B are based on those of the Committee appointed by the Medical Research Council, and published in their *Report on Peripheral Nerve Lesions*, 1942.

When studying these figures it must be clearly understood that the *broken lines* indicate that the nerves on each side of them extend considerably beyond them, the amount of such overlapping being often difficult to define. But, along the *ventral* and *dorsal axial lines*, shown in *heavy black*, overlap is minimal, for the nerves on each side of the line are *not* derived from consecutive spinal nerves, and the intervening nerve or nerves are buried in the substance of the limb in this situation and only reach the skin at a more distal point.

Some observers (Keegan and Garrett 1948) maintain that, in the embryonic development of the dermatomes of the limbs, the sensory nerves grow spirally from the dorsal surface of the limb buds around their preaxial and postaxial borders to meet on their ventral surface along the ventral axial line, and they deny the existence of a dorsal axial line. By plotting the areas of hyposensitivity, particularly hypalgesia (diminished sensibility to painful stimuli), following damage to *individual* nerve roots they have constructed charts of the limb dermatomes that differ considerably from those shown in 7.222. The views of Keegan and Garrett (7.223) were based on observations of a large number of patients with hypalgesia due to herniation of intervertebral discs. These included 165 cases in the upper limb (47 verified surgically) and 1,264 in the lower limb (707 thus verified). The main difference between these observations is that the dermatomes are shown as more continuous strips extending from the trunk into and along the limbs.

Segmental Innervation of Muscles

Each spinal nerve originally supplies the musculature derived from the myotome of the same segment. In cases where the derivatives of any one myotome persist as separate entities, they retain their original nerve supply, but when derivatives of adjoining myotomes fuse, the resultant muscle does not necessarily retain its supply from each of the corresponding spinal nerves, although it may and frequently does so. Since the limb muscles develop *in situ* in the mesodermal core of the developing limb, it is impossible to identify the individual segments from which any muscle is derived by the study of its mode of development. The union of the individual spinal nerves and their branches in the brachial and lumbosacral plexuses renders impossible the identification by dissection of the segmental value of the individual motor nerves.

The notion of immutability of nerve-muscle relationship, originally promoted by Furbinger (1873), has been criticized, and exceptions have been recorded. (Consult Haines 1935, and Minkoff 1974.)

Segmental innervation of the Muscles of the Limbs

Most muscles of the limbs are innervated from more than one segment of the spinal cord and the segments involved for individual muscles are indicated in the section on Myology (p. 529). In the list given below, for a given muscle the *predominant segmental origin* of its nerve supply is recorded; damage to these segments or to the motor nerve roots arising therefrom result in maximum paralysis of the appropriate muscles. The information is based chiefly on clinical evidence (Bumke and Foerster 1936; Villiger 1946; Sharrard 1955), but it must be admitted that there is a difference of opinion in the case of a number of muscles, and not all the muscles of the limbs are included in this list. Moreover, though the evidence for some muscles is incontrovertible, it is scanty and uncertain in many other instances. An important example is provided by the intrinsic muscles of the hand, which are often regarded in clinical teaching as innervated solely through the first thoracic spinal nerve. As indicated by the following table the eighth cervical spinal nerve is also involved.

Upper Limb Muscles

C. 3, 4 Trapezius; levator scapulae.

C. 5 Rhomboids; deltoids; supraspinatus; infraspinatus; teres minor; biceps.

C. 6 Serratus anterior; latissimus dorsi; subscapularis; teres major; pectoralis major (clavicular head); biceps; coracobrachialis; brachialis; brachioradialis; supinator; extensor carpi radialis longus.

C. 7 Serratus anterior; latissimus dorsi; pectoralis major (sternal head); pectoralis minor; triceps; pronator teres; flexor carpi radialis; flexor digitorum superficialis; extensor carpi radialis longus; extensor carpi radialis brevis; extensor digitorum; extensor digiti minimi.

C. 8 Pectoralis major (sternal head); pectoralis minor; triceps; flexor digitorum superficialis; flexor digitorum profundus; flexor pollicis longus; pronator quadratus; flexor carpi ulnaris; extensor carpi ulnaris; abductor pollicis longus;

extensor pollicis longus; extensor pollicis brevis; extensor indicis: abductor pollicis brevis; flexor pollicis brevis; opponens pollicis.

T. 1 Flexor digitorum profundus; intrinsic muscles of the hand (except abductor pollicis brevis; flexor pollicis brevis; opponens pollicis).

Lower Limb Muscles

L. 1 Psoas major; psoas minor.

L. 2 Psoas major; iliacus; sartorius; gracilis; pectineus; adductor longus; adductor brevis.

L. 3 Quadriceps; adductors (magnus, longus, brevis).

L. 4 Quadriceps; tensor fasciae latae; adductor magnus; obturator externus; tibialis anterior; tibialis posterior.

L. 5 Gluteus medius; gluteus minimus; obturator internus; semimembranosus; semitendinosus; extensor hallucis longus; extensor digitorum longus and peroneus tertius; popliteus.

S. 1 Gluteus maximus; obturator internus; piriformis; biceps femoris; semitendinosus; popliteus; gastrocnemius; soleus; peronei (longus and brevis); extensor digitorum brevis.

S. 2 Piriformis; biceps femoris; gastrocnemius; soleus; flexor digitorum longus; flexor hallucis longus; some intrinsic foot muscles.

S. 3 Some intrinsic foot muscles (except abductor hallucis; flexor hallucis brevis; flexor digitorum brevis; extensor digitorum brevis).

(See also p. 873 for a table of lower limb innervation.)

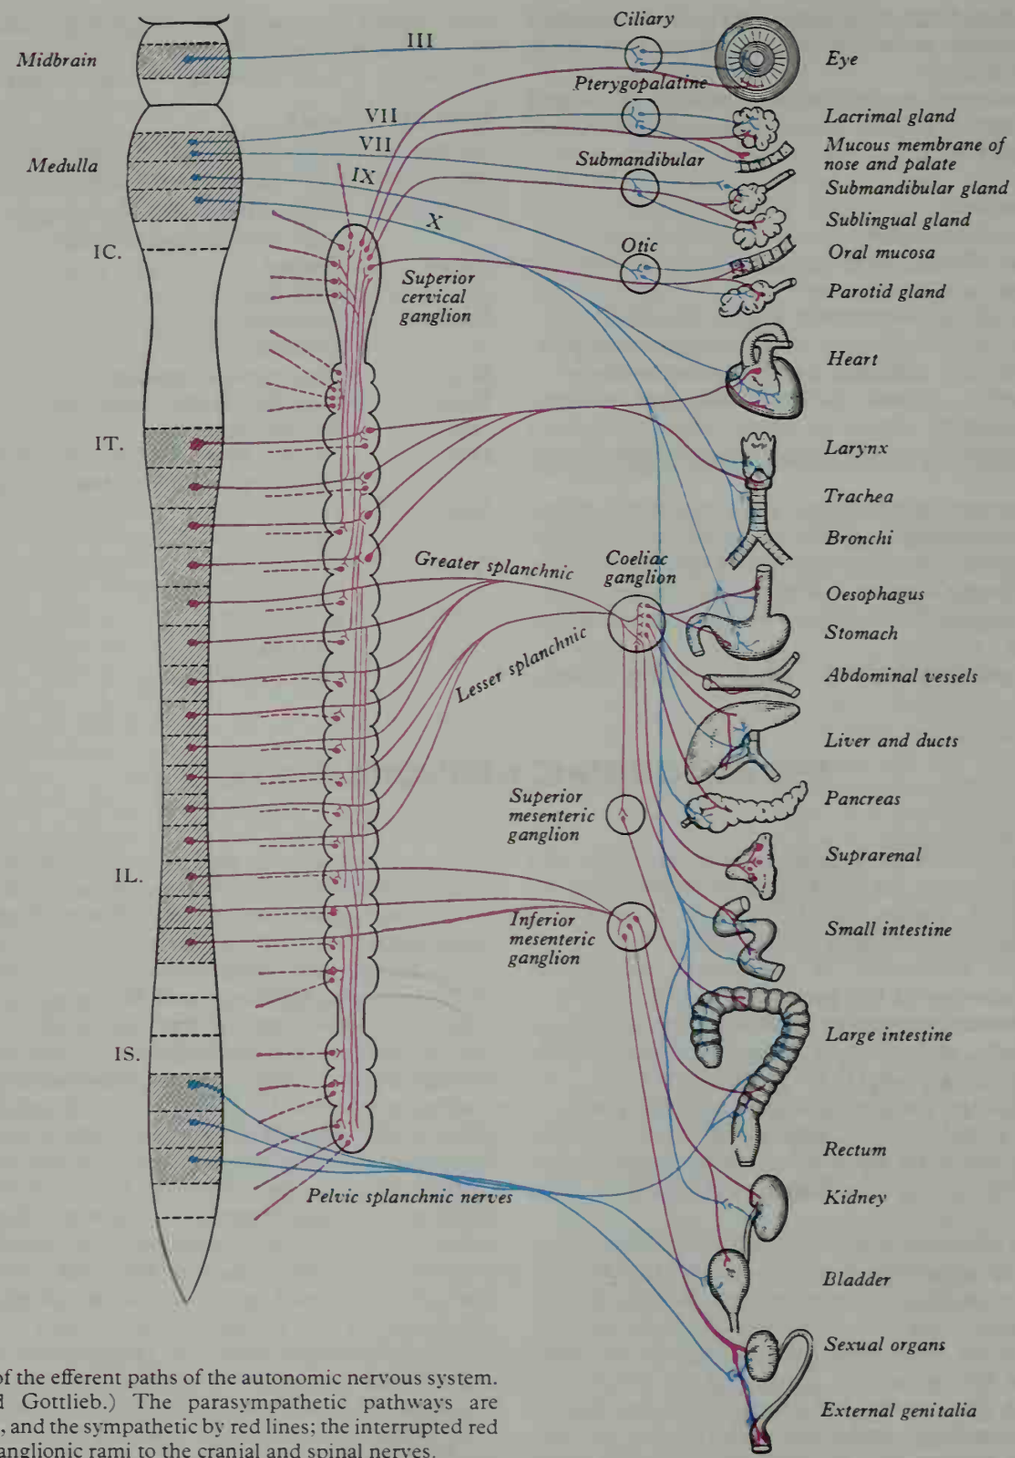
Joint Movements

In terms of movements of joints, the segmental innervation of the limb muscles may be expressed in general as follows:

Shoulder	Abductors and lateral rotators.	C. 5
	Adductors and medial rotators.	C. 6, 7, 8
Elbow	Flexors.	C. 5, 6
	Extensors.	C. 7, 8
Forearm	Supinators.	C. 6
	Pronators.	C. 7, 8
Wrist	Flexors and extensors.	C. 6, 7
Digits	Long flexors and extensors.	C. 7, 8
Hand	Intrinsic muscles.	C. 8, T. 1
Hip	Flexors, adductors, medial rotators.	L. 1, 2, 3
	Extensors, abductors, lateral rotators.	L. 5, S. 1
Knee	Extensors.	L. 3, 4
	Flexors.	L. 5, S. 1
Ankle	Dorsiflexors.	L. 4, 5
	Plantar flexors.	S. 1, 2
Foot	Invertors.	L. 4, 5
	Evertors.	L. 5, S. 1
	Intrinsic muscles	S. 2, 3

THE AUTONOMIC NERVOUS SYSTEM

The autonomic nervous system includes parts of the central and peripheral nervous systems, the latter being concerned with the innervation of viscera, glands, blood vessels and nonstriated muscle. It is the visceral (splanchnic) component of the nervous system. The term 'autonomic' is convenient rather than appropriate. The *autonomy* of this part of the nervous system is illusory. It is intimately responsive to changes in the somatic activities of the body, and while its connexions with somatic elements are not always clear in anatomical terms, the physiological evidence of visceral reflex activities stimulated by somatic events is abundant. (For general information on the anatomy and physiology of the autonomic nervous system consult Sheehan 1936; White *et al.* 1952; Kuntz 1953; Mitchell 1953, 1956; Pick 1970.)



Visceral efferent pathways differ from somatic equivalents in being interrupted by peripheral synapses, at least two neurons being interposed between the central nervous system and the visceral effector organ (7.224). The cells of origin of the primary neurons are sited in the visceral efferent components of cranial nerve nuclei and in the lateral grey columns of the spinal cord. Their axons, which are variably, but usually finely myelinated, traverse the corresponding cranial and spinal nerves to enter ganglia, where they synapse with the dendrites or somata of the secondary neurons. The axons of the secondary or effector neurons are usually nonmyelinated and are distributed to nonstriated muscle or gland cells. There are therefore in the peripheral efferent pathway principal *preganglionic neurons* and *postganglionic neurons*. The latter are more numerous, and one preganglionic neuron may synapse with up to 15 to 20 postganglionic neurons, a circumstance which is associated with the wide diffusion of many autonomic effects. The disproportion between preganglionic and postganglionic neurons is said to be greater in the sympathetic than in the parasympathetic parts of the autonomic nervous system. (Indeed, in an investigation into the human superior cervical ganglion, a ratio of preganglionic to postganglionic fibres of 1 to 196 was claimed—Ebbesson 1968.) The terminations of postganglionic neurons are described on p. 847. The detailed structure of sympathetic ganglia and views concerning further neuronal types, including interneurons is treated on p. 1124.

The visceral afferent paths resemble somatic ones and the cells of origin of the peripheral fibres are unipolar cells in cranial and spinal nerve ganglia. Their peripheral processes are distributed through the autonomic ganglia or plexuses or possibly through somatic nerves without further synapse. Their central processes (axons) accompany the somatic afferent fibres through dorsal spinal nerve roots to the central nervous system (p. 1136).

The autonomic nervous system consists of two complementary parts, the *parasympathetic* and the *sympathetic systems* which differ structurally and in their functions. The preganglionic efferent fibres of the parasympathetic nervous system emerge through certain cranial and sacral spinal nerves and constitute the *craniosacral outflow*. On the other hand the preganglionic efferent fibres of the sympathetic nervous system emerge through the thoracic and upper lumbar spinal nerves and constitute the *thoracolumbar outflow*. The cell bodies of the postganglionic neurons in the parasympathetic system are situated peripherally, either as discrete collections forming ganglia nearer to the structures innervated than to the central nervous system, or sometimes dispersed in the walls of the viscera themselves. The cell bodies of the postganglionic neurons in the sympathetic system are generally situated in ganglia of the sympathetic trunk or as ganglia in more peripheral plexuses, almost always nearer to the spinal cord than to the effectors which they innervate.

Physiologically, parasympathetic reactions are generally localized, whereas sympathetic reactions are mass responses. Thus parasympathetic activity results, for example, in slowing of the heart and increase in the glandular and peristaltic activities of the gut; these may be considered as conservation of body energies. Sympathetic activities result, for example, in general constriction of the cutaneous arteries (with consequent increase in the blood supply to the heart, muscles and brain), acceleration of the heart and increase of the blood pressure, contraction of the sphincters and lessening of the peristalsis of the gut, all of which activities mobilize body energies for dealing with increased activity.

Whereas the passage of nervous impulses along all preganglionic fibres, parasympathetic postganglionic fibres or along somatic efferent fibres is associated with the liberation of *acetylcholine* in the region of the terminals, in the case of the sympathetic postganglionic fibres the substance liberated is *noradrenalin* or *adrenalin*. For this reason the above types of nerves are called *cholinergic* and *adrenergic* respectively. As an exception to this sweat glands are supplied only by postganglionic sympathetic nerves, but these are cholinergic. (*See* also brief references to peripheral *purinergic* fibres on p. 833.)

7.224 A diagram of the efferent paths of the autonomic nervous system. (After Meyer and Gottlieb.) The parasympathetic pathways are represented by blue, and the sympathetic by red lines; the interrupted red lines indicate postganglionic rami to the cranial and spinal nerves.

THE PARASYMPATHETIC NERVOUS SYSTEM

Efferent Pathways

The preganglionic parasympathetic fibres are myelinated and occur in (1) the oculomotor, (2) the facial, (3) the glossopharyngeal, (4) the vagus and accessory, and (5) the second, third and fourth sacral spinal nerves. In the cranial part of the parasympathetic system there are four peripheral ganglia which, though small, are readily identified with the naked eye. They are the *ciliary* (p. 1058), *pterygopalatine* (p. 1064), *submandibular* (p. 1072) and *otic* (p. 1076) ganglia, all of which have been described in detail with the cranial nerves. These ganglia are concerned solely with efferent parasympathetic pathways, unlike the trigeminal, facial, glossopharyngeal and vagal ganglia, which are all concerned with afferent impulses and contain the cells of origin of sensory fibres only. The cranial parasympathetic ganglia are *traversed* by afferent fibres, by postganglionic sympathetic fibres and, in the case of the otic ganglion, even by branchial efferent fibres; but in none are the fibres interrupted during their passage through the ganglia. The postganglionic parasympathetic fibres are usually nonmyelinated and shorter than those of the sympathetic system, since the ganglia where their synapses occur are situated in or near the viscera they supply. Baumann and Gajisin (1975) have emphasized the occurrence of small subsidiary ganglia in the vicinity of those mentioned above, as has been reported by other workers. They claim, in addition, that minute ganglia occur in many other sites in fetal material—along the middle meningeal artery, for example, and in association with certain of the petrosal nerves. These findings, if confirmed, are of physiological importance.

(1) The *oculomotor* parasympathetic fibres commence in the midbrain, and are derived from the accessory oculomotor (Edinger-Westphal) nuclei (p. 1057). The preganglionic fibres travel in the nerve and leave by the branch which it supplies to the inferior oblique to enter the *ciliary ganglion*. There they are relayed, and the postganglionic fibres leave the ganglion in the short ciliary nerves, which pierce the sclera and run forwards in the perichoroidal space, to be distributed to the ciliary muscle (p. 1159) and the sphincter pupillae (p. 1161). These postganglionic fibres are thinly myelinated.

(2) The *facial nerve* contains efferent parasympathetic fibres which are axons of cells in the superior salivatory nucleus (p. 1070) and emerge from the brain in the nervus intermedius. They travel in the facial nerve, leaving it a little above the stylomastoid foramen in the *chorda tympani*, which traverses the tympanic cavity and ultimately reaches the *lingual nerve*. In this way they are conveyed to the submandibular region, where they enter the *submandibular ganglion*, in which the postganglionic secretomotor fibres for the submandibular salivary gland arise. Some preganglionic fibres may synapse around cells in the hilum of the gland (*see* also pp. 1274 and 1275). The secretomotor fibres for the sublingual gland are continued forwards in the lingual nerve after they have arisen in the submandibular ganglion (*see* also pp. 1073 and 1275). Electrical stimulation of the chorda tympani produces dilatation of the arterioles of both these salivary glands in addition to a secretomotor effect. In addition, the facial nerve has usually been said to contain efferent parasympathetic fibres which are secretomotor to the lacrimal gland, travelling by its greater petrosal ramus and nerve of the pterygoid canal and relaying in the pterygopalatine ganglion. The postganglionic branches are said to travel by the zygomatic nerve to the lacrimal gland (p. 1063) and by branches from the ganglion to glands of the nose and palate. Evidence refuting the former route has been reported (Ruskell 1971). This indicated that direct *lacrimal rami* pass to the gland from a *retro-orbital plexus* composed of direct parasympathetic branches of the pterygopalatine ganglion. There is clinical evidence that some of the facial parasympathetic fibres reach the parotid gland (Diamant and Wiberg, 1965: *see* also p. 1070).

(3) The *glossopharyngeal nerve* contains efferent parasympathetic fibres which are secretomotor to the parotid gland. They start in the inferior salivatory nucleus (p. 1074) and travel in the glossopharyngeal nerve and its tympanic branch. After traversing the tympanic plexus, they enter the lesser petrosal nerve and so reach the otic ganglion. There they are relayed and the postganglionic fibres pass by communicating branches to the auriculotemporal nerve, by which they are conveyed to the parotid gland. Electrical stimulation of the lesser petrosal nerve produces a vasodilator as well as a secretomotor effect.

(4) The *vagus nerve* contains efferent parasympathetic fibres which arise in its dorsal nucleus (p. 1076) and travel in the nerve trunk and in its pulmonary, cardiac, oesophageal, gastric, intestinal and other branches. Some cardiac parasympathetic fibres may originate from neurons in or near the nucleus ambiguus. *See* p. 905. The proportion of efferent parasympathetic fibres in the vagus varies at different levels, but is small in relation to its sensory component. These fibres are relayed in minute ganglia which lie in the walls of the individual viscera. The disproportion in the numbers of preganglionic to postganglionic fibres is greater in the vagus than in the efferent parasympathetic components of other cranial nerves and this discrepancy cannot as yet be explained. The cardiac branches are concerned with slowing of the cardiac cycle. They take part in the formation of the cardiac plexuses (p. 1132) and are then relayed in ganglia which are distributed freely over the surfaces of both atria in the subepicardial tissue. The terminal fibres are distributed to the atria and the atrioventricular bundle, and it has been claimed in the past that only through the latter can the vagus exert any control over the ventricular muscle (Cullis and Tribe 1913). The smaller branches of the coronary arteries are innervated mainly by the vagus, whereas their larger branches, though possessing a double innervation, obtain their chief source of supply from the sympathetic system (Wollard 1926). The *pulmonary branches* are motor to the circular nonstriated muscle fibres in the bronchi, and are therefore bronchoconstrictor. The synaptic relays are in the ganglia of the pulmonary plexuses. The *gastric branches* are secretomotor to the glands and motor to the muscular coats of the stomach, but they inhibit the action of the pyloric sphincter. The *intestinal branches* have a corresponding action on the small intestine, caecum, vermiform appendix, ascending colon, right colic flexure and most of the transverse colon, being secretomotor to the glands and motor to the muscular coats of the gut, but inhibitory to the ileocaecal sphincter. The synaptic relays, in this case, are situated in the myenteric (Auerbach's) plexus and the plexus of the submucosa (Meissner's plexus), which are described with the structure of the intestines.

(5) The anterior rami of the *second, third* and often the *fourth sacral spinal nerves* emit visceral branches passing directly to the pelvic viscera. They constitute the *pelvic splanchnic nerves* (7.231), and they unite with branches of the sympathetic pelvic plexuses. Minute ganglia are sited at these points of union and in the walls of the individual viscera. In these ganglia the sacral preganglionic parasympathetic fibres are relayed.

The pelvic splanchnic nerves supply the rectum with motor fibres, the bladder wall with motor and its sphincter with inhibitory fibres, the erectile tissue of the penis or clitoris with vasodilator fibres, the testes or ovaries probably with vasodilator fibres, and the uterine tubes and uterus with vasodilator and possibly inhibitory fibres. In addition, filaments from the pelvic splanchnic nerves pass upwards through the hypogastric plexus to supply the sigmoid colon, descending colon, left colic flexure and terminal part of the transverse colon with visceromotor fibres (Telford and Stopford 1934; Mitchell 1935).

The nervus terminalis (p. 1055) is also considered to contain an as yet unquantified population of visceral efferent fibres by some authorities.

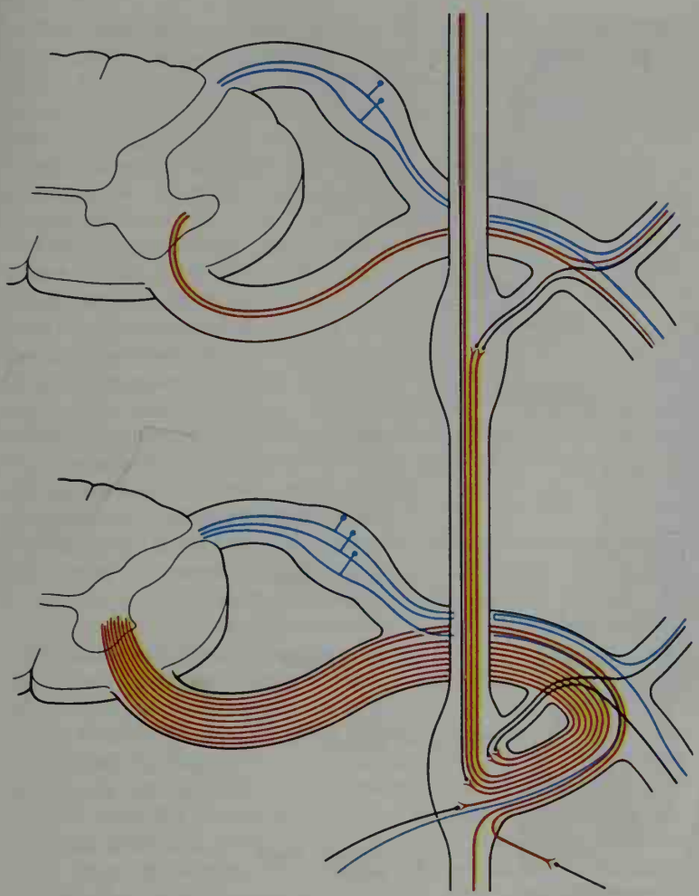
THE SYMPATHETIC NERVOUS SYSTEM

The sympathetic nervous system, which is the larger division of the autonomic, includes the two ganglionated sympathetic trunks, their branches, plexuses and subsidiary ganglia. It has a much wider distribution than the parasympathetic system, for it innervates all the sweat glands of the skin, the arrector muscles of the hairs, the muscular walls of many blood vessels, the heart, lungs and abdomino-pelvic viscera.

Efferent Sympathetic Pathways

The *preganglionic fibres* are the axons of nerve cells in the lateral column of the grey matter of all the thoracic and upper two or three lumbar segments of the spinal cord where they form the intermediomedial and intermediolateral cell groups (p. 872). These fibres are myelinated and have diameters of 1·5 to 4·0 μm. They emerge from the spinal cord through the ventral roots of the corresponding spinal nerves and pass into the spinal nerve trunks and the commencement of their ventral rami, which they leave in the *white rami communicantes*, to join either the corresponding ganglia on the sympathetic trunks or their interganglionic parts. Since this outflow is confined to the thoracolumbar region, typical white rami communicantes are also restricted to the fourteen spinal nerves noted above. However, the possibility of a limited outflow of preganglionic fibres in other spinal nerves has been suggested. It is certain that nerve cells of the same type as those in the lateral grey column also exist at other levels, above and below the thoracolumbar outflow (Mitchell 1953), and that small numbers of their fibres issue in corresponding ventral roots. Dorsal spinal nerve roots may also contain vasodilator fibres. Having reached the sympathetic trunk the preganglionic fibres may behave in a number of different ways (7.225). (*a*) They may

end in the corresponding ganglion by arborizing with the dendrites of ganglion cells. (*b*) They may pass through the corresponding ganglion and either ascend to a ganglion at a higher level or descend to one at a lower level before terminating in a similar manner; it is believed that preganglionic fibres do not divide into ascending and descending branches on entering the sympathetic trunk. A single preganglionic fibre may, through its collateral and terminal branches, synapse with nerve cells in several of the ganglia which it traverses; other preganglionic fibres distribute branches to one ganglion only. (*c*) They may pass through the corresponding ganglion and may ascend or descend without being interrupted and then emerge in one of the medially directed branches of the sympathetic trunk to enter a plexus of the autonomic system, where they terminate in relation to the ganglion cells therein. Occasionally the interruption of preganglionic fibres occurs in ganglia situated proximal to the sympathetic trunks; these are known as '*intermediate ganglia*' and are most numerous on the grey rami communicantes (*vide infra*) in the cervical and lower lumbar regions (Boyd and Munro 1940). They may be of microscopic size and are sometimes situated in the ventral roots or trunks of the spinal nerves. Branches from more than one preganglionic fibre may synapse with a single postganglionic neuron (*vide infra*).



The sympathetic ganglia include collections of cells of the sympathetic trunks, nerve ganglia in the autonomic plexuses and the 'intermediate' ganglia; in addition some ganglion cells are dispersed through the plexuses. Originally the ganglia on the sympathetic trunks correspond numerically to the ganglia on the dorsal roots of the spinal nerves (p. 1086); but fusion of adjoining ganglia has occurred and in man there are rarely more than twenty-two or twenty-three and there may be fewer discrete ganglia. The subsidiary ganglia in the great autonomic nerve plexuses (e.g. coeliac ganglion, superior mesenteric ganglion, etc.) are derivatives of the ganglia of the sympathetic trunks.

The structure of sympathetic ganglia and, of course, their functional characteristics have been subject to experiment and observation with increasing tempo for many decades. For earlier literature consult the general authorities on the autonomic nervous system (p. 1121), and Gabella (1976) and Eränkö (1978) for more recent contributions. The classical studies of Langley and his successors led to an early view of autonomic ganglia as relay stations, a concept largely corroborated by anatomical observations, though it was quickly recognized that a minor fraction of efferent nerve fibres traverse many ganglia without interruption, as do afferent fibres from viscera and glands. This remains a substantially true representation of ganglia in autonomic pathways, but it has been modified somewhat and markedly extended by application of the techniques of electron microscopy, neurohistochemistry, and electrophysiology. For example, the ratio between nerve fibres entering a ganglion and those leaving it is not on a simple 1:1 basis. The superior cervical sympathetic ganglion, which has been most extensively studied in this and other regards, shows ratios varying from 1:28 to 1:176 in different mammalian species (*see* Billingsley and Ranson 1918; Samuel 1953; Ebbeson 1968). Such results demonstrate that a preganglionic neuron makes connexions with a large number of postganglionic nerve cells, thus providing a structural basis for wide *dissemination* or perhaps *amplification* of sympathetic activity, a well-established characteristic, which is not shared, to the same degree at least, by parasympathetic ganglia. These effects might be achieved in several ways: (*a*) by widespread terminal arborizations of preganglionic nerve fibres, (*b*) by the mediation of interneurons, (*c*) by local diffusion within the ganglion of transmitter substances locally produced (*paracrine* effect) or local response to substances produced elsewhere (*endocrine* effect). There is evidence that all of these mechanisms are involved.

The connective tissue capsule of each ganglion, which is continuous with the epineurium of its connecting rami (roots and branches), also extends as septa into the ganglion, surrounding groups of nerve cells and nerve fibres. Finer subdivisions of this stroma spread amongst these cells, each of which is surrounded by collagen fibres and intercellular matrix. In this stroma are a few fibroblasts and many small blood vessels and capillaries. Satellite cells (amphicytes) encapsulate the somata of the ganglionic neurons and their processes. The external aspect of this thin sheath of satellite cells bears a continuous basal lamina, and these two elements together screen the neurons from direct contact with the stroma of the ganglion and its extracellular matrix. Neuronal elements have direct access only to the internal, juxta-neuronal aspect of the satellite cells; but between the two is a narrow interval of about 15–20 nm. These peri-neuronal spaces are, moreover, linked to the stromal compartment of the ganglion by minute channels situated between the processes of satellite cells. The arrangements just described are of great importance in providing anatomical evidence of possible routes for movements of neurotransmitter and hormonal substances between neurons and also between these and the vascular compartment of the ganglion.

Regarding the characteristics of both the neuronal population of sympathetic (and parasympathetic) ganglia a great volume of observation has been recorded, some aspects only of which can be touched upon here. Many attempts to classify the range of neurons in ganglia have been made, but since the criteria employed were arbitrary and divergent, and in their excesses sometimes confusing, they will not be detailed here. The great majority of the nerve cells are multipolar, with somatic dimensions ranging from about 25 to 50 μm in mankind; a smaller type of cell, of about 15 to 20 μm in 'diameter' and less pronounced multipolar shape, also occurs in much smaller numbers, often clustered together in small groups (De Castro and Herneros 1945), and these latter probably correspond to SIF cells (*vide infra*). While varying in size the multipolar neurons display a more marked variation in the distribution and form of their dendritic arrays. According to McLachland (1974) multipolar ganglion cells in the guinea-pig display a mean of 13 dendrites per cell. The complexity of these dendrites, and particularly of small dendrites which ramify within the capsular, perikaryal space, is greater in human ganglion cells. Dendritic glomeruli have been observed in many ganglia. In general ultrastructural details these neurons resemble others (*see* p. 825). Clusters of small, granular vesicles, adrenergic in type, are dispersed superficially in the perikaryon, and these are also prominent in dendrites, probably to be equated with storage of catecholamines. Ganglionic neurons receive large numbers of axodendritic synapses from preganglionic nerve fibres, axosomatic synapses being much less numerous. Each preganglionic fibre forms several synapses with a number of separate dendrites, which may represent a mechanism for dissemination or amplification, or both. The postganglionic fibres (*vide infra*) commonly branch off from the initial stem of a large dendrite and produce few or no collateral rami.

The existence of *interneurons* in sympathetic ganglia has been strongly denied in the past (*see* Samuel 1953); but according to Williams (1967), Williams and Palay (1969), Libet and Crowman (1974), an interneuronal role can be assigned to some, at least, of the 'small intensely fluorescent' (SIF) cells, which have been identified in many sympathetic ganglia and in a variety of mammals, including mankind (Eränkö and Harkonen 1965; Jacobowitz 1970). Small chromaffin cells have been known to occur in sympathetic ganglia since 1898, or even earlier, where they were recognized by Kohn. Coupland (1965), amongst modern workers, has described them as present in all the ganglia of the sympathetic trunk, and in other sites, in neonatal human material. The distinction between SIF cells and chromaffin cells appears to be a matter of uncertainty or controversy in many accounts. The supposed two types of cells, as far as ganglia are concerned, are identified by separate techniques (the chromaffin reaction and formalin-induced fluorescence) which cannot be applied together to any single cell. However, in a recent study (Santer *et al.* 1975) upon the distribution of SIF and chromaffin cells, in sympathetic ganglia of rats, the former were more numerous and their modes of distribution overlapped but showed some differences. Both types of cell contain catecholamines, and it is possible that some cells contain only enough to be revealed by the more sensitive formaldehyde-induced fluorescence technique (Falck-Hillarp), whereas others have a sufficiently high concentration of catecholamines to produce a positive chromaffin reaction (*see* Gabella 1976 for discussion). Both kinds of cells may

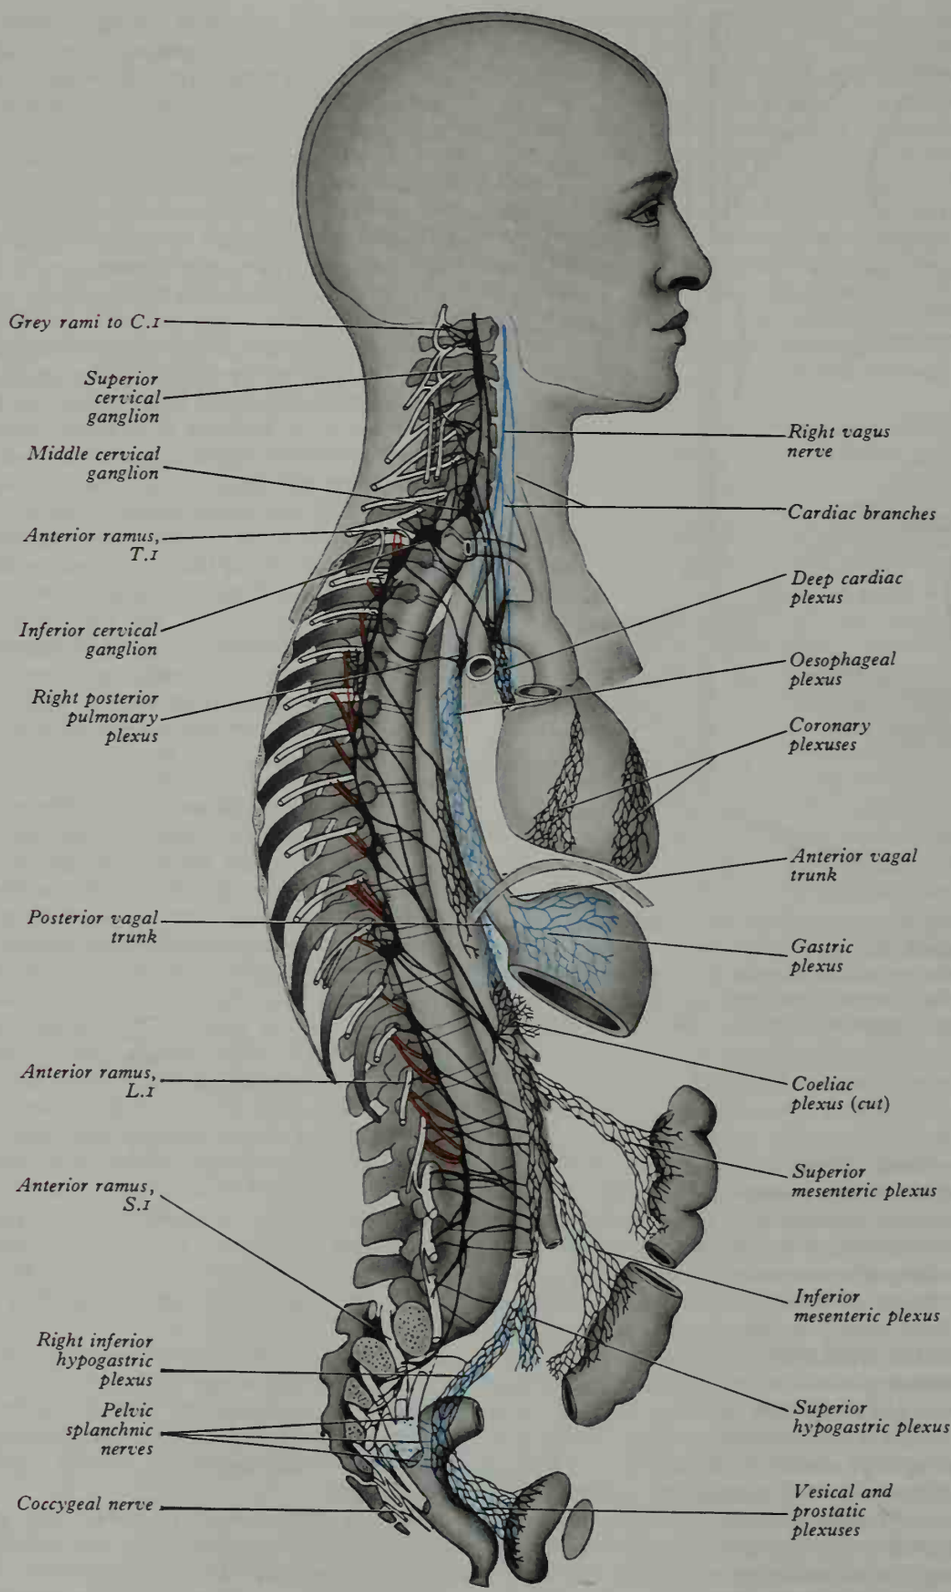
7.225 A scheme showing the constitution of a typical spinal nerve. In the upper part of the diagram the spinal nerve roots show the somatic components; in the lower part of the diagram the spinal roots show the visceral components. *Red:* somatic and preganglionic visceral nerve fibres. *Blue:* somatic and visceral afferent fibres. *Black:* postganglionic afferent visceral fibres.

act as interneurons (Santer *et al.* 1975; Gabella 1976). The putative mode of action of interneuronal SIF cells has been hypothecated by Greengard and Kebabian (1974): dopamine is released by such cells and is united to surface receptors of one or more ganglionic neurons, activating adenylate cyclase and thus increasing the production of cyclic AMP (cyclic adenosine monophosphate), which results in hyperpolarization. In the ganglia of some species two types of SIF cell have been described (Williams 1975): a minority, which have long processes ending near ganglionic neurons and which may therefore be regarded as interneurons (Type I), and a more numerous Type II cell with shorter processes ending in proximity to blood vessels (Chiba *et al.* 1975). In bovine superior cervical sympathetic ganglia 24 per cent of the SIF cells were thus described as belonging to Type I, while in the same ganglion in cats only 20 per cent were ascribed to this group. Although the secretory granules of these Type I cells are regarded as able to act directly upon ganglionic neurons, there is evidence that some SIF cells, presumably of Type II, pass their secretion into the local blood vessels (Polonyi *et al.* 1977), thus exerting more diffuse and distant effects. The role of SIF cells in neurotransmission in sympathetic ganglia has been reviewed by Eränkö (1978).

Quantitative studies of the neuronal populations, in terms of numbers, dimensions, and density of packing, have been recorded for many autonomic ganglia and especially in the superior cervical sympathetic ganglion. Gabella (1976) has assembled and evaluated such data in detail, and the reader is referred to his review for further information.

The axons of the principal ganglion cells are usually fine, non-myelinated fibres and constitute the *postganglionic fibres*. They are distributed to the effector organ in a variety of ways. Postganglionic fibres arising from a ganglion on the sympathetic trunk may (*a*) pass back to the corresponding spinal nerve through a *grey ramus communicans*; this usually joins the spinal nerve trunk just proximal to the white ramus communicans. Its fibres are distributed through the ventral and dorsal rami of the spinal nerves and their branches to the blood vessels, sweat glands and hairs, etc. in their zone of supply. The extent of the segmental area innervated is variable and the territories supplied through adjacent nerves overlap to a considerable degree; the extent of innervation of different effector systems, e.g., sudomotor and vasomotor, by a particular nerve are not necessarily the same. (*b*) They may pass in a medial branch of a ganglion to be distributed to some particular areas or viscera. (*c*) They may pass to blood vessels in the neighbourhood of the sympathetic trunk and supply these or may be carried along the vessels and their branches towards their peripheral distribution. (*d*) They may ascend to a higher level or descend to a lower level before leaving the sympathetic trunk either in one of its medial branches, in a grey ramus communicans or along adjacent blood vessels.

In addition to white and grey rami mixed types are found. Some of these in the thoracic region represent fusion of white and grey rami but some found in the cervical region contain bundles of thick myelinated fibres, which are somatic efferent in character and are utilizing the grey ramus as a convenient route to reach prevertebral muscles (p. 1127). For a detailed description of rami communicantes and their variations from purely preganglionic to purely postganglionic types consult Winckler (1961).



After diffusing through the plexuses the postganglionic fibres which arise in or join the plexuses are distributed mainly along blood vessels and some ducts.

Functional significance. The efferent postganglionic fibres which pass in the grey rami communicantes to the spinal nerve supply vasconstrictor fibres to the blood vessels, secretomotor fibres to the sweat glands and motor fibres to the arrectores pilorum muscles in the areas supplied by the corresponding spinal nerve. Those which accompany the motor nerves to voluntary muscles are probably distributed only to the blood vessels supplying the muscles. Thus most, if not all, peripheral branches derived from the spinal nerves contain postganglionic sympathetic fibres. Those which pass to the viscera and other structures are concerned with vasoconstriction, dilatation of the pupils, dilatation of the bronchioles, glandular secretion, movements of the alimentary tract and the urinary bladder (relaxation of the muscle walls and contraction of the sphincters), etc. It is believed that usually, but not invariably, a single preganglionic fibre synapses with the postganglionic neurons innervating one effector system only; therefore a dissociation of sympathetic effects, such as sudomotor and vasomotor activities, can occur. The same is not necessarily true of visceral afferent fibres (p. 890). While in general the sympathetic and parasympathetic systems exert antagonistic influences on the viscera they supply, this is not always so. In the case of the urinary bladder, for instance, the normal emptying and filling of the viscus are controlled only by the parasympathetic system, the sympathetic being concerned with the supply of the blood vessels of the organ.

Higher autonomic control. The peripheral autonomic nervous system is controlled by the activities of higher levels in the brainstem and cerebral hemispheres. The parts of the brain especially concerned have been described in the section on the Central Nervous System and include the brainstem reticular formation, various thalamic and hypothalamic nuclei, the limbic lobe and the prefrontal neocortex, and a variety of ascending and descending pathways which interconnect these regions.

The sympathetic trunks are two ganglionated nerve cords which extend from the base of the skull to the coccyx. In the neck the trunk is posterior to the carotid sheath and anterior to the transverse processes of the cervical vertebrae; in the thorax it is anterior to the heads of the ribs; in the abdomen it is anterolateral to the bodies of the lumbar vertebrae, and in the pelvis, anterior to the sacrum, medial to the anterior sacral foramina. Anterior to the coccyx the two trunks meet each other in the unpaired terminal *ganglion impar*.

The cervical ganglia are usually reduced to three by fusion of adjoining units, and from the cranial pole of the superior ganglion

7.226 A The right sympathetic trunk and its connexions with the thoracic, abdominal and pelvic plexuses. *Blue:* parasympathetic fibres. *Black:* sympathetic trunk and branches. *Red:* white rami communicantes.

the internal carotid nerve commences. This nerve constitutes an ascending continuation of the sympathetic trunk, and it accompanies the internal carotid artery through its canal into the cranial cavity. In the thorax there are usually eleven ganglia, but the number may be ten or twelve. There are usually four ganglia in the lumbar and four or five in the sacral regions.

CRANIAL PART OF THE SYMPATHETIC SYSTEM

The cranial part of the sympathetic system begins on each side as the **internal carotid nerve**, which is continued up from the superior cervical ganglion of the sympathetic trunk and contains postganglionic fibres derived from its cells. It ascends behind the internal carotid artery, and, entering the carotid canal in the temporal bone, divides into two branches, one of which is lateral and the other medial to the artery.

The *lateral branch*, the larger, gives filaments to the internal carotid artery, and forms the lateral part of the internal carotid plexus.

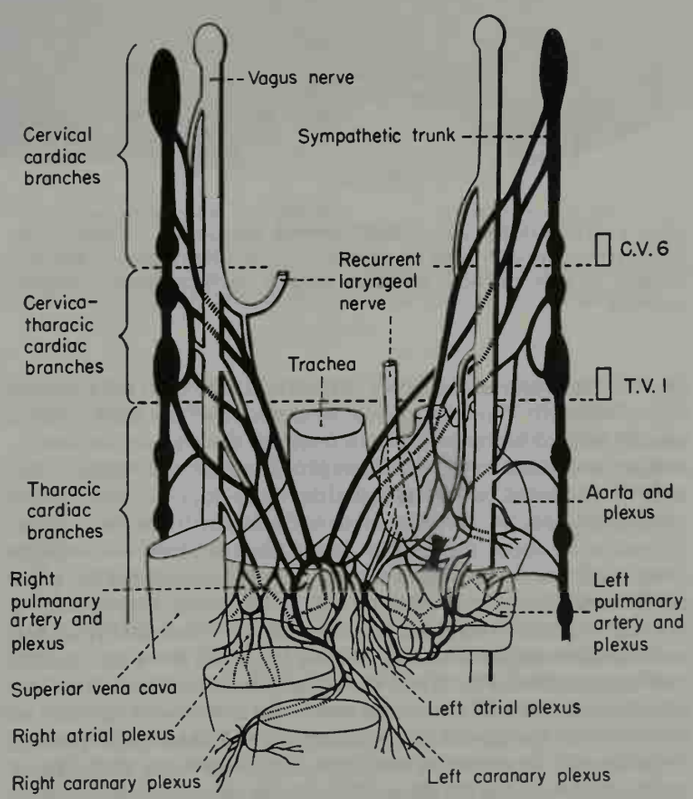
The *medial branch* also supplies filaments to the internal carotid artery, and, continuing onwards, forms the medial part of the internal carotid plexus.

The internal carotid plexus surrounds its artery, and occasionally contains a small swelling on the interior aspect of the vessel, the *carotid ganglion*. In addition to this small ganglion, the rest of the plexus also contains some scattered sympathetic nerve cells. The lateral part of the plexus communicates with the trigeminal and pterygopalatine ganglia, with the abducent nerve and with the tympanic branch of the glossopharyngeal nerve; it distributes filaments to the wall of the internal carotid artery.

The branches communicating with the abducent nerve consist of one or two filaments which join that nerve as it lies upon the lateral side of the internal carotid artery. The communication with the pterygopalatine ganglion is effected by a branch named the *deep petrosal*; this branch perforates the cartilage filling the foramen lacerum, and joins the greater petrosal nerve to form the *nerve of the pterygoid canal*, which passes through the pterygoid canal to the pterygopalatine ganglion. The communications with the tympanic branch of the glossopharyngeal nerve are effected by the *superior* and *inferior caroticotympanic nerves*, which traverse the posterior wall of the carotid canal.

The medial part of the internal carotid plexus is inferomedial to the part of the internal carotid artery which is lateral to the sella turcica, in the cavernous sinus. It gives branches to the internal carotid artery, and communicates with the oculomotor, trochlear, ophthalmic and abducent nerves, and with the ciliary ganglion. It also sends vasomotor twigs along the branches of the internal carotid artery which supply the hypophysis cerebri (p. 1443).

The branch to the oculomotor nerve joins that nerve at its point of division; the branch to the trochlear nerve joins the latter as it lies in the lateral wall of the cavernous sinus; filaments also connect with the medial side of the ophthalmic nerve and one joins the abducent nerve. The filament to the ciliary ganglion arises from the anterior part of the plexus and enters the orbit through the superior orbital fissure; it may join the ganglion directly; it may unite with the communicating branch from the nasociliary nerve to the ganglion (p. 1057), or it may travel via the ophthalmic nerve and its nasociliary branch. Its fibres pass through the ciliary ganglion without being interrupted and run in the short ciliary nerves to be distributed to the blood vessels of the eyeball. The fibres which supply the dilatator pupillae usually travel by the ophthalmic, nasociliary and long ciliary nerves, but occasionally some are carried by the short ciliary nerves. Some fibres may also innervate the ciliaris. The preganglionic fibres concerned leave the spinal cord predominantly in T. 1, and pass to the cervicothoracic ganglion, through which they pass uninterruptedly. They then ascend in the cervical section of the sympathetic trunk to reach the superior cervical ganglion, where they are relayed.



The terminal filaments from the internal carotid plexus are prolonged as plexuses around the anterior and middle cerebral arteries and the ophthalmic artery: along the anterior and middle cerebral arteries they may be traced to the pia mater; along the ophthalmic artery they pass into the orbit where they accompany each of the branches of that vessel. The filaments prolonged on the anterior communicating artery connect the sympathetic nerves of the right and left sides and a small ganglion may be found associated with these filaments. Much of the above detail depends upon comparatively old observations, and disagreement and discrepancy still obtains in regard to such details. Mitchell (1953) and Purves (1972) have reviewed the extensive literature. It can, however, be said that the old controversy regarding the autonomic innervation of the cerebral arterial tree is now settled. Moreover, electron microscopy has permitted clear demonstration that this innervation is substantially like that of other vascular systems (*see*, for example, Iwayama *et al.* 1970). The terminals are adrenergic, a finding confirmed histochemically in various mammals, including man (Iwayama 1970). The source of these sympathetic vasoconstrictor fibres is from the internal carotid and vertebral plexuses, but the precise distribution from each is still unresolved. (Although evidence of cholinergic terminals in the walls of cerebral arteries has been recorded, the existence of vasodilator mechanisms has not been clearly demonstrated.) It has also been claimed (Falck *et al.* 1965, and Edvinsson *et al.* 1973) that adrenergic nerve fibres accompany pial and intracerebral arteries which are *not* derived from known sympathetic sources, but from nerve cells at present merely presumed to be intracranial in location.

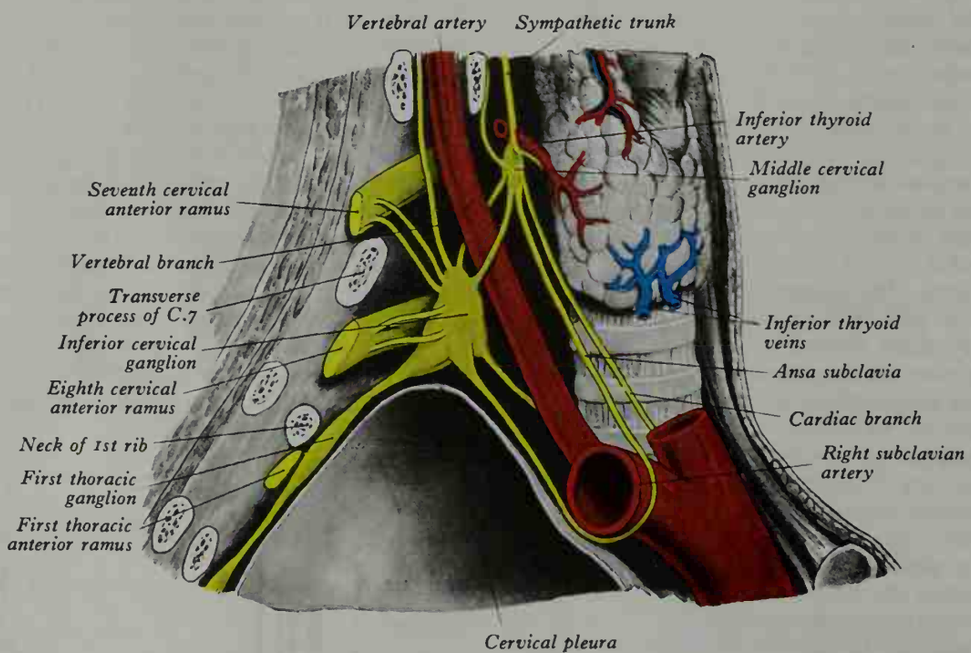
CERVICAL PART OF THE SYMPATHETIC SYSTEM

The cervical part of each sympathetic trunk consists of three ganglia distinguished, according to their positions, as the superior, middle and cervicothoracic, connected by intervening cords (7.226). This part sends grey rami communicantes to all the cervical spinal nerves, but receives no white rami communicantes from them; its spinal fibres are derived from the white rami communicantes of the upper thoracic nerves, which enter the corresponding thoracic ganglia of the sympathetic trunk, through which they ascend into the neck. In their course the grey rami communicantes may pierce the longus capitis or the scalenus anterior. For details of the cervical grey rami *see* Potts (1925), Oxford (1928), Pick and Sheehan (1946), Sunderland and Bedbrook (1949).

The superior cervical ganglion, the largest of the three, adjoins the second and third cervical vertebrae and is believed to be formed by the coalescence of four ganglia, corresponding with the upper four cervical nerves. It is in relation, in front, with the sheath of the internal carotid artery behind, with the longus capitis. The internal carotid nerve (p. 1126) ascends from the upper end of the ganglion into the cranial cavity; the lower end of the ganglion is united by the connecting trunk with the middle cervical ganglion. The branches of the ganglion may be divided into lateral, medial and anterior groups.

The *lateral branches* of the superior cervical ganglion consist of grey rami communicantes to the upper four cervical nerves and to certain of the cranial nerves. Delicate filaments run to the inferior ganglion of the vagus, and to the hypoglossal nerve; a branch, named the *jugular nerve*, ascends to the base of the skull and divides into two twigs, one of which joins the inferior ganglion of the glossopharyngeal, and the other the superior ganglion of the

7.226B The human cardiac plexus—a semi-diagrammatic representation of its source from the cervical parts of the vagus nerves and sympathetic trunks and of its extensions—the pulmonary, atrial, and coronary plexuses. Note the numerous junctions between the sympathetic and parasympathetic (vagal) rami which form the plexus. (For further information, particularly concerning the frequent variations, consult N. J. Mizeres, *Amer. J. Anat.* **112**, 1963, to both of whom we are indebted for permission to use this diagram.)



vagus; other twigs pass to the superior jugular bulb, including its associated jugular glomus or glomera, and some are distributed to the meninges in the posterior cranial fossa.

The *medial branches* of the superior cervical ganglion are the laryngopharyngeal and cardiac branches.

The *laryngopharyngeal branches* supply the carotid body, and pass to the side of the pharynx, where they join with branches from the glossopharyngeal and vagus nerves to form the *pharyngeal plexus* (p. 1313).

The *cardiac branch* arises by two or more filaments from the lower part of the superior cervical ganglion, and occasionally receives a twig from the trunk connecting the superior with the middle cervical ganglion. It is believed to contain only efferent fibres, the preganglionic outflow being from the upper thoracic segments of the spinal cord, and to be devoid of any visceral pain fibres from the heart (p. 1132). It runs down the neck behind the common carotid artery, and in front of the longus colli; it crosses in front of the inferior thyroid artery and recurrent laryngeal surrounding the facial artery supplies a filament to the submandibular ganglion, and the plexus on the middle meningeal artery sends one ramus to the otic ganglion, and another, termed the *external petrosal nerve*, to the ganglion of the facial nerve. Many of the fibres coursing along the external carotid artery and its branches to supply the sweat glands on the face ultimately leave the blood vessels to be distributed through terminal branches of the trigeminal nerve.

The middle cervical ganglion (7.227), the smallest of the three cervical ganglia, is occasionally absent as such, being replaced by minute ganglia in the sympathetic trunk in this region; it may be fused with the superior cervical ganglion. It is usually at the level of the sixth cervical vertebra, anterior or just superior to, the inferior thyroid artery, or it may lie near the cervicothoracic ganglion (p. 1129). It is probably formed by the coalescence of two ganglia corresponding with the fifth and sixth cervical segments, judging by its postganglionic rami, which pass to the fifth and sixth cervical nerves, but also, sometimes to the

7.227 A The middle and inferior cervical ganglia of the right side. Viewed from the right. Note the proximity of the inferior cervical and first thoracic ganglia, usually fused to form a cervicothoracic (stellate) ganglion.

nerve. The course of the nerve of the right side then differs from that of the left. The *right nerve*, at the root of the neck, passes usually behind but sometimes in front of, the subclavian artery, and posterolateral to the brachiocephalic trunk to the back of the arch of the aorta, where it joins the deep (dorsal) part of the cardiac plexus. It is connected with other branches of the sympathetic; about the middle of the neck it receives filaments from the external laryngeal nerve; inferiorly, one or two vagal cardiac branches join it; and as it enters the thorax it is joined by a filament from the recurrent laryngeal nerve. Filaments from the nerve communicate with the thyroid branches from the middle cervical ganglion. The *left nerve*, in the thorax, runs in front of the left common carotid artery and across the left side of the arch of the aorta, to the superficial (ventral) part of the cardiac plexus. Sometimes it descends on the right side of the aorta and ends in the deep (dorsal) part of the cardiac plexus. It communicates with the cardiac branches of the middle cervical and cervicothoracic sympathetic ganglia, and sometimes with the inferior cervical cardiac branches of the left vagus, and branches from these mixed nerves pass down to form a plexus on the ascending aorta.

The *anterior branches* of the superior cervical ganglion ramify upon the common carotid artery, and upon the external carotid artery and its branches, forming around each a delicate plexus in which small ganglia are occasionally found. The plexus fourth and seventh. The ganglion also gives off thyroid and cardiac branches. It is connected to the cervicothoracic ganglion by two or more cords, which are very variable in their disposition. The posterior cord usually splits to enclose the vertebral artery. The more anterior cord loops down in front of and then below the first part of the subclavian artery, medial to the origin of its internal thoracic branch, and supplies rami to it. This loop is the *ansa subclavia*. It is intimately related to the cervical pleura, frequently consists of more than one filament, and generally communicates with the phrenic nerve. It is uncertain whether this last connexion indicates a contribution to or from the phrenic nerve. Similarly, a connexion between the ansa subclavia and the vagus nerve, usually described, is of uncertain significance.

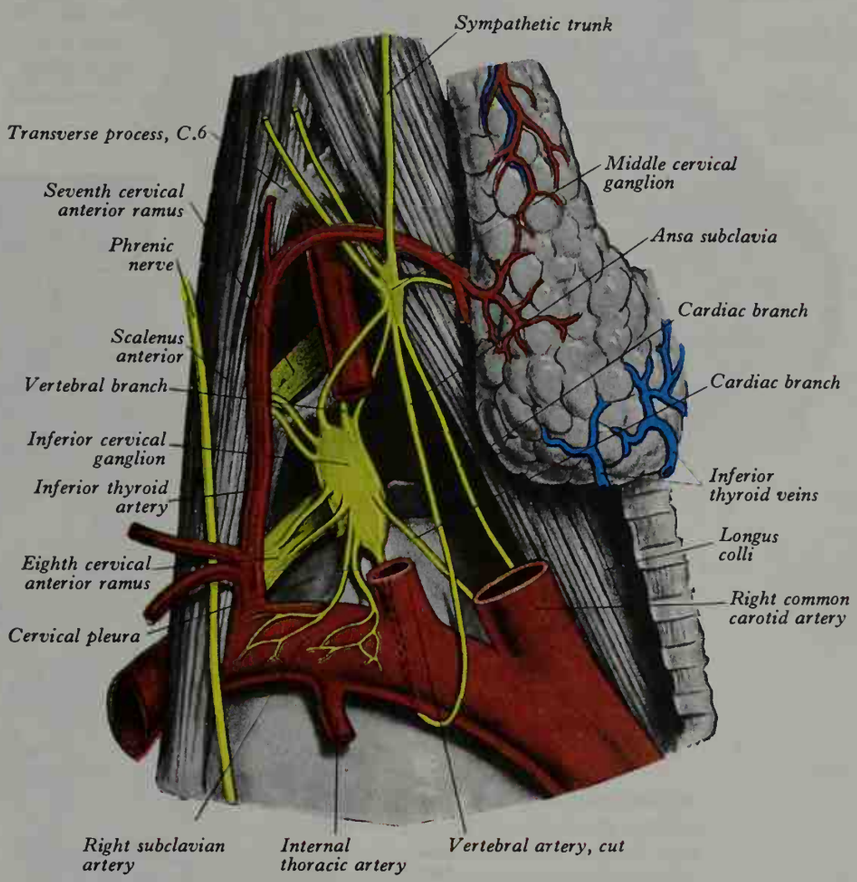
The *thyroid branches* run along the inferior thyroid artery to the thyroid gland; they communicate with the superior cardiac, external laryngeal and recurrent laryngeal nerves and send branches to the parathyroid glands. The supplies to the thyroid and parathyroid glands are in part vasomotor, but some fibres reach the secretory cells (Raybuck 1952).

The *cardiac branch*, the largest of the sympathetic cardiac branches, is derived from the ganglion itself or, more frequently, from the sympathetic trunk cranial or caudal to it. On the *right side* it descends behind the common carotid artery, and at the root of the neck runs either in front of or behind the subclavian artery; it

then descends on the trachea, receives a few filaments from the recurrent laryngeal nerve, and joins the right half of the deep (dorsal) part of the cardiac plexus. In the neck, it communicates with the superior cardiac and recurrent laryngeal nerves. On the *left side*, the nerve enters the thorax between the left common carotid and subclavian arteries, and joins the left half of the deep (dorsal) part of the cardiac plexus.

Fine branches from the middle cervical ganglion also pass to the trachea and oesophagus.

The cervicothoracic (stellate) ganglion is irregularly shaped, and much larger than the middle cervical ganglion, being probably formed by the coalescence of the lower two cervical segmental ganglia with the first thoracic. Sometimes the second (and even the third and fourth) thoracic ganglia are fused with the mass; in other instances the first thoracic ganglion is separate and the upper mass then constituting an *inferior cervical ganglion* (7.226, 227). Owing to the marked change in direction of the sympathetic trunk at the junction of the head and thorax, the long axis of the cervicothoracic ganglion is almost anteroposterior. The ganglion lies on or just lateral to the lateral border of the longus colli and between the base of the transverse process of the seventh cervical vertebra and the neck of the first rib, which are posterior to it, and the vertebral artery and its associated veins which are anterior. Below it is separated from the posterior aspect of the cervical pleura by the suprapleural membrane; the costocervical trunk branches near its lower pole. On its lateral side is the superior intercostal artery.



A small ganglion, the *vertebral ganglion*, may be found on the sympathetic trunk anterior or anteromedial to the commencement of the vertebral artery and directly above the subclavian artery. When present it may give rise to the ansa subclavia and is joined also to the cervicothoracic ganglion by fibres which pass both in front of and behind the vertebral artery. The vertebral ganglion is usually regarded as a detached portion of the middle cervical or cervicothoracic ganglion. Like the middle cervical ganglion it may supply grey rami communicantes to the fourth and fifth cervical spinal nerves.

The cervicothoracic ganglion sends grey rami communicantes to the seventh and eighth cervical and first thoracic nerves, gives off a cardiac branch, supplies branches to neighbouring vessels, and not infrequently sends a branch to join the vagus nerve.

The *grey rami communicantes* to the seventh cervical spinal nerve vary from one to five in number. Two, which is the usual number, are shown in 7.227. Another often ascends medial to the vertebral artery and in front of the transverse process of the seventh cervical vertebra and, after communicating here with the seventh cervical nerve, sends a small branch upwards through the foramen transversarium of the sixth cervical vertebra in company with the vertebral vessels to join the sixth cervical nerve as it emerges from the intervertebral foramen. Another inconstant branch may pass through the foramen transversarium of the seventh vertebra. The grey rami to the eighth cervical spinal nerve are also multiple and vary from three to six in number.

A *cardiac branch* arises from the cervicothoracic ganglion. It descends behind the subclavian artery and along the front of the trachea, to join the deep part of the cardiac plexus. Behind the subclavian artery it communicates with the recurrent laryngeal nerve and the cardiac branch of the middle cervical ganglion. It is often replaced by a variable number of fine branches derived from the cervicothoracic ganglion and the ansa subclavia.

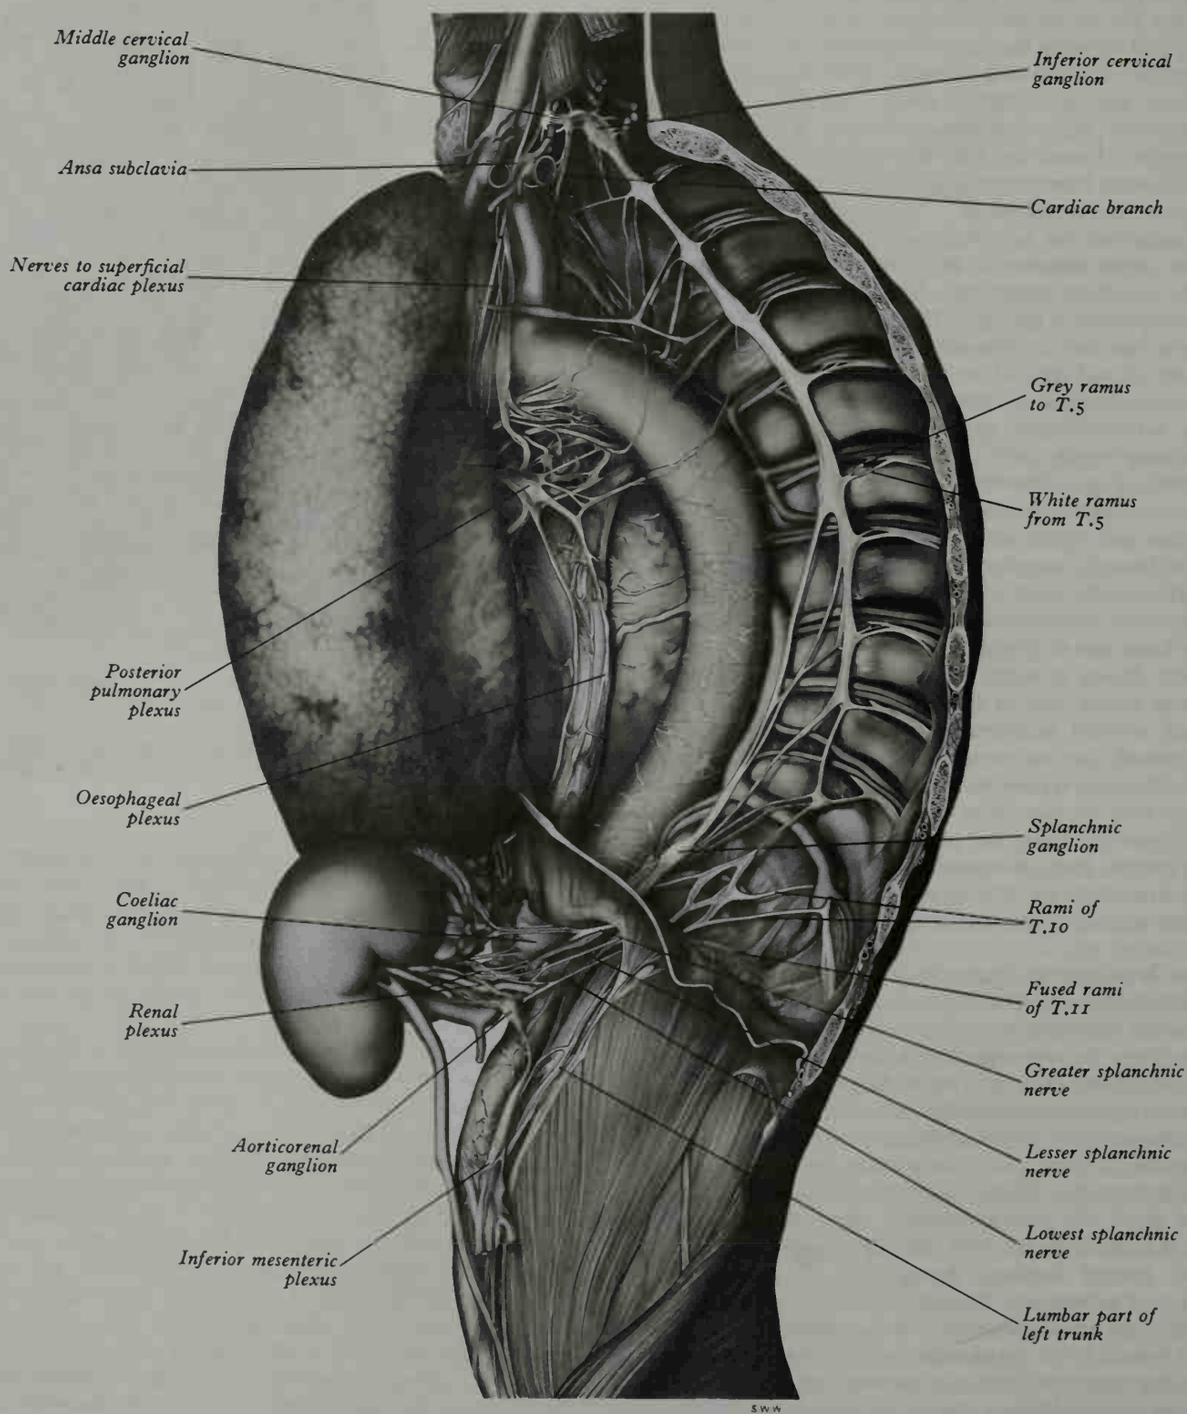
The *branches to blood vessels* form plexuses on the subclavian artery and its branches. The plexus around the subclavian artery is derived from the cervicothoracic ganglion and the ansa subclavia; it extends to the first part of the axillary artery, but fibres may extend further, though not in large numbers. According to Pearson and Sauter (1971) the extension of the subclavian plexus which passes on to the internal thoracic artery is joined by a branch from the phrenic nerve (see also p. 1094). The plexus on the vertebral artery is derived mainly from a thick branch of the cervicothoracic ganglion which ascends behind the vertebral artery to the foramen transversarium of the sixth cervical vertebra, reinforced by branches from the vertebral ganglion or the cervical sympathetic trunk which pass cranially on the ventral aspect of the artery. From the plexus, branches (*deep rami communicantes*) pass to the anterior rami of the upper five or six cervical spinal nerves. The plexus contains a number of nerve cells. The plexus is continued into the skull along the vertebral and basilar arteries and their branches as far as the posterior cerebral artery, where it meets the plexus derived from that on the internal carotid artery. Some authorities consider that the vertebral plexus represents the main intracranial extension of the sympathetic system (Lazorthes 1949; Mitchell 1952). The plexus on the inferior thyroid artery accompanies the artery to the thyroid gland, and communicates with the recurrent and external

7.227 B Anterior view of the same structures as in 7.227 A. Part of the vertebral artery has been excised to show the inferior cervical ganglion.

laryngeal nerves, with the cardiac branch of the superior cervical ganglion, and with the plexus on the common carotid artery.

The preganglionic fibres for the head and neck leave the spinal cord through the upper five thoracic nerves (mainly the upper three); they pass up the sympathetic trunk to synapse about cells in the cervical ganglia, whence postganglionic fibres are distributed as indicated above.

The preganglionic fibres concerned with supplying the upper limb are derived from the upper thoracic segments of the spinal cord, probably T. 2–6 (or 7). These fibres ascend the sympathetic trunk to synapse with cells mainly in the cervicothoracic ganglion, whence postganglionic fibres pass to the brachial plexus, mainly the lower trunk. Most of the vasoconstrictor fibres supplying the arteries of the upper limb emerge from the spinal cord in the ventral roots of the second and third thoracic nerves. These arteries can thus be denervated surgically by cutting the sympathetic trunk below the third thoracic ganglion, severing the rami communicantes connected with the second and third thoracic ganglia, or cutting (intradurally) the ventral roots of the second and third thoracic spinal nerves. The white ramus to the cervicothoracic ganglion is not cut, partly because it does not convey many vasomotor or sudomotor fibres to the upper limb, but mainly because it contains most of the preganglionic fibres which pass up the sympathetic trunk to the superior cervical



ganglion, from which postganglionic branches pass to supply vasoconstrictor and sudomotor nerves to the face and neck, secretory fibres to the salivary glands, the dilatator pupillae (and probably ciliaris oculi), the non-striated muscle in the upper and lower eyelids and the orbitalis. Destruction of this nerve would result in constriction of the pupil, drooping of the upper eyelid (ptosis), enophthalmos and absence of sweating on the face and neck (*Horner's syndrome*), and possibly some disturbance of accommodation. For a review of such procedures consult Haxton (1954).

The blood vessels of the upper limb beyond the first part of the axillary artery receive their sympathetic nerve supply by means of branches from the brachial plexus through nerves adjacent to the arteries, e.g. the median nerve supplies branches to the brachial artery and palmar arches, the ulnar nerve supplies the ulnar artery and palmar arches and the radial nerve supplies the radial artery.

The first and second (and occasionally the third) intercostal nerves are sometimes connected together in front of the necks of the ribs by filaments which contain postganglionic fibres derived from the grey rami associated with these nerves; these fibres provide another pathway by which postganglionic nerves from the upper thoracic ganglia may pass to the brachial plexus.

THORACIC PART OF THE SYMPATHETIC SYSTEM

The thoracic part of each sympathetic trunk (7.226, 228) contains a series of ganglia, which usually correspond approximately in number to that of the thoracic spinal nerves, but their number is variable. (The number is 11 in more than 70 per cent, occasionally 12, rarely 10 or 13.) The first thoracic ganglion is usually fused with the inferior cervical to form the cervicothoracic ganglion. Jit and Mukerjee (1960) found a fused ganglion in 80 of 100 dissections. Rarely, the middle cervical or second thoracic ganglion may be included.) The succeeding ganglion is called the

7.228 The thoracic part of the sympathetic system of the left side. (Drawn from a dissection by the late Dr. G. D. Channell.) Note that the diaphragm has been divided close to its posterior attachment, and the left lung and the left kidney have been drawn forwards and rotated to the right, so as to expose the posterior surface of the left kidney and suprarenal gland.

second thoracic ganglion in order that each thoracic ganglion should correspond numerically with the other segmental structures. With the exception of the last two or three, the thoracic ganglia rest against the heads of the ribs, and are posterior to the costal pleura; the last two or three are placed on the sides of the bodies of the corresponding vertebrae. Inferiorly, the thoracic sympathetic trunk passes dorsal to the medial arcuate ligament (or through the crus of the diaphragm) to become continuous with the lumbar sympathetic trunk. The ganglia are small and are connected together by the intervening portions of the trunk.

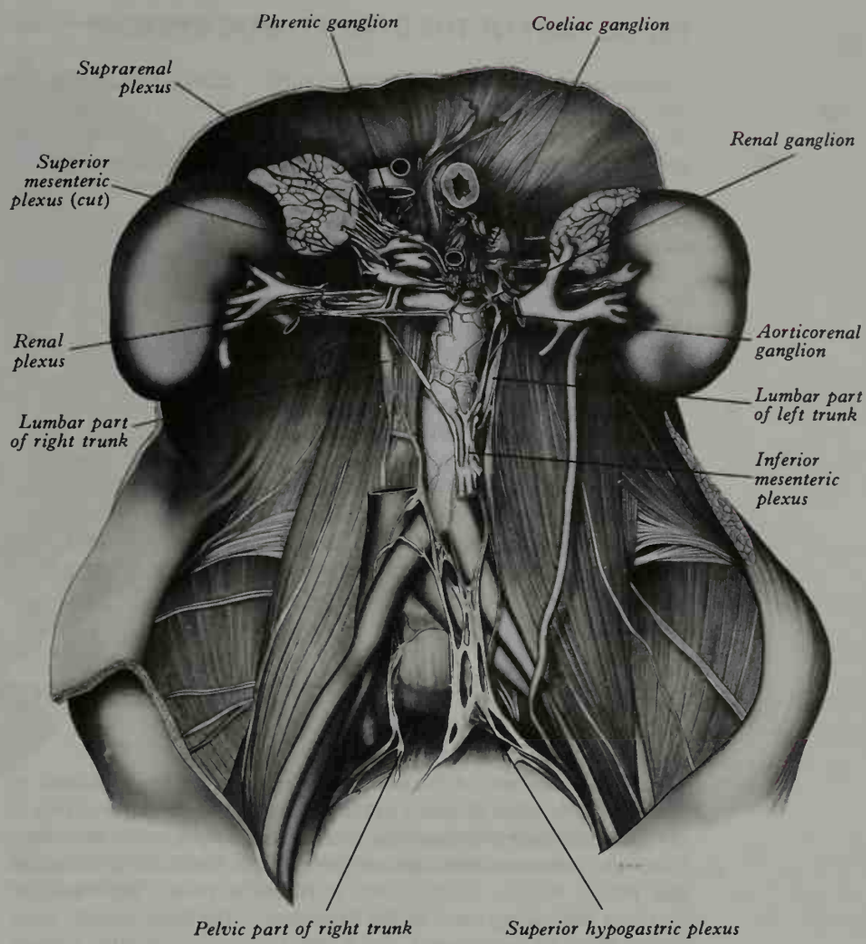
Two or more rami communicantes, white and grey, connect each ganglion with its corresponding spinal nerve, the white rami joining the spinal nerve farther distally than the grey. Sometimes a grey and white ramus may be fused to form a single 'mixed' ramus (p. 1123).

The *medial branches from the upper five ganglia* are very small; they supply filaments to the thoracic aorta and its branches. On the aorta they form a delicate plexus (*thoracic aortic plexus*) together with filaments from the greater splanchnic nerve. Twigs from the second to fifth or sixth ganglia enter the posterior pulmonary plexus; others, from the second, third, fourth and fifth ganglia, pass to the deep (dorsal) part of the cardiac plexus. Small branches from these pulmonary and cardiac nerves pass to the oesophagus and trachea.

The *medial branches from the lower seven ganglia* are large; they distribute filaments to the aorta, and unite to form the greater, the lesser and the lowest splanchnic nerves, the last of which is not always identifiable.

The *greater splanchnic nerve* consists mainly of myelinated, preganglionic and visceral afferent fibres; it is formed by branches from the fifth to the ninth or tenth thoracic ganglia, but the fibres in the higher branches may be traced upwards in the sympathetic trunk as far as the first or second thoracic ganglion. Its roots of origin may vary from 1 to 8, 4 being most usual. It descends obliquely on the bodies of the vertebrae, supplies fine branches to the descending thoracic aorta, perforates the crus of the diaphragm, and ends mainly in the coeliac ganglion, but partly in the aorticorenal ganglion and the suprarenal gland. A *splanchnic ganglion* exists on this nerve opposite the eleventh or twelfth thoracic vertebra in 17 to 68 per cent of *dissections* (*see* Jit and Mukerjee 1960 for details); but Mitchell (1953) reported that *microscopic* evidence showed it to be always present.

The *lesser splanchnic nerve* is formed by filaments from the ninth and tenth, sometimes the tenth and eleventh, thoracic ganglia, and from the trunk between the ganglia. It pierces the diaphragm with the preceding nerve, and joins the aorticorenal ganglion.



The *lowest splanchnic nerve* (or renal nerve) arises from the last thoracic ganglion. It gains the abdomen with the sympathetic trunk, and ends in the renal plexus.

Jit and Mukerjee (1960) have described in great detail dissections of the thoracic sympathetic system in 50 cadavers and have surveyed previous findings. For example, the incidence of the splanchnic nerves, according to seven observers is as follows: greater—always present, lesser—94 per cent (86–100 per cent), least—56 per cent (16–98 per cent). A fourth (accessory) splanchnic nerve has been described by de Sousa (1955), but its existence has not been confirmed.

LUMBAR PART OF THE SYMPATHETIC SYSTEM

The lumbar part of each sympathetic trunk (7.228, 229) usually consists of four lumbar ganglia, connected together by the intervening portions of the trunk. It is in the extraperitoneal connective tissue anterior to the vertebral column, along the medial margin of the psoas major. Posterior to the medial arcuate ligament it continues as the thoracic part of the trunk and inferiorly, by passing posterior to the common iliac artery, with the pelvic part. On the right side it is overlapped by the inferior vena cava; on the left by the lateral aortic lymph nodes. It lies in front of the lumbar vessels, but some lumbar veins may pass anterior to it.

The first and second, and sometimes the third, lumbar ventral rami send *white rami communicantes* to the corresponding ganglia.

7.229 The abdominal part of the sympathetic system. (Drawn from a dissection by the late Dr. G. D. Channell, Guy's Hospital Medical School.)

Grey rami communicantes pass from all the ganglia to the lumbar spinal nerves. These rami are of considerable length and accompany the lumbar arteries round the sides of the bodies of the vertebrae, medial to the fibrous arches to which the psoas major is attached.

Generally four *lumbar splanchnic nerves* pass from the ganglia to join the coeliac, intermesenteric (abdominal aortic) and superior hypogastric plexuses. The first lumbar splanchnic nerve arises from the first ganglion and joins the coeliac, renal and intermesenteric plexuses. The second nerve arises from the second (and sometimes also the third) ganglion and joins the lower part of the intermesenteric plexus. The third nerve issues from the third or fourth ganglion and passes in front of the common iliac vessels to join the superior hypogastric plexus. The fourth lumbar splanchnic, from the lowest ganglion, goes dorsal to the common iliac vessels to join the lower part of the superior hypogastric plexus or the hypogastric 'nerve'.

Vascular branches from all the lumbar ganglia pass to the intermesenteric (aortic) plexus. From the lower lumbar splanchnic nerves, fibres pass to the common iliac arteries, around which they form a plexus continued thence along the internal iliac artery and around the external iliac artery, in the latter case as far as the proximal part of the femoral artery. Many of the postganglionic fibres in the grey rami, connecting the lumbar ganglia to the lumbar spinal nerves, travel in the femoral nerve, and thence in its muscular, cutaneous and saphenous branches, to supply vasoconstrictor nerves to the femoral artery and its branches in the thigh. Other postganglionic fibres travel in the obturator nerve to the obturator artery. Considerable uncertainties persist with regard to the sympathetic supply to the lower limb (*see* Wilde 1951; Wyburn 1956; Pick 1970).

PELVIC PART OF THE SYMPATHETIC SYSTEM

The pelvic part of each sympathetic trunk (7.229) is situated in the extraperitoneal tissue in front of the sacrum, medial or anterior to the anterior sacral foramina. It comprises four or five sacral ganglia, connected by the intervening sections of the trunk. It is continuous cranially with the lumbar part, while caudally, the two pelvic sympathetic trunks converge, and unite on the front of the coccyx in the small *ganglion impar*.

Grey rami communicantes pass from the ganglia to the sacral and coccygeal spinal nerves. No white rami communicantes pass to this part of the sympathetic trunk.

The *medial branches of distribution* communicate on the front of the sacrum with the corresponding branches from the opposite side; twigs from the first two ganglia join the inferior hypogastric plexus (pelvis plexus) or the hypogastric nerve, and others form a plexus on the median sacral artery. Filaments are distributed to the glomus coccygeum from the loop uniting the two trunks. The 'hypogastric nerve', which is itself usually plexiform, is a somewhat redundant term for the connexions, right and left, which exist between the superior and inferior hypogastric plexuses. (*See* p. 1125.)

Vascular branches. Through the grey rami many postganglionic fibres pass to the roots of the sacral plexus, particularly those forming the tibial nerve, to be conveyed to the popliteal artery and its branches in the leg and foot. Others are conveyed by the pudendal and superior and inferior gluteal nerves to the accompanying arteries. Branches to lymph nodes are also described (Woźniak 1967).

The preganglionic fibres concerned with supplying the lower limb are derived from the lower three thoracic and upper two or three lumbar segments of the spinal cord. They reach the lower thoracic and upper lumbar ganglia through the white rami and some pass down the sympathetic trunk to synapse about cells in the lumbar ganglia, whence postganglionic fibres pass to the femoral nerve to be distributed to the femoral artery and its branches in the thigh; other fibres pass down the sympathetic trunk to synapse with cells in the upper two or three sacral ganglia, whence postganglionic axons pass to the tibial nerve to supply the popliteal artery and its branches in the leg and foot. Sympathetic denervation of the vessels of the lower limb can thus be produced by removing the upper three lumbar ganglia and the intervening parts of the sympathetic trunk, all the preganglionic fibres to the lower limb thus being divided.

PLEXUSES OF THE AUTONOMIC NERVOUS SYSTEM

The larger plexuses of the autonomic system are aggregations of nerves and ganglia, situated in the thoracic, abdominal and pelvic cavities, and named the cardiac, coeliac and hypogastric plexuses. From the plexuses branches are given to the thoracic, abdominal and pelvic viscera. Extensions from these major perivascular plexuses pass along most of the branches of the large vessels with which they are associated. Such extensions are usually named after the branch artery along which they are distributed. This leads to a plethora of named plexuses, receiving separate description, the details of which may overshadow the essential continuity of the vascular plexuses in the thorax, abdomen and pelvis.

THE CARDIAC PLEXUSES

The cardiac plexus (7.226, 228) is situated at the base of the heart, and is divided into a *superficial* and a *deep* (dorsal) *part*, which are closely connected. Several small ganglia are found in the plexus, the largest and most constant being the *cardiac ganglion* described below. Mizeres (1963) has emphasized the unity of the cardiac plexus, division of which into superficial and deep parts he considered an artefact of dissection; he was, however, prepared to accord regional names to the coronary, pulmonary, atrial and aortic extensions of the plexus. Since, however, major regions of the plexus are situated as described here, the terms superficial and deep have been retained.

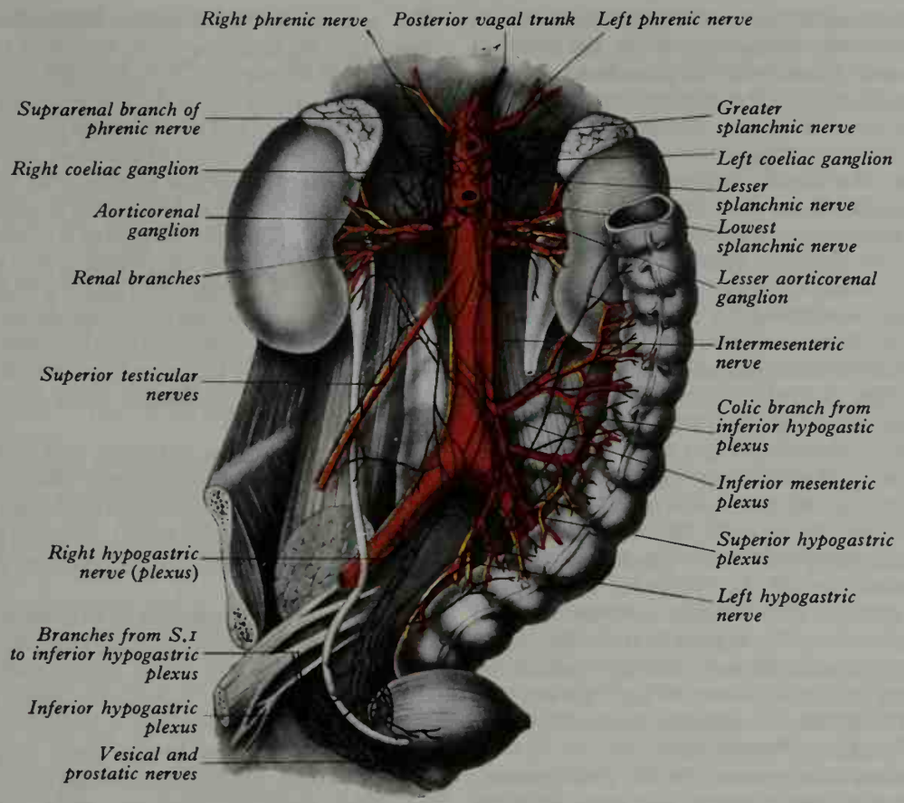
The superficial (ventral) part of the cardiac plexus lies below the arch of the aorta, anterior to the right pulmonary artery. It is formed by the cardiac branch of the superior cervical ganglion of the left sympathetic trunk, and the lower of the two cervical cardiac branches of the left vagus. A small ganglion, termed the *cardiac ganglion*, is usually present in this plexus, and is situated immediately below the arch of the aorta, on the right of the ligamentum arteriosum. The superficial part of the cardiac plexus gives branches (*a*) to the deep part of the plexus, (*b*) to the right coronary plexus, (*c*) to the left anterior pulmonary plexus.

The deep (dorsal) part of the cardiac plexus is situated in front of the bifurcation of the trachea, above the point of division of the pulmonary trunk, and posterior to the aortic arch. It is formed by the cardiac nerves derived from the cervical and upper thoracic ganglia of the sympathetic trunk, and the cardiac branches of the vagus and recurrent laryngeal nerves. The only cardiac nerves which do not join the deep part of the cardiac plexus are those already noted as joining the superficial part of the plexus.

The branches from the *right half* of the deep part of the cardiac plexus pass, some in front of, and others behind, the right pulmonary artery; the former, the more numerous, transmit a few filaments to the right anterior pulmonary plexus, and are then continued onwards to form part of the right coronary plexus; those behind the pulmonary artery distribute a few filaments to the right atrium, and are then continued onwards to form part of the left coronary plexus.

The *left half* of the deep part of the cardiac plexus is connected with the superficial part of the plexus, and gives filaments to the left atrium, and to the left anterior pulmonary plexus, and is then continued to form the greater part of the left coronary plexus.

The left coronary plexus is larger than the right, and accompanies the left coronary artery; it is formed chiefly by filaments prolonged from the left half of the deep part of the cardiac plexus, and by a few from the right half. It gives branches to the left atrium and ventricle.



The right coronary plexus is formed partly from the superficial and partly from the deep parts of the cardiac plexus. It accompanies the right coronary artery, and gives branches to the right atrium and ventricle.

The atrial plexuses, as described by Mizeres (1963), are derivatives of the right and left continuations of the cardiac plexus which extend along the pulmonary arteries. Their fibres are distributed to the corresponding atria, overlapping with those of the coronary plexuses.

All the cardiac branches of the vagus and the sympathetic contain both afferent and efferent fibres, except the cardiac branch of the superior cervical sympathetic ganglion which contains efferent (postganglionic) fibres only.

The *efferent* preganglionic sympathetic fibres arise in the upper four or five thoracic segments of the spinal cord; they pass by white rami communicantes to synapse about cells in the upper thoracic ganglia on the sympathetic trunk, though many travel up the trunk to synapse in the cervical ganglia. From the thoracic and cervical ganglia, postganglionic fibres emerge to form the sympathetic cardiac nerves, the functions of which are cardiac acceleration and dilatation of the coronary arteries. Of the sympathetic fibres arising from the first four or five segments of the spinal cord, the upper ones pass to the ascending aorta, pulmonary trunk and ventricles, while the lower ones supply the atria.

The *efferent* cardiac parasympathetic fibres are derived from the dorsal nucleus of the vagus and from cells near the nucleus ambiguus, and run in the cardiac branches of the vagus to synapse about cells in the cardiac plexuses and in the walls of the atria. These vagal fibres are concerned with slowing of the heart and

7.230 Autonomic nerves and plexuses in the abdomen and pelvis. (After G. A. G. Mitchell, *Anatomy of the Autonomic Nervous System*, by courtesy of the author and the publishers.) Note the ascending branches of the inferior hypogastric plexus passing up to supply the descending colon. The sympathetic trunks are not shown on the right side; note the upper, middle and lower ureteric nerves.

with constriction of the coronary arteries (see also p. 1121). In man (and most mammals) the intrinsic cardiac nerve cells are limited to the atria and the interatrial septum (Davies *et al.* 1952; King and Coakley 1958); they are most numerous in the subepicardial connective tissue and near the sinuatrial and atrioventricular nodes. For an exposition of variations in the human sympathetic cardiac innervation, consult Ellison and Williams (1969).

THE PULMONARY PLEXUSES

The pulmonary plexuses lie on the anterior and posterior aspects of the bronchial and vascular structures in the hila of the lungs, the anterior pulmonary plexus being much smaller than the posterior. (According to Mizeres 1963, these plexuses are continuous with extensions from the cardiac plexus along the right and left pulmonary arteries.) The plexuses are formed by branches from the vagus and the sympathetic. The efferent parasympathetic fibres arise from the dorsal nucleus of the vagus. The efferent sympathetic fibres are postganglionic branches of the second to fifth thoracic ganglia of the sympathetic trunk.

The *anterior part of the pulmonary plexus* is formed by branches from the cardiac branches of the vagus and cervical sympathetic trunk as well as direct branches from both these sources. The *posterior part of the pulmonary plexus* is formed by rami of the cardiac branches of the vagus, from the cardiac plexus and from the second to fifth or sixth thoracic sympathetic ganglia, the left plexus receiving additional branches from the left recurrent laryngeal nerve.

From the plexuses, nerves pass into the lung to form networks around the branches of the bronchi and the pulmonary and bronchial vessels, extending as far as the visceral pleura. On these nerves, near the hila of the lungs, there are minute collections of nerve cells with which the efferent preganglionic vagal fibres synapse. (In a number of organs, notably the small intestine, *interstitial cells* have been described in the terminal autonomic network which is characteristic in many sites. The presence of these in thoracic organs, apart perhaps from the oesophagus, has not been substantiated—Dijkstra 1969.) The efferent vagal fibres are bronchoconstrictor, secretomotor to the mucous bronchial glands and vasodilator in function. The efferent sympathetic fibres are bronchodilator and vasoconstrictor.

THE COELIAC PLEXUS

The coeliac plexus (7.226, 229), the largest of the three great autonomic plexuses, is situated at the level of the last thoracic and the upper part of the first lumbar vertebra, and is a dense network of nerve fibres which unite together two large *coeliac ganglia*. It surrounds the coeliac artery and the root of the superior mesenteric artery. It lies posterior to the stomach and the omental bursa, anterior to the crura of the diaphragm and the commencement of the abdominal aorta, and between the suprarenal glands. The plexus and the ganglia are joined by the greater and lesser splanchnic nerves of both sides and some filaments from the vagus and phrenic nerves and extend as numerous secondary plexuses along the neighbouring arteries.

The *coeliac ganglia* are two irregularly shaped masses placed, one on each side of the median plane, between the suprarenal gland and the origin of the coeliac artery, and in front of the crura of the diaphragm, that on the right side being placed behind the inferior vena cava and that on the left side behind the splenic vessels. The upper part of each ganglion is joined by the greater splanchnic nerve, while the lower part, which is more or less detached and is named the *aorticorenal* ganglion, receives the lesser splanchnic nerve and gives off the greater part of the renal plexus. The position of the ganglion is very variable, being anywhere in the general vicinity of the origin of the renal artery from the aorta. For a detailed description and discussion of its connexions, and the distribution of its fibres to tubules and glomeruli, in the kidney, consult Norvell (1968).

The secondary plexuses springing from or connected with the coeliac plexus are the phrenic, splenic, hepatic, left gastric, intermesenteric, suprarenal, renal, testicular or ovarian, superior mesenteric, and inferior mesenteric.

The phrenic plexus accompanies the corresponding inferior phrenic artery to the diaphragm, some filaments passing to the suprarenal gland. It arises from the upper part of the coeliac

ganglion, and is larger on the right than on the left side. It receives one or two branches from the phrenic nerve. At the point of junction of the right phrenic plexus with the phrenic nerve there is a small mass, the *phrenic ganglion*. This plexus distributes some branches to the inferior vena cava, and to the suprarenal and hepatic plexuses.

The hepatic plexus, the largest derivative of the coeliac plexus, also receives filaments from the left and right vagus and right phrenic nerves. It accompanies the hepatic artery and portal vein and their branches into the liver, and in the liver the nerves are confined to the vicinity of the blood vessels. Branches from the plexus accompany all the branches of the hepatic artery. Those passing to the gall bladder form a scanty *cystic plexus*; branches also pass to the bile ducts. The branches accompanying the right gastric artery supply the pylorus. A considerable plexus accompanies the gastroduodenal artery and its branches. From this plexus branches pass to the pylorus and superior part of the duodenum. Many of the nerves pass with the right gastro-epiploic artery to supply the right part of the stomach and the greater curvature. Others pass with the superior pancreaticoduodenal artery and supply the descending part of the duodenum, head of the pancreas and the lower part of the bile duct. The hepatic plexus contains both afferent and efferent sympathetic and parasympathetic fibres, and it is believed that the vagal constituents are motor to the musculature of the gall bladder and bile ducts and inhibitory to the sphincter of the bile duct. A distinct nerve to the sphincter was identified in twenty-three out of twenty-five human dissections (Petkov 1968).

The left gastric plexus accompanies the left gastric artery along the lesser curvature of the stomach, and joins with the gastric branches of the vagus nerves. The gastric sympathetic nerves are motor to the pyloric sphincter but inhibitory to the muscular coats of the stomach.

The splenic plexus is formed by branches from the coeliac plexus, left coeliac ganglion and right vagus nerve. It accompanies the splenic artery to the spleen, giving off, in its course, subsidiary plexuses along the various branches of the artery. The fibres are principally, if not wholly, sympathetic in origin and terminate on the blood vessels and unstriped muscle of the splenic capsule and trabeculae.

The suprarenal plexus is formed by branches from the coeliac ganglion, coeliac plexus and the greater splanchnic nerve. Relative to its size, the suprarenal gland has a larger autonomic supply than any other organ. The nerves have hitherto been described as myelinated and preganglionic in nature. In the rat, however, the non-myelinated fibres are ten times as numerous as the myelinated; these non-myelinated fibres are regarded as preganglionic. They terminate in synapses, often deeply invaginated, in contiguity with large chromaffin cells, the phaeochromocytes, which are hence homologous with postganglionic sympathetic neurons (p. 1458). A space of 150–200 nm separates the contiguous plasma membranes which often exhibit electron-dense zones. Small vesicles and large vesicles with electron-dense granular contents are present in the endings. Only non-myelinated fibres have been seen innervating chromaffin cells, all of which are related to one or more nerve terminal. Multipolar nerve cell bodies are also found in the adrenal medulla and some of the preganglionic non-myelinated nerve fibres form axodendritic synapses with these cells. The destination of the axons of these nerve cells is not known (Coupland 1965*a*). A preponderance of non-myelinated fibres in the suprarenal plexus has also been described in man (Coupland 1965 *a* and *b*; Grottel 1968).

The renal plexus is a rich plexus formed by filaments from the coeliac ganglion, coeliac plexus, aorticorenal ganglion, lowest thoracic splanchnic nerve, first lumbar splanchnic nerve and aortic plexus. Small collections of nerve cells are found in the plexus, the largest usually lying behind the commencement of the renal artery. The plexus is continued into the kidney around the branches of the renal artery to supply the vessels and the renal glomeruli and tubules, particularly the tubules in the cortex of the kidney (Norvell 1968). For the main part the renal nerves are vasomotor in function. From the renal plexus branches are given to the ureteric and the testicular (or ovarian) plexuses.

The *ureteric plexus* receives fibres from three sources, the upper part by branches from the renal and aortic plexuses, the middle part by branches from the superior hypogastric plexus and the hypogastric nerve, and the lower part by branches from the hypogastric nerve and the inferior hypogastric plexus. The nerves to the ureter are believed to influence its inherent motility.

The testicular plexus accompanies the gonadal artery to the testis. Its upper part is formed by branches from the renal and aortic plexuses. Distally the plexus is reinforced by branches from the superior and inferior hypogastric plexuses. Branches from the plexus pass to the epididymis and the ductus deferens.

The ovarian plexus accompanies the ovarian artery and is distributed to the ovary and uterine tube. The upper part of the plexus is formed by branches from the renal and aortic plexuses; lower down it is reinforced from the superior and inferior hypogastric plexuses.

The nerves in the testicular and ovarian plexuses contain efferent and afferent sympathetic fibres; the efferent fibres are vasomotor in nature and are derived from the tenth and eleventh thoracic segments of the spinal cord; the parasympathetic fibres, derived from the inferior hypogastric plexuses, are probably vasodilator in nature.

The superior mesenteric plexus is a continuation of the lower part of the coeliac plexus, and receives a branch from the junction of the right vagus nerve with the latter plexus. It surrounds the superior mesenteric artery, accompanies it into the mesentery, and divides into a number of secondary plexuses which are distributed to the parts supplied by the artery—pancreatic branches to the pancreas; jejunal and ileal branches to the small intestine; ileocolic, right colic, and middle colic branches, which supply the corresponding parts of the large intestine. The *superior mesenteric ganglion* is situated in the upper part of the plexus, usually immediately above the origin of the superior mesenteric artery.

The sympathetic nerves to the intestine are motor to the ileocaecal sphincter but inhibitory to the muscle of the gut. In addition, they convey vasoconstrictor fibres.

The abdominal aortic plexus (intermesenteric plexus) is formed by branches from the coeliac plexus and ganglia, and receives filaments from the first and second lumbar splanchnic nerves. It is situated upon the sides and front of the aorta, between the origins of the superior and inferior mesenteric arteries. It is not a dense plexus but consists of four to twelve nerves (intermesenteric nerves) connected by obliquely arranged branches. It is continuous above with the coeliac plexus and the coeliac and aorticorenal ganglia, and below with the superior hypogastric plexus. From this plexus parts of the testicular, the inferior mesenteric, the iliac and the superior hypogastric plexuses arise; it also distributes filaments to the inferior vena cava.

The inferior mesenteric plexus is derived chiefly from the aortic plexus, but also receives branches from the second and third lumbar splanchnic nerves. It surrounds the inferior mesenteric artery and is distributed along its branches; thus the left colic plexus supplies the left part of the transverse colon, the descending colon and sigmoid colon, and the superior rectal plexus supplies the rectum. Just above, or below, the origin of the inferior mesenteric artery, a ganglion (the *inferior mesenteric ganglion*) may sometimes be found, but more often small discrete ganglia are scattered about the commencement of the artery in the proximal part of the plexus. In one study (Southam 1959) an inferior mesenteric ganglion occurred in every one of twenty-two human stillborn infants examined. The colic sympathetic nerves are inhibitory to the muscular coats of the colon and rectum. Branches from the parasympathetic pelvic splanchnic nerves run up occasionally through but usually near the superior hypogastric and the inferior mesenteric plexuses to supply the large intestine from the left part of the transverse colon down as far as the rectum (p. 1123 and *vide infra*); impulses along these nerves cause contraction of the musculature of the gut. It is to be emphasized that the parasympathetic supply to the distal colon is largely by these direct branches of the pelvic splanchnic nerves and not *via* the hypogastric and inferior mesenteric plexuses (Mitchell 1935; Woodburne 1956).

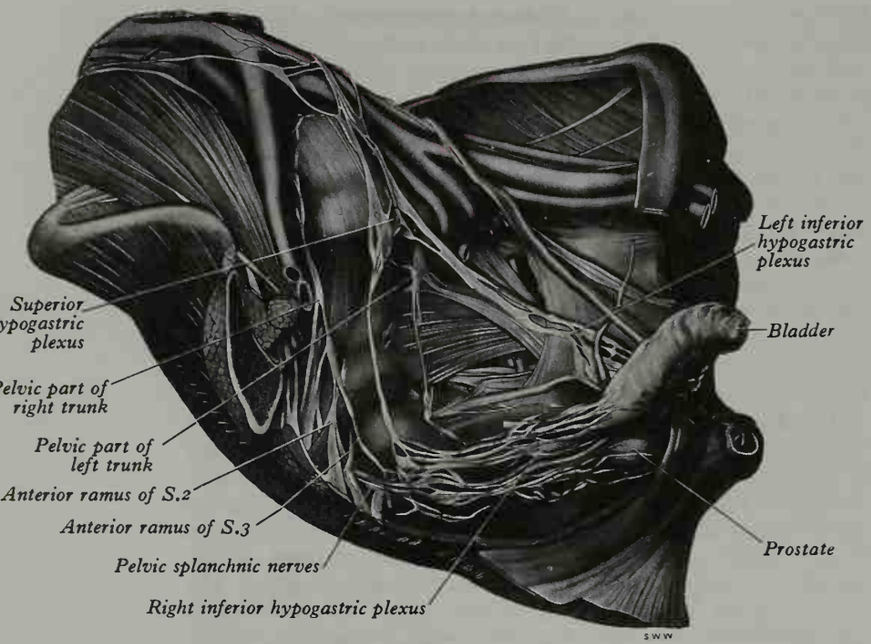
THE SUPERIOR HYPOGASTRIC PLEXUS

The superior hypogastric plexus (7.229–231) is situated in front of the bifurcation of the abdominal aorta, the left common iliac vein, the median sacral vessels, the body of the last lumbar vertebra and the promontory of the sacrum, and between the two common iliac arteries. It is often referred to as the *presacral nerve*, but the plexus is seldom sufficiently condensed to resemble a single nerve and moreover the plexus is prelumbar rather than presacral in position. It lies in the extraperitoneal connective tissue, and the parietal peritoneum can easily be stripped off its anterior surface. The plexus varies in breadth and in the degree of condensation of its constituent nerves, and it often lies a little to one side of the median plane (more often to the left side); the root of the sigmoid mesocolon, containing the superior rectal vessels, lies to the left side of the lower part of the plexus. Scattered nerve cells are found in the plexus.

Above, the plexus is formed by the union of branches from the aortic plexus with the third and fourth lumbar splanchnic nerves. Below, the plexus divides into the right and left hypogastric nerves which descend to the two inferior hypogastric plexuses. The superior hypogastric plexus gives off branches to the ureteric and testicular (or ovarian) plexuses and to those on the common iliac arteries. In addition to the sympathetic fibres which descend to form the superior hypogastric plexus, it may contain parasympathetic fibres (from the pelvic splanchnic nerves) which ascend from the inferior hypogastric plexus, though usually these parasympathetic fibres run up to the left of the superior hypogastric plexus and across the sigmoid vessels and the branches of the left colic vessels. These parasympathetic fibres are distributed partly along the branches of the inferior mesenteric artery, but also as independent retroperitoneal nerves, to supply the left part of the transverse colon, the left colic flexure, the descending colon and the sigmoid colon (*see* p. 1123 and 7.230).

THE INFERIOR HYPOGASTRIC PLEXUSES

The superior hypogastric plexus divides below into the right and left *hypogastric 'nerves'*, each of which runs down in the extraperitoneal connective tissue into the pelvis, medial to each internal iliac artery and its branches, to become the inferior hypogastric plexus (7.231). Each nerve may be single or may form an elongated narrow plexus consisting of two or three longitudinal nerves connected by anastomosing filaments. (The hypogastric nerves can scarcely be distinguished from their continuations, the inferior hypogastric plexuses. The latter are joined by the pelvic splanchnic nerves, but this distinction is minimized by the fact that both the nerves and the plexuses contain sympathetic and parasympathetic fibres. Some authorities prefer to describe the superior hypogastric plexus as dividing into two inferior hypogastric plexuses.) From each hypogastric nerve branches may pass to the testicular or ovarian plexus, the ureteric plexus, the plexus on the internal iliac artery and to the sigmoid colon, and each nerve may be joined near its commencement by the lowest lumbar splanchnic nerve, i.e. from the last lumbar sympathetic ganglion.



The inferior hypogastric (or pelvic) plexus lies in the extraperitoneal connective tissue. In the male it is situated on the side of the rectum, seminal vesicle, prostate and the posterior part of the urinary bladder; in the female, each plexus is placed on the side of the rectum, uterine cervix, vaginal fornix and posterior part of the urinary bladder, and extends into the base of the broad ligament of the uterus. Laterally are the internal iliac vessels and their branches and tributaries, levator ani, coccygeus and obturator internus. Behind are the sacral and coccygeal plexuses and above are the superior vesical and obliterated umbilical arteries. The plexuses contain numerous small ganglia. Each plexus is formed by the hypogastric nerve, which conveys most of the sympathetic fibres to the plexus, and by branches from the ganglia, which convey only a few fibres to the plexus; the parasympathetic fibres in the plexus are derived from the pelvic splanchnic nerves. The preganglionic efferent sympathetic fibres originate in the lower three thoracic and upper two lumbar segments of the spinal cord; some of these relay in the ganglia in the lumbar and sacral parts of the sympathetic trunk, while others synapse about cells in the lower part of the aortic plexus and in the superior and inferior hypogastric plexuses. The preganglionic parasympathetic fibres originate in the second, third and fourth sacral segments of the spinal cord, reach the plexus in the pelvic splanchnic nerves and synapse with cells in the plexus or in the walls of the viscera supplied by the branches of the plexus. From the plexus numerous branches are distributed to the pelvic (and some abdominal) viscera, either directly or by accompanying the branches of the internal iliac artery.

Parasympathetic fibres pass back into the superior hypogastric plexus, or as separate filaments accompanying it, to reach the inferior mesenteric plexus, through the medium of the aortic plexus. By this route the descending and sigmoid parts of the colon receive a parasympathetic innervation.

The middle rectal plexus arises from the upper part of the inferior hypogastric plexus; the fibres pass to the rectum either directly or along the middle rectal artery. The plexus communicates above with branches of the superior rectal plexus and extends inferiorly as far as the internal anal sphincter. The nerve supply of the rectum and anal canal is derived from (*a*) the superior rectal plexus, (*b*) the middle rectal plexus, and (*c*) the inferior rectal (haemorrhoidal) nerves, which are branches of the pudendal nerve. The parasympathetic preganglionic fibres from the superior and middle rectal plexuses synapse with postganglionic neurons in the myenteric plexus, which is well developed in this region. The sympathetic afferents pass through this plexus without interruption. The efferent sympathetic fibres in the rectal plexuses are concerned with inhibition of the expulsive musculature and contraction of the sphincter. Afferent pain impulses pass along both the sympathetic and parasympathetic nerves, but the parasympathetic afferent and efferent fibres are more active in the normal process of defaecation. The inferior rectal nerves supply motor fibres to the external anal sphincter and sensory (somatic) fibres to the lower (ectodermal) part of the anal canal (pp. 202, 1364).

The vesical plexus arises from the anterior part of the inferior hypogastric plexus. It is composed of numerous nerves which accompany the vesical arteries to the bladder. Branches from the plexus pass to the seminal vesicles and deferent ducts. Many small collections of nerve cells are present among the nerve fibres in the muscular wall of the bladder. The sympathetic preganglionic efferent fibres in the plexus arise from the lower two thoracic and upper two lumbar segments of the spinal cord; the cells about which they synapse are scattered in the superior and inferior hypogastric plexuses and in the wall of the bladder. The parasympathetic preganglionic efferent fibres arise from the second, third and fourth sacral segments of the spinal cord and synapse about cells near to or in the walls of the bladder. These neurons convey motor fibres to the muscular coats of the bladder and inhibitory fibres to the sphincter. The efferent sympathetic nerves convey motor fibres to the sphincter and inhibitory fibres to the muscular coats, though some observers maintain that the sympathetic fibres are mainly vasomotor in function and that filling and emptying of the bladder are normally controlled exclusively by the parasympathetic nerves.

The prostatic plexus arises from the lower part of the inferior hypogastric plexus and is composed of relatively large nerves which enter the base and sides of the prostate and contain collections of nerve cells. The nerves are distributed to the prostate, seminal vesicles, prostatic urethra, ejaculatory ducts, corpora cavernosa, corpus spongiosum, membranous and penile parts of the urethra and the bulbo-urethral glands. The nerves supplying the corpora cavernosa form two sets, the lesser and the greater cavernous nerves of the penis; these arise from the front part of the prostatic plexus, join with branches from the pudendal nerve and then pass forwards below the pubic arch. The filaments of the *lesser cavernous nerves* pierce the fibrous covering of the penis near its root and supply the erectile tissue of the corpus spongiosum and the penile urethra. The *greater cavernous nerves* run forwards on the dorsum of the penis, communicate with the dorsal nerve of the penis and are distributed to the erectile tissue; some of the filaments pass to the erectile tissue of the corpus spongiosum. The sympathetic nerves supplying the male genital

7.231 The pelvic part of the sympathetic system, viewed from in front and from the right side, a large part of the right hip bone having been removed. The superior hypogastric plexus is seen to divide below into the right and left hypogastric nerves (which are not labelled), which run down to the inferior hypogastric plexuses. (Drawn from a dissection by the late Dr. G. D. Channell, Guy's Hospital Medical School.)

organs produce vasoconstriction, while the parasympathetic produce vasodilatation.

The seminal vesicles are supplied by nerves derived from the vesical plexus, the prostatic plexus and the lower part of the inferior hypogastric nerves. From these nerves filaments pass to the ejaculatory ducts and to the deferent duct. It is generally believed that constriction of the seminal vesicles and seminal ejaculation are brought about by the sympathetic supply, which also produces inhibition of the bladder musculature and contraction of its sphincter during ejaculation, thus preventing reflex of the seminal fluid into the bladder. It has been, however, suggested that contraction of the seminal vesicles is due to parasympathetic impulses (Matthews and Raisman 1969).

The *uterine nerves* arise from the inferior hypogastric plexus, predominantly from the part of the plexus lying in the base of the broad ligament and known as the **uterovaginal plexus**. From the plexus some nerves pass down with the vaginal arteries, while others pass directly to the cervix uteri, or upwards with or near the uterine arteries in the broad ligament. The nerves passing to the cervix form a plexus in which small *paracervical* ganglia are found, one ganglion sometimes being large and called the *uterine cervical ganglion*. The uterine nerves passing upwards with the uterine arteries supply branches to the body of the uterus and, in the upper part of the broad ligament, they supply branches to the uterine tube and communicate with the tubal nerves from the inferior hypogastric plexus and with the nerves of the ovarian plexus. The branches of the uterine nerves ramify in the myometrium and endometrium; most of these nerves accompany the vessels. The efferent preganglionic sympathetic fibres supplying the uterus are derived from the last thoracic and first lumbar segments of the spinal cord; the sites of the cells about which they synapse are not known. The preganglionic parasympathetic fibres arise in the second, third and fourth sacral segments of the cord and relay in the paracervical ganglia. While activity of the sympathetic nerves may produce uterine contraction and vasoconstriction, and that of the parasympathetic nerves produce uterine inhibition and vasodilatation, the results of the activities of these two systems are complicated by the pronounced hormonal control of uterine functions.

The *vaginal nerves* arise from the lower parts of the inferior hypogastric and uterovaginal plexuses, and follow the vaginal arteries and their branches to be distributed to the walls of the vagina, the erectile tissue of the vestibular bulbs and the clitoris (cavernous nerves of the clitoris), the urethra and the greater vestibular glands. The nerves contain numerous parasympathetic fibres which have a vasodilator effect on the erectile tissue.

Afferent Autonomic Pathways

The efferent autonomic fibres to the viscera and blood vessels are accompanied by others which may be regarded as their sensory counterparts and designated *general visceral afferent* fibres, or perhaps more appropriately as *autonomic afferents*. These nerve fibres are the peripheral processes of unipolar cells in some of the cranial and spinal nerve ganglia. Their central processes (axons) pass in the corresponding nerves to the central nervous system. Their peripheral process (dendrites), which may be myelinated fibres of various sizes or non-myelinated fibres, are distributed with the pre- and post-ganglionic fibres of the parasympathetic and sympathetic subdivisions of the autonomic nervous system, but are not interrupted in autonomic ganglia. Their terminals are variously described as knobs, loops, rings, tendril-like endings and sometimes more elaborate encapsulated endings in the walls of the viscera, including their epithelial linings and serous coverings, and in the walls of blood vessels.

Afferent impulses conducted along these neurons initiate visceral reflexes, but usually they do not reach the level of consciousness. They are also believed to be concerned with organic visceral sensations such as hunger, nausea, sexual sensation, rectal distension, etc. It is also probable that visceral pain fibres follow these peripheral pathways. Although the viscera are insensitive to cutting, crushing or burning, excessive tension and contraction of nonstriated muscle and certain pathological conditions produce visceral pain. It is not always easy to draw a line between what is acceptably pathological and that which is little more than exaggeration of normal activity. 'Abdominal' pain due to excessive intestinal contractions is extremely commonplace. In pathological conditions affecting a viscus vague pain may be felt in the region of the viscus itself (true visceral pain) or in a region of skin or other somatic tissue, the sensory nerve fibres from which enter the same segments of the spinal cord as those which receive pain fibres from the viscus. The latter phenomenon is known as *referred pain*. In addition, if inflammation spreads from a diseased viscus to the parietal serous membrane (e.g. peritoneum) related to it, the somatic pain fibres will be stimulated and cause local somatic pain in this region of the body wall. True visceral pain is poorly localized and dull or heavy; it is also commonly colic in type. Referred pain is often associated with tenderness of the skin surface at the site of reference.

General visceral afferent fibres occur in the vagus and glossopharyngeal nerves and possibly other cranial nerves, in the second, third and fourth sacral nerves, from which they are distributed with the pelvic splanchnic nerves, and in the thoracic and upper lumbar spinal nerves, where they are distributed through the rami communicantes and along the pathways for efferent sympathetic innervation of the viscera and blood vessels.

The vagus is believed to have a large general visceral afferent component. The fibres have their cells of origin in the superior and inferior ganglia of the nerve, which appear to be predominantly sensory ganglia, despite contrary views in respect of the inferior ganglion (p. 1076). Their central processes terminate in the dorsal nucleus of the vagus in the medulla oblongata, or, according to some authorities, in the nucleus of the tractus solitarius. Their peripheral processes have a wide distribution. Their terminals in the walls of the pharynx and oesophagus, together with the terminals of the general visceral afferent fibres in the glossopharyngeal nerve in the pharynx, are concerned with swallowing reflexes. Afferent fibres are also ascribed to the thyroid and parathyroid glands. In the thorax the general visceral afferent fibres are widely distributed. Some terminate in the heart, walls of the great vessels and aortic bodies; some end in pressor receptors in the walls of the great vessels and are stimulated by distension of the vessel walls resulting from raised intravascular pressure. Fibres from the vagus reach the

lungs through the pulmonary plexuses and are distributed to (*a*) the bronchial muscosa; these are probably involved in cough reflexes; (*b*) the bronchial muscle where they encircle the muscle cells and end in tendril-like arrangements which have been regarded as 'muscle spindles' which are believed to be stimulated by alteration in the length of the muscle cells; (*c*) the interalveolar connective tissue where they end in knob-like swellings; these, together with the endings on the smooth muscle cells, may initiate the Herring-Breuer reflex; (*d*) the adventitia of the pulmonary arteries where they may be pressor receptors and the intima of the pulmonary veins where they may function as chemoreceptors. Afferent fibres from the visceral pleura and air passages are also believed to travel with the sympathetic supply to the lungs and to mediate nociceptive responses.

General visceral afferent fibres in the vagus also terminate in the various coats of the stomach and intestines, the digestive glands and in the kidney. The fibres which terminate in the gut and ducts leading to it are said to be stimulated by distension (stretch) or muscle contraction. Impulses from the stomach may be responsible for the sensations of hunger and nausea.

The general visceral afferent element of the glossopharyngeal nerve includes fibres which innervate the posterior region of the tongue, the tonsil and pharynx; the epithelia of all these parts are derived from endoderm. The innervation of the taste buds in these regions is not included, for these are more properly regarded as *special* visceral afferents, and are treated elsewhere (p. 1140). In addition the glossopharyngeal nerve innervates the carotid sinus and carotid body, the receptors there in being sensitive to tension in the vessel wall and to changes in the chemical composition of the blood respectively. Impulses from these receptors play an essential part in circulatory and respiratory reflexes. The cells of origin of the general visceral afferent fibres lie in the ganglia on the glossopharyngeal nerve, and their terminations in the medulla oblongata are probably similar to those of the general visceral afferent fibres in the vagus nerve.

Sensory fibres coursing in the pelvic splanchnic nerves innervate the pelvic viscera and the distal part of the colon. In the urinary bladder, sensory receptors are described at all levels in its wall. Those in muscle strata are connected with heavily myelinated fibres which reach the spinal cord through the pelvic splanchnic nerves; they are believed to be stretch receptors but may be activated by contraction of the muscle. Pain fibres from the bladder and proximal part of the urethra pass in both the pelvic splanchnic nerves and through the inferior hypogastric plexus, the hypogastric nerves, superior hypogastric plexus and lumbar splanchnic nerves to reach their cells of origin in the ganglia on the dorsal roots of the lower thoracic and upper lumbar nerves. The significance of this double sensory pathway is uncertain; lesions of the cauda equina abolish pain resulting from over-distension of the bladder, but section of the hypogastric nerve is ineffective in relieving pain from the organ.

Though fibres from the pelvic splanchnic nerves, some of which are believed to be afferent, are described in the ovary, no supply from this source to the testis has been demonstrated.

Pain fibres from the body of the uterus pass with sympathetic nerves through the hypogastric plexus and the lumbar splanchnic nerves to cells on the dorsal roots of the lowest thoracic and upper lumbar nerves. Thus, surgical section of the hypogastric nerves has been employed for the relief of dysmenorrhoea. Afferent fibres from the cervix, however, pass in the pelvic splanchnic nerves to their cells of origin in the dorsal roots of the upper sacral nerves. Dilatation (stretch) of the cervix uteri causes pain, but cauterization and removal of small portions of mucosa for biopsy do not.

In general the afferent fibres which accompany the pre- and post-ganglionic fibres of the sympathetic system have a segmental arrangement. They end in the same spinal cord segments as the preganglionic fibres of the efferent pathway to the region or viscus (*vide infra*). The general visceral afferent fibres entering the thoracic and upper lumbar spinal segments are, in the main, concerned with the conduction of pain impulses. Painful sensations from the pharynx, oesophagus, stomach, intestines, kidney, ureter, gall bladder and bile ducts seem to be carried along sympathetic pathways. Such impulses from the heart enter the spinal cord through the first to fifth thoracic spinal nerves. They are carried mainly in the middle and inferior cardiac nerves; a few pass directly into the second to fifth thoracic nerves. There are no general visceral afferent fibres in the superior cardiac nerves. Peripherally the fibres pass through the cardiac plexuses and along the coronary arteries. Anoxia of the heart muscle may give rise to the characteristic symptoms of angina pectoris in which there is presternal pain, referred pain over a large part of the left side of the chest, radiating to the left shoulder and inner side of the left arm, upwards along the left side of the neck to the jaw and occiput and downwards to the epigastrium. Occasionally the pain is felt on both sides or confined to the right side. Afferent fibres from the heart are also carried in the cardiac branches of the vagus nerve. These nerves are concerned with cardiac reflex depressing the activity of the heart. In some animals (e.g. rabbit) a separate depressor cardiac nerve is present as a branch of the vagus or of the superior laryngeal nerve. In man, the depressor fibres do not form a separate nerve but run in branches of the superior or internal laryngeal nerves which join in a variable manner, cardiac branches of the vagus or sympathetic.

The pain fibres from the ureter, which also accompany sympathetic fibres, are probably concerned in the painful reflex of renal colic when this duct is obstructed by a calculus.

The afferent (pain) fibres from the testis and ovary run through the corresponding plexuses; their cells of origin are in the ganglia in the dorsal roots of the tenth and eleventh thoracic nerves.

It must be realized that reflex activities in the autonomic nervous system are not initiated solely by impulses conducted through general visceral afferent pathways, nor do impulses travelling in these pathways necessarily activate the general visceral efferent pathways. Indeed, in most situations calling for general sympathetic activity in preparation for effort, the afferent element is almost always somatic, involving either the special senses or skin sensibility. Rises in blood pressure and dilatation of the pupil may result from stimulation of somatic afferent nerves, the receptors of which are located in the skin and other tissues. Conversely, contraction of the rectus abdominis, a somatic structure may result from irritation of abdominal viscera. There is also evidence that reflexes (axon reflexes) may be evoked at the terminals of autonomic postganglionic fibres.

Denervation often has no appreciable effect on the effector organs, nonstriated muscle or glands, innervated by the autonomic system. The contraction of such muscle may be uninfluenced by denervation and no structural changes ensue. This has been variously attributed to the continued activity of ground plexuses or to the intrinsic activity of the visceral muscle cells. In some instances severance of the preganglionic efferent fibres results in hypersensitivity of the postganglionic neurons. In other instances denervation results in cessation of activity, as in the sweat glands, pilomotor muscle, nonstriated muscle of the orbit and in the adrenal medulla (Pick 1970).

DEGENERATION AND REGENERATION IN THE AUTONOMIC NERVOUS SYSTEM

Though these processes have still to be systematically studied, degeneration in the autonomic nervous system is believed to be similar to that in the cerebrospinal nervous system. There is some evidence that the rate of degeneration differs in different regions or with different types of nerve fibre. Regeneration of preganglionic fibres may be influenced by the site of the lesion and, in the case of postganglionic neurons, regeneration may be followed by re-innervation from neighbouring intact nerve fibres.

As far as available experimental evidence goes, the integrity of Schwann cell sheaths is as important a factor in the regeneration of autonomic nerve fibres, whether myelinated or not, as in the case of somatic fibres (Evans and Murray 1954; Kapeller and Mayor 1967; Williams 1971; King and Thomas 1971; Landon 1976). In some studies observations have suggested that the presence of myelinated fibres in proximity to regenerating non-myelinated fibres is necessary to the latter process (Evans and Murray 1954; Williams 1971). With these as yet incomplete studies it is pertinent to mention earlier experiments in which relatively large defects in the sympathetic trunk, in monkeys and

other mammals, have apparently been made good by growth of fibres (which might be pre- or post- ganglionic) across a complete gap in the trunk (Tower and Richter 1931; Haxton 1954). Conflicting evidence has been derived from human sympathectomies. The functional recoveries sometimes observed may be explained in other ways, such as incomplete interruption of a sympathetic supply, alternative routes of fibres being overlooked. On the whole the experience of surgeons corroborates the experimental findings stated above (Pick 1970).

SEGMENTAL SYMPATHETIC SUPPLIES

Head and neck	T. 1–5
Upper limb	T. 2–5
Lower limb	T. 10–L. 2
Heart	T. 1–5
Bronchi and lung	T. 2–4
Oesophagus (caudal part)	T. 5–6
Stomach	T. 6–10
Small intestine	T. 9–10
Large intestine as far as splenic flexure	T. 11–L. 1
Splenic flexure to rectum	L. 1–2
Liver and gall bladder	T. 7–9
Spleen	T. 6–10
Pancreas	T. 6–10
Kidney	T. 10–L. 1
Ureter	T. 11–L. 2
Suprarenal	T. 8–L. 1
Testis and ovary	T. 10–11
Epididymis, ductus deferens and seminal vesicles	T. 11–12
Urinary bladder	T. 11–L. 2
Prostate and prostatic urethra	T. 11–L. 1
Uterus	T. 12–L. 1
Uterine tube	T. 10–L. 1

Applied Anatomy. Various parts of the sympathetic nervous system are removed surgically in the treatment of a number of clinical conditions. In operations directed towards the efferent side of the sympathetic, ganglia on the sympathetic trunk are removed, or preganglionic fibres cut, rather than postganglionic fibres severed, since the latter procedure may be followed by regeneration of the nerves. For example, the arteries of the limbs may be denervated in conditions of vascular spasm (Raynaud's disease) or in organic arterial disease where spasm is also present; the parts of the system removed are described above (pp. 1129, 1131). In the treatment of essential hypertension, much more extensive sympathectomy has been performed, involving bilateral removal of the sympathetic trunks (from the eighth thoracic to the first lumbar ganglia) and the greater and lesser thoracic splanchnic nerves.

Sympathectomy is also performed for the relief of pain, for example in cases of severe angina pectoris (*see* p. 1137). Division of the superior hypogastric plexus (presacral neurectomy) does not completely relieve pain associated with disease of the pelvic organs, since, as noted above, many of the pain fibres pass in the pelvic splanchnic nerves. The pain fibres from the body of the uterus, however, pass in the sympathetic nerves via the superior hypogastric plexus, so that this operation is successful in cases of intractable painful menstruation (dysmenorrhoea).

In the male, resection of the superior hypogastric plexus is followed by loss of the power of ejaculation and consequent sterility, owing to the interruption of the sympathetic pathway to the seminal vesicles, deferent ducts and prostate. Knowledge of the pathways pursued by these nerves between the ganglia on the sympathetic trunk and the superior hypogastric plexus is less exact and the pathways may vary in different cases, but in certain individuals the outflow from the first lumbar, and possibly the twelfth thoracic, ganglion is of major importance, while in others the fibres from the third lumbar ganglion are chiefly concerned (White *et al.* 1952). For an extensive text on surgical anatomy of the autonomic nervous system consult Pick (1970).

THE PERIPHERAL APPARATUS OF THE SPECIAL SENSES

In the present section the detailed anatomy of the taste buds, the olfactory epithelium and nasal cavity, the eye and the ear are considered. It should also be noted that the development of these structures is treated in the section devoted to Embryology, and their neurons and nervous connexions are further detailed in the parts of this volume concerned with the Central Nervous System and with the Cranial Nerves.

The Gustatory Apparatus

The peripheral gustatory organs are the *taste buds* (*gustatory caliculi*), which are composed of modified epithelial cells arranged in piriform groups (7.323–235) in the epithelium covering the tongue, the inferior surface of the soft palate, the palatoglossal arches, the posterior surface of the epiglottis and the posterior wall of the oral part of the pharynx. They are most numerous on the sides of the vallate papillae of the tongue (7.233), less so on the walls surrounding these papillae; they are plentiful over the folia linguae and the posterior third of the tongue, but are distributed sparingly on the fungiform papillae of the tongue, the soft palate, epiglottis and pharynx. They are more numerous in the infant than the adult and their atrophy increases with age; those in the extreme posterior part of the tongue and in the epiglottis disappear early in life. There are no taste buds in the mid-dorsal region of the oral part of the tongue.

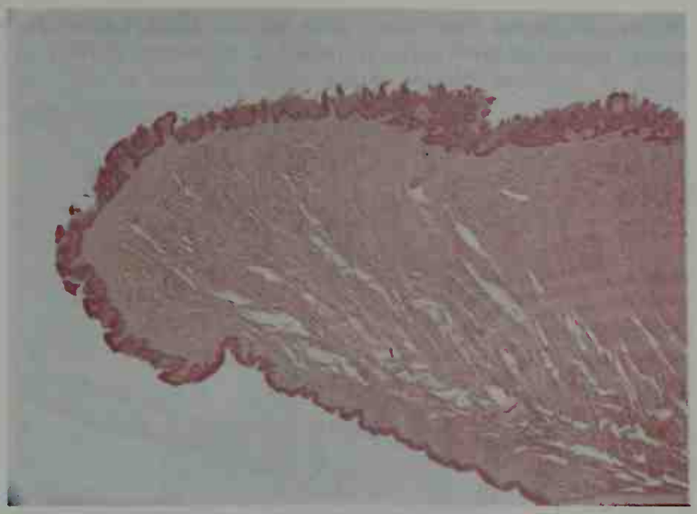
MICROSCOPIC STRUCTURE OF TASTE BUDS

Each taste bud (7.234) is separated by a basement membrane from the underlying dermis, and opens on to the surface of the epithelium by an aperture termed the *gustatory pore*. In longitudinal section the cells of the taste bud are crescentic in profile, their pointed apices converging on a small cavity which connects with the gustatory pore (7.234, 235). Some of these cells bear 'gustatory hairs' which, ultrastructurally, are seen to be groups of fine microvilli. The base of each taste bud is penetrated by a group of afferent gustatory nerve fibres which give off branches to ramify and spiral around some of the epithelial cells within the taste bud.

It has long been known that the gustatory sensory cells are modified epithelial elements which establish contacts like synapses with the terminal branches of the afferent gustatory fibres. The identification of the gustatory cells amongst the other types of cell in the taste bud has, however, been the subject of some debate. Investigations involving three-dimensional reconstruction of taste buds from electron micrographs of serial sections (Murray and Murray 1970) suggest that there are at least five distinct epithelial cell types, two of which appear to be receptor cells and others supportive, ensheathing or generative in their functions (7.235). The receptor cells are typified by the presence of synaptic contacts with afferent nerve terminals at various points on their surfaces; these show the typical asymmetrical thickening and presynaptic aggregates of small (50 nm) clear synaptic vesicles within the receptor cell, although these appear to be less prominent than in other comparable synapses (p. 828). Also, one of these types of epithelial cell contains dense-cored vesicles about 70 nm in diameter within its cytoplasm, similar to those which have been identified in other sites of the nervous system as catecholamine-containing vesicles (p. 830), whereas in the other type these are absent. It is possible that the two types of cell represent different stages in the maturation of receptors, which are continually being lost and replaced (*vide infra*). It is interesting that at the apices of the

receptor cells few microvilli are usually present, and the 'gustatory hairs' of light microscopists are mainly to be found on the supporting cells which surround and enclose the receptors except at their apical surfaces (Miller and Chaudry 1976). One of these non-sensory cell types appears to form a peripheral sheath for the whole taste bud, separating it from the surrounding epithelium; another type is basal in position where it probably forms a blastemal cell capable of giving rise to new cells of the other types by mitosis. The third type is a true supporting cell which insulates each receptor from its neighbours and also provides sheaths at its basal extremities for the afferent nerve fibres which lose their Schwann sheaths on entering the taste bud. Ultrastructurally the true supporting cells contain, together with the usual complement of cell organelles, dense bodies of a secretory nature. These are probably the origin of the material rich in polysaccharides which occupies the apical cavity of the taste bud and into which the sensory terminals project. Gustatory molecules must pass through this material before the sensory surface can be reached, and it may play an important, although undetermined, role in the gustatory process. Occluding junctions are present between the apices of the various cells of the taste bud, preventing ready access of chemical stimuli to non-apical parts (Akisaka and Oda 1978).

The nerve fibres which reach the taste buds from the dermal plexus are complex in their distribution within the tongue, as deduced by electrophysiological recordings from individual nerve fibres within the more proximal fasciculi of the main gustatory nerves (chorda tympani and glossopharyngeal). Each fibre may possess many terminal branches which spread to innervate widely distant taste buds, and, within these structures, to end in relation to more than one sensory cell. Conversely, each taste bud and each of its contained receptor cells, may be innervated by the terminal branches of several different nerve fibres. This cross innervation of taste buds may be of great physiological importance (*vide infra*, and Beidler 1970). No evidence has yet emerged concerning the presence of efferent terminals or of inhibitory phenomena in taste buds.



THE REPLACEMENT OF TASTE BUD CELLS

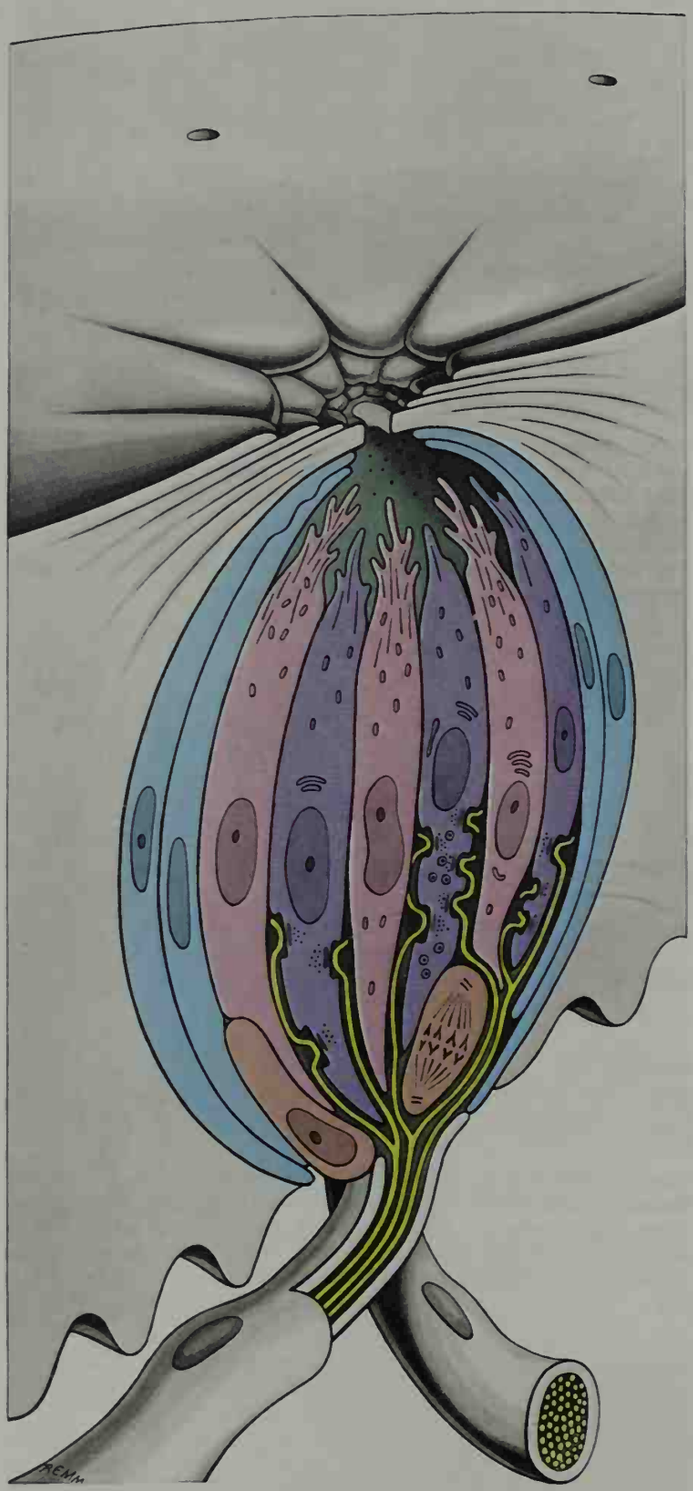
The cells of the taste bud resemble the cells of the surrounding epithelium in undergoing continual renewal (Beidler and Smallman 1965). Isotopic labelling shows that none of the elements of the taste bud live for more than a few days, except for the basal cells, from which the other types of cell are presumably replaced by mitosis. Newly formed sensory cells must therefore make new synaptic contacts with nerve fibre terminals, and experiments indicate that the precise sensitivity characteristics of the sensory cells are determined by the trophic influence of the nerve fibre and not the reverse (*see* p. 862).

The continual degeneration and replacement of cells in taste buds means that, within a single bud, cells of different types show a spectrum of morphological appearances which adds to the difficulties of precise identification of cells on structural criteria alone.

THE PHYSIOLOGY OF GUSTATORY RECEPTORS

In many aquatic vertebrates chemoreceptors with all the characteristics of gustatory endings are widely distributed over the surface of the body; in terrestrial groups this sense is confined to the buccal cavity and adjoining regions of the pharynx. The sense of taste in man, as commonly understood, is largely a result of the activity of lingual receptors, although others which are palatal and laryngopharyngeal in position may also play a significant part. Classically, four groups of subjective taste qualities have been distinguished, each pertaining to zones of special sensitivity on the surface of the tongue, comprising sweet and salt at the tip of the tongue, sour (acid) at the sides, and bitter at the pharyngeal end. Although these qualities represent subjective sensations, it seemed at one time possible that their special effectiveness in particular areas of the tongue might reflect the presence of receptor cells specific for these general groups. However, the electrophysiological evidence suggests that this is

7.232 A low-power light micrograph of a sagittal section through the tip and anterior part of a human tongue, showing: muscle fibres orientated in three different directions; a delicate non-keratinized stratified squamous epithelium on the ventral surface; and a partly keratinized epithelium on the dorsum. The latter is convoluted to produce filiform and fungiform papillae. Dermal papillae project into the deep surface of the epidermal irregularities. Haematoxylin and eosin. Magnication × 10



7.233 A light micrograph of a human vallate lingual papilla showing the numerous taste buds clustered along its lateral surfaces. A connective tissue papilla forms the core of the whole structure, and serous glands, situated between the muscle blocks deep to the corium, open into the lateral recesses of the papilla. Haematoxylin and eosin. Magnification × 150

7.234 A light micrograph of a group of taste buds in a vallate lingual papilla, showing the apical cavity and various fusiform cells within the epithelial capsule. Haematoxylin and eosin. Magnification × 400

an over-simplified view, since each afferent fibre, subserving widely separated taste buds, responds to a variety of different types of chemical stimuli. Some fibres respond to all four qualities, others to less or only to one. Within a particular class of taste qualities receptors are also differentially sensitive to a wide range of similar chemicals. It would therefore seem likely that the sensation of taste represents the results of the analysis of a complex pattern of differential responses over particular areas of the tongue, so that even if there are only a relatively few specific types of taste receptor cells, much more information may be gained about the precise nature of the taste, and its intensity, than if the innervation were of a simpler kind (Beidler 1970; Beidler and Smallman 1965; Pfaffman 1970).

7.235 A schematic reconstruction of the structure of a taste bud, cut away to expose the various cell types. Presumed sensory cells of two types, one with dense-cored vesicles, the other without, are indicated in purple, and their innervation in yellow. The supporting cells are indicated in magenta, and basal cells in brick red. A dense mucosubstance is present in the apical cavity beneath the apical aperture.

THE GUSTATORY NERVES

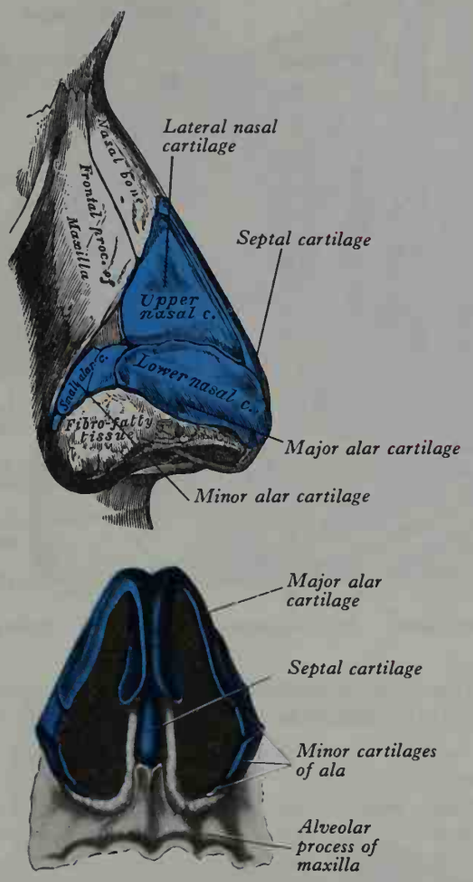
The nerve fibres of taste are the peripheral processes of unipolar nerve cells in the genicular ganglion of the facial nerve, the inferior ganglion of the glossopharyngeal nerve and the inferior ganglion of the vagus. The central processes of these cells form the tractus solitarius (p. 903), and their terminals synapse with the neurons which form the nucleus of that tract. The axons of the latter cross the midline, and many then ascend through the brainstem in the dorsomedial part of the medial lemniscus to approach and synapse with the most medially situated neurons of the *nucleus ventralis posterior medialis* (VPM) of the thalamus (in a region sometimes termed the *accessory arcuate nucleus*). From the VPM axons radiate through the internal capsule to reach the antero-inferior part of the sensorimotor cortex and the region of the limen insulae. Broadly, electrophysiological recording from the VPM and the cerebral cortex confirms these anatomical pathways; some units react to one type of stimulus only, whilst others react to a number of different stimuli. Other ascending pathways have been described as ending in a number of the hypothalamic nuclei, through which gustatory information may reach the limbic system (p. 968), and which allow appropriate readjustments of the autonomic nervous system to be made. (*See* also p. 1085.)

The nerve of taste for the anterior part of the tongue, excluding the vallate papillae, is the chorda tympani (through the lingual nerve); these taste fibres in most individuals pass in the chorda tympani to the ganglion of the facial nerve. In a few individuals, they leave the chorda tympani by anastomotic branches connecting it to the otic ganglion and proceed thence in the greater petrosal nerve to the ganglion of the facial nerve (Schwartz and Weddell 1938). This part of the tongue, its *oral* region, is derived from the mandibular branchial arch, and is limited posteriorly by the *sulcus terminalis*. The taste buds in the inferior surface of the soft palate are also supplied mainly by the facial nerve, through the greater petrosal nerve, the nerve of the pterygoid canal and the middle and posterior palatine nerves; the glossopharyngeal also contributes to their supply. The taste buds in the vallate papillae and the pharyngeal part of the tongue, and in the palatoglossal arches and the oral part of the pharynx are innervated by the glossopharyngeal, while those in the extreme back part of the tongue and in the epiglottis are supplied by the internal laryngeal part of the superior laryngeal branch of the vagus. (For discussion of the literature concerning gustatory pathways consult Rollin 1979.) These nerve supplies accord with the embryological development of the tongue (p. 197). It is customary to describe the mandibular and glossopharyngeal territories as the 'anterior two-thirds' and 'posterior third' of the tongue. But since there is an easily recognizable boundary between them—the sulcus terminalis—it is uninformative and misleading to divide so variable an organ in this arbitrary and inevitably inexact manner. *Pre-* and *post-sulcal* regions are better terms.

THE OLFACTORY APPARATUS

The peripheral olfactory organs are said to include the *external nose*, and the *nasal cavity*, which are both divided by a septum into right and left parts. However, the essential olfactory structures are the olfactory epithelium and its nervous connexions.

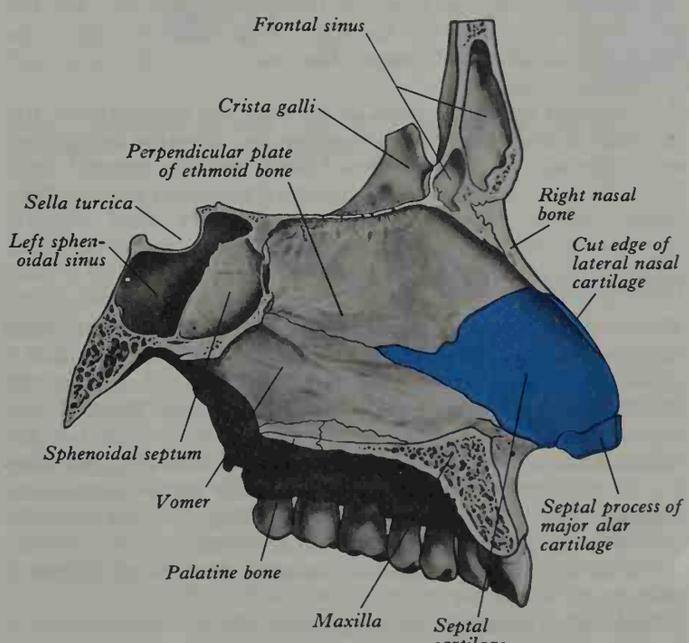
THE EXTERNAL NOSE



The external nose is pyramidal, and its upper angle, or *root*, is continuous with the forehead; its free angle or tip is termed the *apex*. Its inferior aspect carries two roughly elliptical apertures, the external *nares* or *nostrils*, which are separated from each other by the septum. The lateral surfaces of the nose form, by their union in the median plane, the *dorsum nasi*, the shape and direction of which varies considerably in different individuals; the upper part of the external nose is kept patent by the nasal bones and the frontal processes of the maxillae. The lateral surfaces end below in the rounded *alae nasi*.

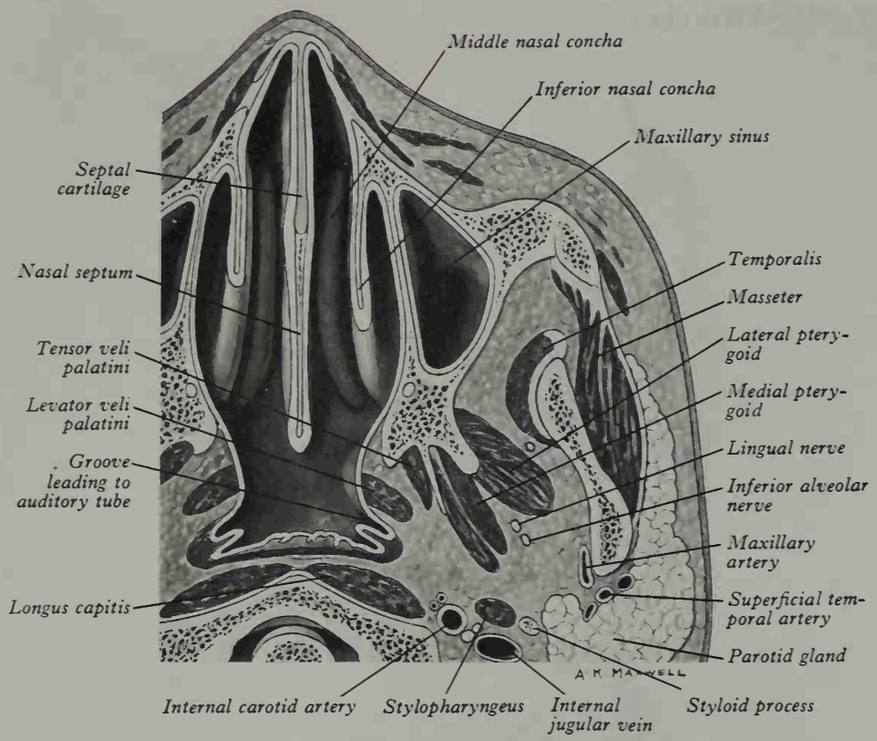
The framework of the external nose (7.236) is composed of bones and hyaline cartilages. The *bony framework*, which supports its upper part, consists of the nasal bones, the frontal processes of the maxillae, and the nasal part of the frontal bone. The *cartilaginous framework* consists of the septal, lateral, and major and minor alar nasal cartilages (7.236, 237). These are connected with one another and with the bones by the continuity of the perichondrium and the periosteum. These junctions are of considerable interest, although they have attracted little attention. The cartilages and their intervening connective tissue regions, which surround the nares, have been regarded as a form of valve, controlling the intake of air (Cottle 1960; Galindo *et al.* 1977).

The *septal cartilage* (7.236B, 237), somewhat quadrilateral in form, and thicker at its margins than at its centre, forms almost the whole of the septum between the anterior parts of the nasal cavity. The upper part of its anterosuperior margin is connected to the posterior border of the internasal suture; the middle part is continuous with the lateral cartilages; the lower part is attached to these cartilages by the perichondrium. Its antero-inferior border is connected on each side to the septal process of the major alar cartilage. (Because of this fusion Galindo *et al.* 1977 have suggested that the two lateral and the septal cartilages should be regarded as a unit—the *septodorsal cartilage*. This represents resuscitation of an older view, the term having been used in the Jena Nomina Antomica.) Its posterosuperior border is joined to the perpendicular plate of the ethmoid bone, and its postero-inferior border is attached to the vomer and to the nasal crest of the maxillae and the anterior nasal spine. The cartilage of the septum may extend backwards (especially in children) as a narrow process, termed the *sphenoidal process*, for some distance between the vomer and the perpendicular plate of the ethmoid bone. The antero-inferior part of the nasal septum between the two nostrils is freely movable, and hence is named the *septum mobile nasi*; it is not formed by the cartilage of the septum, but by the septal processes of the major alar cartilages and by the skin.



The *lateral* (upper) *nasal cartilage* (7.236A) is triangular in shape. Its anterior margin is thicker than the posterior, and the upper part is continuous with the cartilage of the septum, but the lower part is separated from this cartilage by a narrow fissure; its superior margin is attached to the nasal bone and the frontal process of the maxilla; its inferior margin is connected by fibrous tissue with the major alar cartilage.

The *major alar* (lower) *cartilage* (7.236A and B) is a thin flexible plate which is situated below the lateral nasal cartilage, and is bent acutely around the anterior part of the naris. The medial part of the plate is narrow, and is termed the *medial crus* (septal process). The latter is loosely connected by fibrous tissue with that of the opposite cartilage, and to the antero-inferior part of the septal cartilage, thus helping to form the septum mobile nasi. The *lateral crus*, which is lateral to the narial orifice, is little more than the inferior free border of the main part of the major alar cartilage. The upper border of the lateral part of the major alar cartilage is attached by fibrous tissue to the lower border of the lateral nasal



7.236 A The cartilages of the right side of the nose. Lateral aspect. B The cartilages of the nose. Inferior aspect. (Note changes in terminology.)

cartilage. Its posterior, narrow end is connected with the frontal process of the maxilla by a tough fibrous membrane, in which three or four small cartilaginous plates, termed the *minor cartilages of the ala* (7.236A), are found. According to Drumheller (1969) the junction between the adjoining borders of the major alar and lateral cartilages is variable; the two edges may abut each

7.237 The right side of the septum of the nose, showing its constituent bones and cartilages. (Note changes in terminology.)

7.238 A transverse section through the anterior part of the head at a level just inferior to the apex of the odontoid process. Superior aspect.

other or they may overlap, the lateral cartilage being then the more lateral at the junction. Its lower free edge (lateral crus) falls short of the lateral margin of the naris, the lower part of the ala nasi being formed by fatty and fibrous tissue covered with skin. In front, the major alar cartilages are separated by a notch which can be felt at the apex of the nose.

The *muscles* acting on the external nose have been described on p. 531.

The *skin* of the dorsum and sides of the nose is thin, and loosely connected with the subjacent parts; but over the apex and alae it is thicker and more firmly adherent, and is furnished with numerous large sebaceous glands, the orifices of which are usually very distinct.

The *arteries* of the external nose are the alar and septal branches of the facial artery, which supply the ala and lower part of the septum, the dorsal nasal branch of the ophthalmic artery, and the infraorbital branch of the maxillary artery, which supply the lateral aspects and the dorsum. The *veins* end in the facial and ophthalmic veins.

The *nerves* for the muscles of the nose are derived from the facial nerve, while the skin receives branches from the ophthalmic nerve, through its infratrochlear branch and the external nasal nerve (p. 1061), and from the infraorbital branch of the maxillary nerve.

THE NASAL CAVITY

The nasal cavity is divided into right and left halves by the nasal septum (7.238). These two halves open on the face through the nares or nostrils, and communicate behind with the nasal part of the pharynx through the posterior nasal apertures. The *nares* are somewhat piriform apertures, narrower in front than behind. Each measures from 1·5 cm to 2 cm anteroposteriorly, and from 0·5 cm to 1 cm transversely. The *posterior nasal apertures* or *choanae* are two oval openings, each measuring about 2·5 cm in the vertical and 1·25 cm in the transverse direction.

For the description of the bony boundaries of the nasal cavity, *see* p. 313.

Each half of the nasal cavity can be described as having a floor, a roof, a lateral wall and a medial (septal) wall. It consists of three regions—vestibular, olfactory, and respiratory.

The *nasal vestibule* is a slight dilatation just inside the aperture of the nostril (7.239), bounded laterally by the ala and the lateral part of the lower nasal cartilage, and medially by the septal process of the same cartilage; it extends as a small recess towards the apex of the nose. The vestibule is lined with skin, and coarse hairs and sebaceous and sweat glands are found in its lower part; the hairs (vibrissae) curve downwards and forwards to the naris, and tend to arrest the passage of foreign substances carried with the current of inspired air. In the male, after middle age, they increase considerably in size. The vestibule is limited above and behind by a curved elevation, named the *limen nasi*, which corresponds to the upper margin of the lower nasal cartilage, and along which the skin of the vestibule is continuous with the mucous membrane of the nasal cavity.

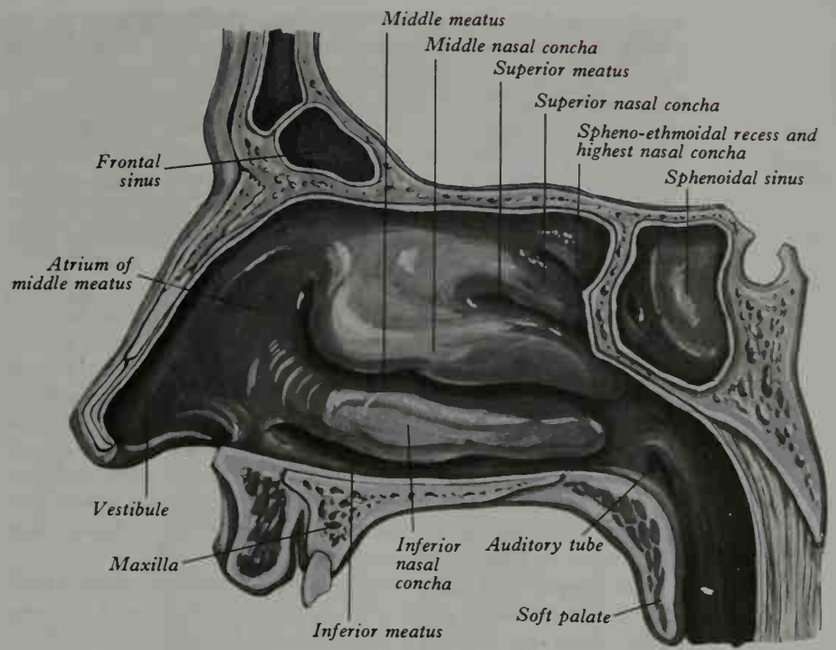
The *olfactory region* is limited to the superior nasal concha, the opposed part of the septum and the intervening roof.

The *respiratory region* comprises the rest of the cavity.

The lateral wall of the nasal cavity (7.239, 240) is marked by three elevations, the *superior*, *middle* and *inferior nasal conchae*, and below and lateral to each concha is the corresponding nasal passage or *meatus*. Above the superior concha a triangular fossa, the *spheno-ethmoidal recess*, includes the opening of the sphenoidal sinus. Sometimes a fourth or *highest nasal concha* occurs on the lateral wall of the spheno-ethmoidal recess (7.239); the highest or *supreme nasal meatus* related to it may contain the opening of a posterior ethmoidal sinus. The *superior meatus* is a short oblique passage extending about half-way along the upper border of the middle concha; the posterior ethmoidal sinuses open, usually by one aperture, into the front part of this meatus. The *middle meatus*, deeper in front than behind, is below and lateral to the middle concha, and is continued anteriorly into a shallow depression situated above the vestibule and named the *atrium* of the middle meatus. Above the atrium an ill-defined curved ridge, termed the *agger nasi* (p. 340), runs forwards and downwards from the upper end of the anterior free border of the middle concha; it is better developed in the newborn child than in the adult. When the middle concha is raised or removed the lateral wall of this meatus is displayed fully. A rounded elevation, termed the bulla ethmoidalis and, below, and extending upwards in front of it, a curved cleft, termed the hiatus semilunaris, form the principal features of this wall. The *bulla ethmoidalis* is caused by the bulging of the middle ethmoidal sinuses, which open on or immediately above it, and the size of the bulla varies with that of its contained sinuses. The *hiatus semilunaris*, which is bounded inferiorly by a sharp concave ridge produced by the uncinate process of the ethmoid bone, leads forwards and upwards into a curved channel, which is named the *ethmoidal infundibulum*. The anterior ethmoidal sinuses open into the infundibulum, which in rather more than 50 per cent of subjects is continuous with the frontonasal duct or passage leading from the frontal sinus. In other cases the ethmoidal infundibulum ends blindly in front by forming one or more of the anterior ethmoidal sinuses (*infundibular sinuses*), and the frontonasal duct opens directly into the anterior end of the middle meatus. The opening of the maxillary sinus is situated below the bulla ethmoidalis, and is usually hidden by the flange-like lower edge of the hiatus semilunaris; in a coronal section of the nose this opening is seen to be placed near the roof of the sinus (7.244). An accessory opening of the maxillary sinus is frequently present below and behind the hiatus semilunaris. The *inferior meatus* is below and lateral to the inferior nasal concha; the nasolacrimal duct opens into this meatus under cover of the anterior part of the inferior concha.

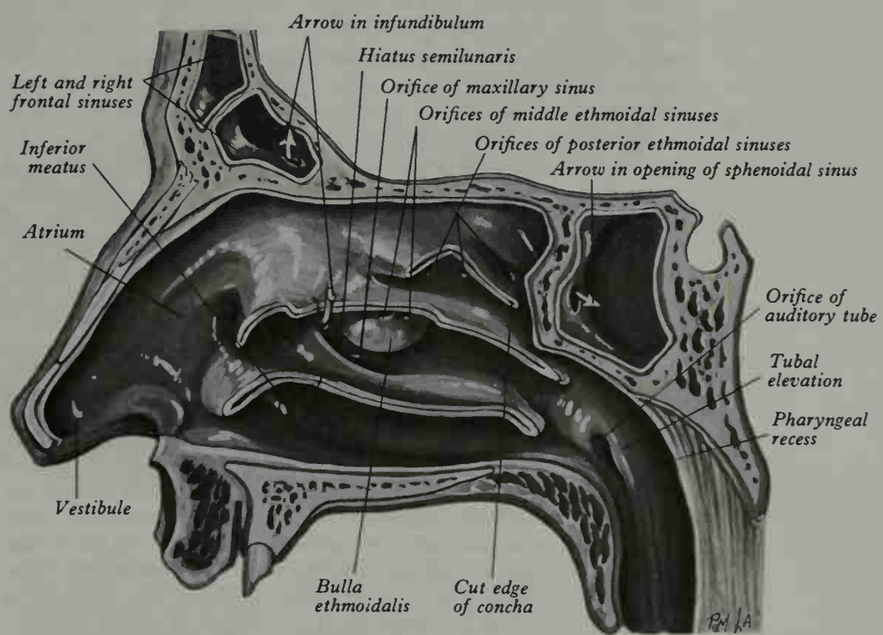
The medial wall or nasal septum (7.237) is often deflected from the median plane, thus lessening the size of one half of the nasal cavity and increasing that of the other; ridges or spurs of bone sometimes project from the septum on either side. Immediately superior to the incisive canal at the lower edge of the cartilage of the septum a depression is sometimes seen; it points downwards and forwards, and occupies the position of a canal which connected the nasal with the buccal cavity in early fetal life. On each side of the septum close to this recess a minute orifice may be discerned; it leads backwards into a blind tubular pouch, 2 to 6 mm long, the vestigial *vomeronasal organ*, which is supported by a strip of cartilage named the *vomeronasal cartilage*; it is lined by epithelium consisting mainly of a single layer of tall columnar

cells and contains many glands. This organ is particularly prominent in amphibia and reptiles, and moderately well developed in most mammals, but is vestigial in adult primates including mankind (Graziadei 1974). When present it apparently plays a part in the sense of smell, since it is supplied by twigs of the olfactory nerve and is lined with epithelium similar to that in the olfactory region of the nose. (See also p. 994.)



The roof of the nasal cavity is narrow transversely, except at its posterior part, and may be divided, from behind forwards, into sphenoidal, ethmoidal and frontonasal parts, corresponding to the bones which enter into its formation (pp. 141 and 313). The ethmoidal part is almost horizontal, but the frontonasal and sphenoidal parts slope downwards and forwards, and downwards and backwards, respectively. The cavity is therefore deepest where its roof is formed by the cribriform plate of the ethmoid bone.

The floor is transversely concave, anteroposteriorly flat and almost horizontal; its anterior three-fourths are formed by the palatine process of the maxilla, its posterior one-fourth by the horizontal part of the palatine bone. About 2 cm behind the anterior end of the floor a slight depression in the mucous membrane overlies the incisive canals (p. 341).



The nasal conchae add greatly to the surface area of the nasal cavity, especially in macrosmatic mammals such as the Carnivora (Negus 1958). This may not only serve to augment the olfactory area but also to increase turbulence and perhaps improve olfaction by somewhat delaying passage of air through the olfactory part of the cavity. Humidification and warming of the inhaled air is also favoured by the increased area of mucous membrane and by turbulence, even in a microsmatic mammal such as man (Cole 1954). Swirling currents also aid in the trapping of particulate material by the mucous secretion.

The nasal mucous membrane lines the nasal cavities with the exception of the vestibules, and is intimately adherent to the periosteum or perichondrium. It is continuous with the mucous membrane of the nasal part of the pharynx through the posterior nasal apertures, with the conjunctiva, through the nasolacrimal duct and lacrimal canaliculi, and with the mucous membranes of the sphenoidal, ethmoidal, frontal and maxillary sinuses, through their openings.

The mucous membrane is thickest and most vascular over the nasal conchae, especially at their extremities. It is also thick over the nasal septum, but very thin in the meatuses, on the floor of the nasal cavity, and in the various sinuses. The thickness of the membrane reduces materially the size of the bony cavity and the apertures communicating with it. The epithelium of the mucous membrane differs in its characteristics according to the functions of the part of the nose in which it is found. In the *olfactory region*, which extends over the upper 10 mm or so of the septum and over the superior concha and the lateral walls above it, the mucous membrane is yellowish in colour and the epithelium is of a distinctive type.

STRUCTURE OF THE OLFACTORY EPITHELIUM

The olfactory epithelium is considerably thicker than the surrounding non-sensory epithelium of the nasal cavity, and is composed of three chief types of cell (7.241, 242), namely the olfactory receptor cells, supporting (sustentacular) cells and basal cells (Moulton and Beidler 1967), together constituting a pseudostratified epithelium up to 100 μm thick.

The receptor cells are of particular phylogenetic interest since they are *primary sensory neurons*, the cell bodies of which lie close to the sensory surface, a common feature of invertebrates but unique in the vertebrate classes. These cells are *bipolar* neurons, positioned vertically within the olfactory epithelium, the cell bodies being restricted to the basal two-thirds of the epithelial thickness. Basally, a non-myelinated axon stems from each receptor cell body, to run with other axons in small bundles within the epithelium amongst the processes of supporting and basal cells and, finally, to penetrate the basal lamina, where each bundle becomes ensheathed by Schwann cells (Frisch 1967). Such ensheathed bundles (*fila olfactoria*) join with others to form the *fasciculi* of the *olfactory nerve*, and eventually these enter the olfactory bulb, where they synapse with second-order sensory neurons (mitral cells, basket cells, periglomerular cells, see p. 992). The olfactory axons are amongst the most slender of nerve fibres, being about 0·2 μm in diameter. Within the fila of the olfactory nerve, the axons are typically grouped together in invaginations of the Schwann cell membrane without any intervening Schwann cell processes (Gasser 1956), perhaps providing possibilities of electrical interaction between adjacent axons.

At the peripheral aspect of the receptor perikaryon (7.243), a single unbranched dendrite extends to the free surface of the epithelium where it expands slightly to form a bulbous olfactory ending (*rod*, *knob*, or *vesicle*), projecting above the general level of the epithelial surface (Frisch 1967; Reese 1965; Graziadei 1971, 1974; Naessen 1971). Scattered over the surface of the ending itself are numerous *olfactory cilia* which project into the layer of liquid overlying the epithelium. The cilia possess a '9 plus 2' pattern of microtubules internally, similar to that of motile non-sensory cilia elsewhere (p. 18). Amongst the different groups of

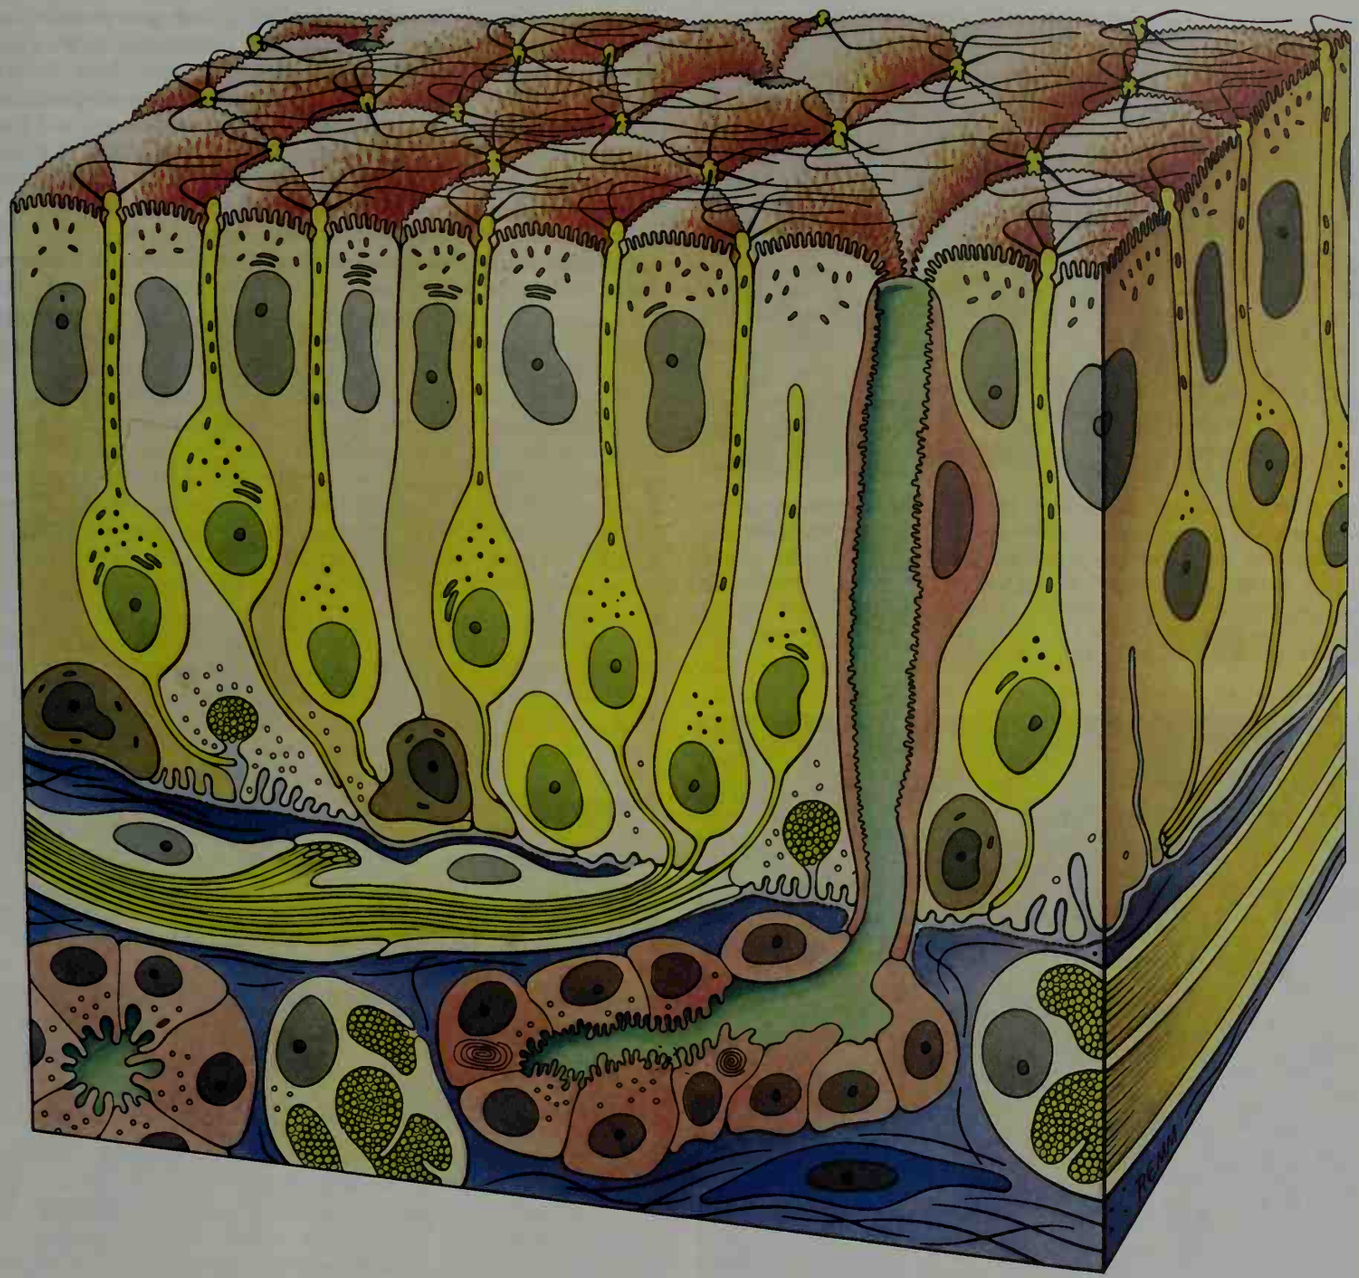
vertebrates the length and precise form of the olfactory cilium varies considerably, but in mammals it usually takes the form of a short relatively thick 'shaft' tapering after a few microns to a long, thin, distal tip with reduced numbers of microtubules. Deeper in the dendrite, numerous mitochondria are present, indicative of high energy consumption, along with other organelles typical of neuronal dendrites—microtubules, smooth and rough coated vesicles, agranular endoplasmic reticulum and ribosomes; centrioles are also often present, especially in young animals. The *perikaryon* is rich in granular and agranular endoplasmic reticulum, Golgi bodies, and lysosomes, all indicating a high level of metabolism. The nucleus is elliptical and relatively heterochromatic. The exposed regions of the olfactory dendrite and its cilia are covered with a plasma membrane containing a high density of intramembranous particles demonstrable with freeze-fracturing methods (Kerjaschki and Hörandner 1976; Menco *et al.* 1976). It is likely that these particles represent sites of odour reception and of ionic movements associated with sensory activity, and their large numbers can be correlated with the extreme sensitivity of the olfactory receptors to extremely low concentrations of airborne chemicals (Menco 1976).

The supporting cells are irregular columnar elements which separate and partially enclose the receptors. Their large elongate euchromatic nuclei form a distinct layer above the level of the receptor perikarya. The surface of supporting cells is marked by the presence of numerous, long, irregular microvilli which, with the olfactory cilia, form a complex meshwork in the layer of fluid upon the general epithelial surface. Within the cytoplasm are many mitochondria, granular and agranular endoplasmic reticulum and, at the base of the epithelium, lamellated dense bodies which may be similar to the lipofuscin granules of neurons (p. 825), representing the remains of autophagic lysosomes and because of their coloration causing the whole olfactory area to be pigmented yellowish-brown. A prominent Golgi apparatus and lysosomes are also found in the apical parts of supporting cells. Near the epithelial surface, fine microfilaments attaching to desmosomes probably give mechanical coherence to the epithelium. Tight junctions are also reported to occur between supporting cells and olfactory receptors at the level of the epithelial surface (Reese and Brightman 1970).

The basal cells are of two types, one probably supportive and the other capable of continued cell division and so often termed *blastemal cells* (Andres 1966). The first of these classes is confined to the immediate vicinity of the basal lamina of the epithelium, and consists of irregular polygonal cells with rather irregular heterochromatic nuclei and a thin layer of cytoplasm containing numerous tonofibrils attached to desmosomal contacts with adjacent sustentacular cells. From their appearance it is likely that these basal cells strengthen the base of the epithelium. The *blastemal cells* form a layer of variable thickness near the base of the epithelium, and are particularly prominent in young animals. Mitotic figures are often seen amongst these cells, and their nuclei can be labelled with tritiated thymidine and examined with autoradiographic methods. Structurally the blastemal cells have many of the characteristics of embryonic neuroblasts, being rounded, with a large euchromatic nucleus and a layer of basophilic cytoplasm which under the electron microscope is seen to contain numerous free ribosomes with scattered mitochondria and occasional clusters of centrioles. Often some of the basal cells show signs of differentiating into olfactory receptors by sprouting dendrites and other receptor organelles.

Various studies have shown that the blastemal cells constitute a pool of immature stem cells which are constantly contributing new receptor cells by migration into the more apical parts of the epithelium. During early development including the postnatal period (at least in those species which have been examined), this type of recruitment is needed for the expansion of the epithelium, both in its thickness and its surface area, but a slower and continuous addition to the receptor population also occurs throughout life, balanced by the degeneration and death of existing receptor cells which (in rodents) may only last for 2–3 weeks (Moulton, Celebi and Fink 1970; Graziadei 1974). The degenerating receptors are phagocytosed by the neighbouring supporting cells, and their remnants after hydrolysis in lysosomes, contribute to the olfactory pigment seen at the base of the epithelium (Bannister and Dodson 1975).

This continuous turnover of the olfactory receptor population is no doubt an advantage because of the exposed position of the olfactory endings and their liability to damage from inhaled noxious agents, and also provides possibilities of regeneration if the olfactory epithelium is more seriously damaged, for example by virus infection, although in the latter case functional regeneration appears to depend on the absence of scar tissue which may prevent the regrowth of axons (Douek, Bannister and Dodson 1975). However, it must be remarked that this ability to regenerate primary sensory neurons is unique in the nervous system of mammals, and represents a phenomenon of great neurobiological interest (*see* Graziadei 1978).



The olfactory glands (of Bowman) (7.241, 242) are branched tubular structure beneath the olfactory epithelium, on to the surface of which they pour their secretions, through narrow, vertical ducts. The secretory acini of these glands are composed of cells with basally placed nuclei and granular cytoplasm. Ultrastructurally, two gland cell types have been reported, both containing dense secretory vesicles, but one showing a denser cytoplasm than the other. Their secretions have been reported in some mammals to contain enzymes (acid phosphatase, esterase) and in mice sulphated acid mucosubstances have been demonstrated as a major component. Since this fluid forms the immediate environment of the receptor endings after it has been secreted, it may play an important part in the diffusion of odours from the air to the olfactory receptors and in regulating the passage of ions to and from the sensory cell during electrical activity. It may also possess bactericidal properties.

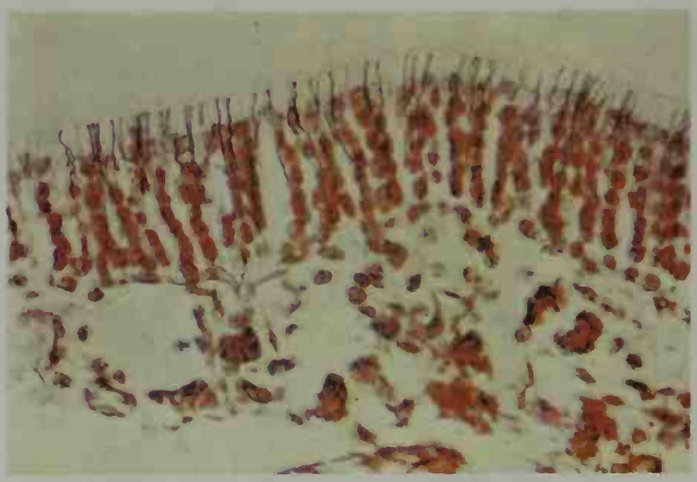
In addition to the structures described above, a variable population of lymphocytes is often present, particularly in the basal region of the epithelium, as elsewhere in the upper respiratory tract. During life there is a gradual reduction in the number of olfactory receptors and their axons, up to 1 per cent being lost each year; the sensory epithelium may be replaced by ciliated columnar epithelium similar to that of the non-sensory respiratory epithelium lining the adjacent regions of the nasal cavity. These changes parallel the gradual loss of the olfactory sense which usually accompanies aging.

Development of the olfactory epithelium

The olfactory tissue develops from the embryonic olfactory placode in a manner resembling the early ontogeny of the neural tube (p. 157). The cuboidal ectodermal cells of the olfactory placode gradually become taller but remain as a single layer throughout development. Initially, mitosis occurs only near the apical surface of the placode, the dividing cells rounding up then afterwards re-extending to the base of the epithelium, but later, mitoses are seen deeper in the epithelium then finally are confined to the basal layers where cell division persists throughout postnatal life (Smart 1971; Cuschieri and Bannister 1975*a*). Electron microscopic studies have shown that receptor cells begin to differentiate quite early in development, sprouting apical dendrites and basal axons with large growth cones, growing back to the olfactory bulb to eventually make synaptic contact with second order neurons (Hinds and Hinds 1972; Cuschieri and Bannister 1975*b*; Farbman 1975). After they reach the apical surface, the dendrites expand at their tips to form spherical bulbs into which centrioles migrate from the receptor cell body, eventually sprouting cilia at the receptor ending. Later, the supporting cells, glands and supportive basal cells differentiate so that the olfactory apparatus is in full functional order before birth.

In the **vomeronasal organ** (of Jacobson), present in most mammals but rudimentary in man (p. 1142), the cellular components are similar to those of the olfactory epithelium except for the reduction or absence of a basal cell layer, the larger size of the receptors, and the presence of microvilli instead of cilia at the sensory endings (Kolnberger 1971). The absence of cilia is particularly interesting since these have been claimed to be the site of chemoreception in the olfactory epithelium; it seems probable that the whole exposed plasma membrane is the chemoreceptive area and that the cilia or microvilli merely serve to increase the surface at which reception of stimuli may take

7.241 A schematic reconstruction showing the chief cytological features of the olfactory epithelium. Receptor cells (yellow) are situated among columnar supporting cells. The axons of the receptor cells emerge from the epithelium in groups ensheathed in Schwann cells. Observe the rounded basal epithelial cells and the sub-epithelial glands of Bowman with their intra-epithelial ducts. One of the basal cells is in process of differentiating into a receptor cell. At the surface are cilia of the receptor cells and microvilli of the supporting cells.



place. Electrical recordings show that vomeronasal receptors respond to odours in much the same way as olfactory receptors, although possibly to a narrower range of chemical substances.

Other chemoreceptors in the nasal cavity include various terminals capable of signalling the presence of strong concentrations of odours and of noxious chemicals in aerial solution, for example, ammonia and sulphur dioxide, even in the absence of the olfactory pathway, which may, for instance be interrupted after fracture of the cribriform plate or severance of the olfactory tract. The major nerves supplying the epithelium of the nasal chamber with possible chemosensory endings include trigeminal fibres from ethmoidal branches of the ophthalmic, and various maxillary nerve branches (p. 1148) which give off myelinated fibres; small bundles of such fibres have been detected by Graziadei and Gagne (1973) at the base of the olfactory epithelium, losing their sheaths to penetrate amongst the supporting cells. Another possible chemosensory nerve is the *nervus terminalis*, the functions of which are as yet unknown but which terminates widely in the nasal cavity in those species which have been studied (*see* Graziadei 1974 and p. 1055).

THE PHYSIOLOGY OF OLFACTORY RECEPTORS

The chemical sense subserved by the olfactory epithelium differs from that of the gustatory and other chemical senses in detecting and discriminating between a wide range of *airborne* molecules at very low concentrations. Although in man the sense of smell is only moderately well developed compared with that of macrosmatic species, in which odours play an important, even dominant role, there is evidence that olfaction may be more significant than previously imagined. In mammals, including primates, the production of specific scents ('pheromones') which affect the social or sexual behaviour of others of the same species is becoming recognized as a common phenomenon, and the close relationship between the olfactory pathways and areas of the brain associated with emotional behaviour in man may be important clues to the significance of odours in general. (*See* the limbic system, p. 990.)

Turning to more specific aspects of olfaction, the mechanism of odour reception and signalling to the brain have been approached chiefly by the technique of recording electrical changes in or at the

7.242 A A vertical section through the olfactory epithelium of the mouse, stained with Holmes' silver method to show the olfactory dendrites and their terminal expansions (above). The nuclei of the receptor neurons are arranged in columns in this preparation; the fila olfactoria can also be seen emerging from the base of the epithelium (below). (Kindly provided by Dr. A. Cuschieri, Depts. of Anatomy, Guy's Hosp. Med. Sch. and Univ. of Kuwait.)

surface of the epithelium when it is exposed to odorous stimuli (Moulton and Beidler 1967). Two types of electrical changes can be recorded, namely a slow negative wave (the *electro-olfactogram*) found at the surface and a short distance below it, representing summated ionic fluxes stemming from many individual receptor dendrites; deeper in the epithelium, and in the olfactory nerve bundles, *action potentials* representing all-or-none activity in the axons can be detected instead.

Precisely how an array of receptors provides information about the stimulus type and intensity is the subject of much controversy. It might be imagined that individual receptors could be classified into specific types, each responsive to a particular odour. However, it is possible to distinguish between a large variety of different odours, and it would be necessary to postulate a tremendous range of receptor specificity, each group capable of detecting slight differences in molecular properties, if there is a one-to-one relationship between receptor type and odour. Electrophysiological recording indicates that single receptors can respond in different ways to a wide variety of odours, and that different receptors exhibit diverse patterns of response to single odours. It seems likely that discrimination in the olfactory system results from the analysis of a pattern of differential activity in a wide range of receptors (Gesteland *et al.* 1965).

The precise mode of interaction between odours and receptors is also debatable, and many theories have been proposed. The most widely accepted view is provided by the stereochemical theory first elaborated by Amoore (*see* the review by Amoore 1971); in outline, this proposes that there are various receptor molecules on or in the olfactory receptor cell, each class being able to recognize and respond to particular chemical groups on odorant molecules dissolved in the nasal mucus, rather in the same manner as an enzyme recognizing and acting on its specific substrate (a 'lock and key' phenomenon). Thus the shape of some part of the odorant would correspond to a complementary site in the receptor molecule. In early studies of the relationship between molecular shape and the subjective experience of odour quality it was thought that there might be a quite simple basis for the observed quality coding, depending on perhaps seven or eight 'primary odours' analogous to primary colours in colour vision (e.g. floral, fruity, minty, pungent, musky, etc.). More recent studies indicate that, unfortunately, the position is more complex than this; investigations into specific anosmia, that is, the condition in which one or a few classes of odours cannot be detected although the sense of smell is in general unaffected, suggests that there are perhaps thirty or more 'primary odours' in humans. There is also evidence that the receptor sites are present on the surface of the olfactory receptor cell, embedded in the exposed plasma membrane, and that the odorant binds loosely and transiently to each site to cause a change in the permeability of the membrane to ions. However, further studies at the cellular level are necessary for an understanding of the general nature of the sense of smell which in the past has been rather neglected by scientists.

THE RESPIRATORY EPITHELIUM

Those regions of the mucous membrane of the nasal cavity and associated sinuses which are not formed of olfactory epithelium are composed of columnar or pseudo-stratified ciliated epithelium interspersed with goblet cells, non-ciliated columnar cells with microvilli, and basal cells (Mygind 1975, 1978), collectively termed the *respiratory epithelium* (Negus 1958). In some areas these cells may be low columnar to cuboidal. Beneath the basal lamina are groups of serous and mucous glands which show much variation in cytological detail, opening by branched ducts on to the epithelial surface. The *cavernous tissue* lying beneath the respiratory mucosa in these areas is extensive (*vide infra*), and vascular disturbances cause alterations in the contours of the epithelial surface visible as swelling or shrinkage of the nasal lining.

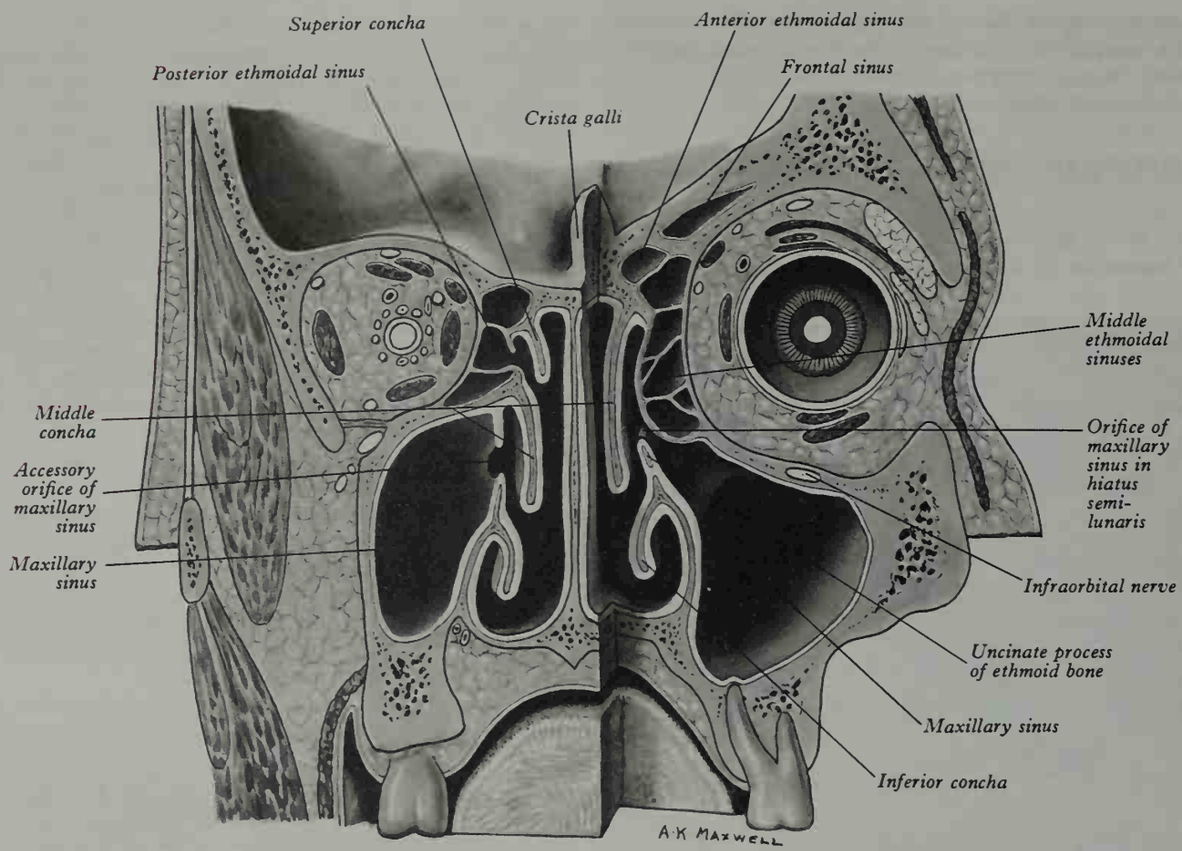
The endothelium of these cavernous sinuses is particularly interesting since fenestrations have been demonstrated; it is possible that the muscular coats which are associated with changes in blood pressure in their lumina are under endocrine rather than direct autonomic control (Cauna and Hinderer 1969; Cauna *et al.* 1972). Immediately basal to the epithelium and its basement membranes there is a fibrous layer infiltrated with lymphocytes, forming in many parts a diffuse lymphoid tissue, and under this is a nearly continuous layer of mucous and serous glands, the ducts of which pass through the lymphoid layer before opening upon the surface. The abundant amount of mucus secreted by the glands and goblet cells makes the surface of the mucosa moist and sticky. Because of this the dust in the inspired air is deposited on the surface and the air is humidified. The rich vascularity of the membrane ensures warming of the inspired air and accounts for its pink colour. The contaminated mucous film covering the membrane is moved by ciliary action downward and backward, away from the olfactory region and into the

nasopharynx at a rate of about 6 mm per minute (Proctor *et al.* 1978). Palate movements then transfer it to the oral pharynx and it is swallowed. Some, however, is passed anteriorly into the vestibule of the nasal cavity.

VASCULATURE AND NERVES OF THE NASAL CAVITY

The *arteries of the nasal cavity* are the anterior and posterior ethmoidal branches of the ophthalmic artery, which supply the ethmoidal and frontal sinuses and the roof of the nose; the sphenopalatine branch of the maxillary artery, which supplies the mucous membrane covering the conchae, the meatuses, and septum; the terminal part of the greater palatine artery which ascends through the incisive canal (p. 341); the septal ramus of the superior labial branch of the facial artery, which supplies the part of the septum in the region of the vestibule, anastomosing with the sphenopalatine artery, and is a common site of bleeding from the nose (epistaxis); the infraorbital and superior (anterior and posterior) alveolar branches of the maxillary artery which supply the lining membrane of the maxillary sinus; the pharyngeal branch of the same artery, which is distributed to the sphenoidal sinus. The ramifications of these vessels form a close plexiform network, beneath and in the substance of the mucous membrane.

The *veins of the nasal cavity* form a close cavernous plexus beneath the mucous membrane. Arteriovenous communications are present (Harper 1947). The plexus is especially marked over the lower part of the septum and over the middle and inferior conchae. Some of the veins open into the sphenopalatine vein; others join the facial vein; some accompany the ethmoidal arteries, and end in the ophthalmic veins; a few communicate with the veins on the orbital surface of the frontal lobe of the brain, through the foramina in the cribriform plate of the ethmoid bone. When the foramen caecum is patent it transmits a vein from the nasal cavity to the superior sagittal sinus.



The *nerves of the nasal cavity* include branches of the trigeminal and olfactory cranial nerves.

7.243A An electron micrograph of an olfactory cilium (bovine) attached at its basal end to an olfactory dendrite terminal, freeze-fractured to expose the numerous intramembranous particles which are thought to be sites of odour reception. An extensive ciliary necklace is present at the base of the cilium, and microvilli of a supporting cell are visible on the left. Magnification × 60,000. (Kindly supplied by Dr. B. Menco, University of Utrecht, Netherlands.)

7.243B An electron micrograph of a group of non-sensory cilia from the respiratory epithelium of the nasal cavity (bovine), freeze-fractured to show the distribution of intramembranous particles. Note the presence of ciliary necklaces at the bases of cilia, and the relative paucity of particles elsewhere on the cilia (compare with 7.243A). Magnification × 80,000. (Kindly supplied by Dr. B. Menco, University of Utrecht, Netherlands.)

7.244 A coronal section through the nasal cavity, viewed from the posterior aspect. On the right side the plane of the section is more anterior. The normal orifice of the maxillary sinus is shown on the right side, and the not uncommon accessory orifice on the left side.

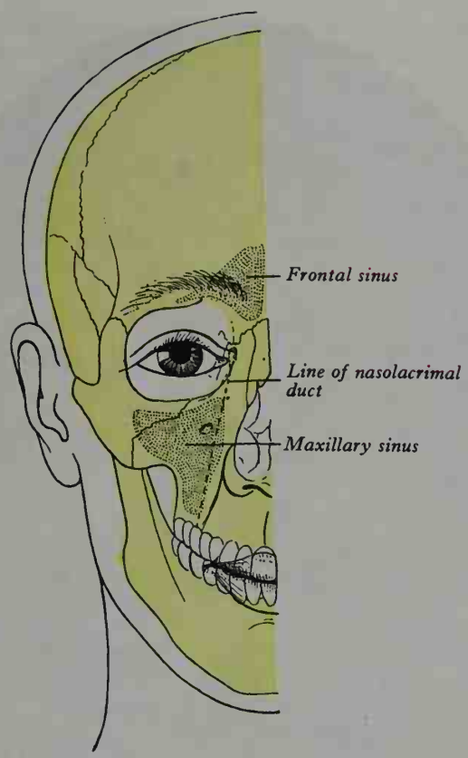
The *lymph vessels* are described on p. 787.

The *nerves of ordinary sensation* (7.171, 178) supplying the nasal cavity are as follows: the anterior ethmoidal branch of the nasociliary nerve, which supplies the anterior and upper part of the septum, the anterior part of the roof and the anterior parts of the middle and inferior conchae with the lateral wall in front of these; the infraorbital nerve, which supplies the vestibule; the anterior superior alveolar nerve, which supplies the part of the septum and floor near the anterior nasal spine and the anterior part of the lateral wall as high as the opening of the maxillary sinus; the lateral posterior superior nasal and the medial posterior superior nasal nerves (including the nasopalatine nerve), which are branches of the pterygopalatine ganglion, and the posterior inferior nasal branches of the anterior palatine nerve supplying the posterior three-quarters of the lateral wall, roof, floor and septum; branches from the nerve of the pterygoid canal which supply the upper and back part of the roof and septum. It is to be noted that, with the exception of the nasociliary nerve, all the non-olfactory nerves supplying the nasal cavity are derived from the maxillary division of the trigeminal nerve.

Accompanying the sensory fibres in these nerves are postganglionic vasomotor sympathetic fibres to the nasal blood vessels, whilst running with the branches from the pterygopalatine ganglion are postganglionic parasympathetic fibres from the latter which are secretomotor to the nasal glands.

The *olfactory nerves* are, of course, distributed to the olfactory region of the mucosa, and their fibres arise from the bipolar olfactory cells, described above, and are destitute of myelin sheaths. They unite in fasciculi which cross one another in various directions, thus giving rise to the appearance of a plexus in the mucous membrane, and then ascend in grooves or canals in the ethmoid bone; they pass into the skull through the foramina in the cribriform plate of the ethmoid and enter the inferior surface of the olfactory bulbs, in which they ramify and form synapses with the dendrites of the mitral cells, and other varieties of neuron (7.118, see also p. 992). Closely associated with the olfactory nerves are the *nervi terminales* (p. 1055).

THE PARANASAL SINUSES



The frontal, ethmoidal, sphenoidal and maxillary paranasal sinuses (7.238, 239, 240, 244, 245, 246) vary in size and form in different individuals, and are lined with mucous membrane continuous with that of the nasal cavity, an important fact in connexion with the spread of infections. The mucous membrane resembles that of the respiratory region of the nasal cavity, but is thinner, less vascular and more loosely adherent to the bony walls of the sinuses. The mucus secreted by the glands in the mucous membrane is swept into the nose through the apertures of the sinuses by the movement of the cilia covering the surface. The cilia are not uniformly distributed in the lining mucous membrane but are always present near the opening into the nasal cavity. The function of the sinuses is doubtful. They lighten the skull and add resonance to the voice, but the saving in weight would be trivial, for absence of sinuses does not entail an equivalent volume of *solid* bone, and the weight of trabecular bone which would occupy such a volume is small. It is more probable that some, at least, of the sinuses are manifestations of the exceptional growth pattern of the bones in which they occur. They vary considerably in size in different individuals. Most are rudimentary, or even absent, at birth; they enlarge appreciably during the time of eruption of the permanent teeth and after puberty, and this growth is a factor in the alteration in the size and shape of the face at these times.

Two frontal sinuses are posterior to the superciliary arches, between the outer and inner tables of the frontal bone. When of average size, each underlies a triangular area on the surface, the angles of which are formed by the nasion, a point about 3 cm above the nasion and the junction of the medial third with the rest of the supraorbital margin (3.116, 7.245, 246). However, they are rarely symmetrical, because the septum between them frequently deviates from the median plane. Their average measurements are as follows: height, 3·2 cm, breadth, 2·6 cm, depth from before backwards, 1·8 cm. Each extends upwards above the medial part of the eyebrow and backwards into the medial part of the roof of

the orbit. The frontal sinus is sometimes divided into a number of intercommunicating recesses by incomplete bony partitions. Rarely, one or both sinuses may be absent, and the degree of prominence of the superciliary arches is no indication of the presence or size of the frontal sinuses. The part of the sinus extending upwards in the frontal bone may be small and the orbital part large, or vice versa. Sometimes one sinus may overlap in front of the other. The sinus may extend posteriorly as far as the sphenoid (lesser wing), but does not invade it. Each opens into the anterior part of the corresponding middle meatus of the nose, either through the *ethmoidal infundibulum* or through the *frontonasal duct*, which traverses the anterior part of the labyrinth of the ethmoid. Rudimentary or absent at birth, they are generally fairly well developed between the seventh and eighth years, but reach their full size only after puberty (see also p. 334). They are usually more prominently developed in males, giving the profile of the forehead an obliquity which contrasts with the vertical or convex outline usual in children and females. The arterial blood supply of the sinus is from the supraorbital and anterior ethmoidal arteries, and the venous drainage is into the anastomotic vein in the supraorbital notch connecting the supraorbital and superior ophthalmic veins. The lymph drainage is to the submandibular nodes. The nerve supply is derived from the supraorbital nerve.

The ethmoidal sinuses (*see* pp. 335, 336) consist of thin-walled cavities in the ethmoidal labyrinth, completed by the frontal, maxillary, lacrimal, sphenoidal and palatine bones. They vary in number and size from three large to eighteen small sinuses on each side, and their openings into the nasal cavity are very variable. They lie between the upper part of the nasal cavity and the orbits, and are separated from the latter by the extremely thin orbital plates of the ethmoid; infection may spread from the sinuses into the orbit and produce orbital cellulitis. On each side they are arranged in three groups—anterior, middle, and posterior, though some anatomists divide them into two groups, anterior and posterior, the anterior group including those described below as the anterior *and* middle groups. The three groups are not sharply delimited from each other and one group may encroach on the territory generally occupied by another. The groups are really only distinguishable on the basis of their sites of communication with the nasal cavity. In each group the sinuses are partially separated by incomplete bony septa. The *anterior group* vary up to eleven in number and open into the ethmoidal infundibulum or the frontonasal duct by one or more orifices; one sinus frequently lies in the agger nasi and the most anterior sinuses may encroach upon the frontal sinus. The *middle group* (bulbar sinuses) generally comprise three cavities which open into the middle meatus by one or more orifices on or above the ethmoidal bulla. The *posterior group* vary from one to seven in number and usually open by one orifice into the superior meatus inferior to the superior concha, though one may open into the highest meatus (when present), and one or more sometimes open into the sphenoidal sinus. The posterior group are very closely related to the optic canal and optic nerve. The ethmoidal sinuses are small, but of clinical importance, at birth; they grow rapidly between the sixth and eighth years and after puberty. They derive their arterial blood supply from the sphenopalatine (p. 684) and the anterior ethmoidal and posterior ethmoidal arteries and are drained by the corresponding veins. The lymphatics of the anterior and middle groups drain into the submandibular nodes and those of the posterior group into the retropharyngeal nodes. The ethmoidal sinuses are supplied by the anterior and posterior ethmoidal nerves and the orbital branches of the pterygopalatine ganglion.

The two sphenoidal sinuses (p. 323, **3**.77, 78), are sited posterior to the upper part of the nasal cavity. Contained within the body of the sphenoid bone, they are, therefore, related above, to the optic chiasma and the hypophysis cerebri, on each side, to the internal carotid artery and the cavernous sinus. If the sinuses are small, they lie in front of the hypophysis cerebri. They vary in size and shape, and, owing to the lateral displacement of the intervening septum, are rarely symmetrical. Frequently one sinus is much the larger of the two and extends across the median plane behind the sinus of the opposite side; occasionally one sinus may overlap above the other, and rarely there is a communication between the two sinuses. Occasionally one or both sinuses may extend close to and even partially encircle the optic canal on its own side. The following are their average measurements: vertical height, 2 cm; transverse breadth, 1·8 cm; anteroposterior depth, 2·1 cm. When exceptionally large they may extend into the roots of the pterygoid processes or greater wings of the sphenoid, and may invade the basilar part of the occipital bone. Occasionally there are gaps in the bony walls and the mucous membrane may lie directly against the dura mater. Bony ridges, produced by the internal carotid artery and the pterygoid canal, may project into the sinuses from the lateral wall and floor respectively. A posterior ethmoidal sinus may extend into the body of the sphenoid and largely replace a sphenoidal sinus. Each sinus communicates with the spheno-ethmoidal recess by an aperture in the upper part of its anterior wall. They are present as minute cavities at birth, but their main development takes place after puberty. Their blood supply is by means of the posterior ethmoidal vessels and the lymph drainage is to the retropharyngeal nodes. Their nerve supply is from the posterior ethmoidal nerves and the orbital branches of the pterygopalatine ganglion.

7.245 An outline of the bones of the face, showing the positions of the frontal and maxillary sinuses.

The two maxillary sinuses, which are the largest accessory air sinuses of the nose, are pyramidal cavities in the bodies of the maxillae (**3**.117; 7.244, 245, 246). The base of each is formed by the lateral wall of the nasal cavity; the apex extends into the zygomatic process of the maxilla. The roof, which is the orbital floor, is frequently ridged by the infraorbital canal, while the floor is formed by the alveolar process and is usually about 1·25 cm below the level of the floor of the nose, on a line drawn laterally from the lower border of the ala. Several conical elevations corresponding with the roots of the first and second molar teeth project into the floor, which is sometimes perforated by one or more of these roots. Sometimes the roots of the first and second premolars and the third molar, and occasionally the root of the canine, also project into the sinus (*see* p. 1302). The size of the maxillary sinus varies in different skulls, and even on the two sides of the same skull; when large, its apex may invade the zygomatic bone. The following measurements are those of an average-sized air sinus: vertical height opposite the first molar tooth, 3·5 cm; transverse breadth, 2·5 cm; anteroposterior depth, 3·2 cm. The sinus communicates with the lower part of the hiatus semilunaris through an opening in the anterosuperior part of its base (7.244); a

7.246 The skull of an adult woman which has been decalcified and then cleared in methyl salicylate; the specimen was transilluminated and then photographed from the ventral aspect. Note particularly the profiles of the frontal and maxillary paranasal air sinuses, the orbits and superior orbital fissures, and the nasal cavities and conchae. (The specimen was prepared by Dr. D. H. Tompsett of the Royal College of Surgeons of England.)

second orifice is frequently seen in, or immediately below, the hiatus. Both are nearer the roof than the floor of the sinus. The maxillary sinus appears as a shallow groove on the medial surface of the bone about the fourth month of intrauterine life, but does not reach its full size until after the eruption of all the permanent teeth. The blood supply of the sinus is by means of the facial, infraorbital and greater palatine vessels; the lymph drainage is to the submandibular nodes. The nerve supply is derived from the infraorbital and the anterior, middle and posterior superior alveolar nerves.

For further details of the human and comparative anatomy of the paranasal sinuses consult Negus (1958).

RADIOLOGICAL APPEARANCES

Normal sinuses are radiolucent, whereas diseased sinuses show varying degrees of opacity. Radiographs also reveal the extent of development of the sinuses. In anteroposterior view (**3**.62, 68), the sinuses appear as follows. The frontal sinuses are seen above the nasal cavity and the medial part of the orbits and their asymmetry, vertical extent and the presence of bony septa can be assessed. The ethmoidal sinuses are superimposed on each other as well as on the sphenoidal sinus in the radiograph; they lie between the orbits, below the shadow of the cribriform plate. The sphenoidal sinus is not clear in this view. The maxillary sinus forms a pyramidal-shaped translucent area below the orbit and lateral to the lower part of the nasal cavity; inferiorly it extends into the alveolar process of the maxilla. In lateral view, the extent of the frontal sinus both upwards into the frontal bone and backwards into the orbital roof can be seen. The ethmoidal sinuses are seen extending from the shadow of the frontal process of the maxilla as far back as the sphenoidal sinus, the latter being clear and distinct below and in front of the fossa for the hypophysis, though of course the areas of the two sphenoidal sinuses are superimposed, and the individual sphenoidal sinuses are best seen in a superior view. The maxillary sinus is well seen in a lateral view; it lies below the orbit and its extent in relation to the roots of the teeth can be clearly seen.

The maxillary and frontal sinuses can also be examined by the method of trans-illumination. In a dark room an electric torch is placed in the mouth, in the case of the maxillary sinus, or against the superomedial angle of the orbital opening, for the frontal sinus. Normally, a red glow is seen in the region of these sinuses, which may be absent where they are diseased. (For a view of the frontal and maxillary sinuses in a cleared preparation see **7**.246.)

Applied Anatomy. Congenital deformities of the nose occur occasionally, such as complete absence of the external nose, an aperture only being present, or perfect development on one side, and suppression or malformation on the other.

The septum of the nose may be displaced or may deviate from the median plane as a result of an injury or of some congenital defect. Sometimes the deviation may be so great that the septum may come into contact with the lateral wall of the nasal cavity, producing complete unilateral obstruction.

Suppuration in the paranasal sinuses is of frequent occurrence, and it is important to note that the middle meatus is of such a form that pus running down from the frontal sinus or the anterior ethmoidal sinuses is directed by the hiatus semilunaris into the opening of the maxillary sinus, so that the latter sinus may, in some cases, act as a secondary reservoir for pus discharged from these sinuses. All the paranasal sinuses can be infected from the nasal cavity, but it should be noted that in the case of the maxillary sinus, the infection may originate from the vicinity of the teeth (p. 1302). This sinus is the one most frequently the seat of chronic suppuration, which may result in loss of cilia from the surface of the mucosa and hence impairment of mucus flow. The normal opening of the maxillary sinus is high above the floor and is poorly placed for natural drainage. Surgical drainage may be effected by puncturing the lateral wall of the inferior nasal meatus, or the canine fossa on the anterior surface of the maxilla.

THE VISUAL APPARATUS

Introduction

Considering the all-pervading medium of sunlight, in which almost all animal and botanical life is immersed, it is inevitable that responses to this form of electromagnetic radiation should occur. The photosynthetic processes widespread in plant forms have a parallel in the photochemical receptors which occur almost universally in the animal kingdom. Although the range of frequencies in solar electromagnetic radiation is much wider, the spectrum of visible light (400–760 nm) is the range within which most animal 'light' receptors or *photoreceptors* function. There is evidence that some animal forms have receptors which react outside this range, either in the ultraviolet or infra-red frequencies; in vertebrates, some vipers and boas (Walls 1963) have facial pit organs which respond to infra-red radiation. In general, however, the *visual pigments*, which provide the basis of the photochemical response, display absorption maxima at various points within the visible spectrum. For example, human *rhodopsin* (visual purple) has a maximum at 497 nm. It is a rod pigment; *iodopsin*, a cone pigment, has been identified in some

avian species, and several such pigments are present in human cones, where their differing absorption maxima probably account for colour vision, but full details are not yet available (Rushton and Henry 1968). The basis of the response is a light-induced 'bleaching' process, during which the pigment changes to another form, with an associated electrical change, which is propagated through the photoreceptors to the first-order neurons. A rapid restoration process is, of course, a *sine qua non*. A multiplicity of visual pigments have been identified and studied; further details may be obtained in a number of monographs (e.g. Rushton 1962; Pirenne 1967; Davson 1976).

The next elaboration in visual organs is the introduction of a lens, to concentrate light energy upon the photoreceptor and to impart an element of directional sensibility. Many adaptations of this kind have occurred in invertebrates, mostly in two directions: eyes—as we may now call them—with a large number of separate lens-photoreceptor units, the *compound eyes* familiar in most insects and crustaceans, and the *single lens*, focusing light on to an array of photoreceptors, as present in snails and squids. It is the latter type of eye which is universal in vertebrates.

True eyes are able not only to respond to variations in *luminance*—a simple function of photoreceptors; by projecting a focused image upon an array of receptors, each with neural pathways of some degree of specificity, a new modality of vision is introduced—sensitivity to *form*. In both cases movement, which is of great biological significance, may be detected, but the vertebrate type of focusing eye has potentialities for much greater precision in this respect.

Primitively, vision appears to be employed as a form of *distance reception* capable of activating warning systems, and of orientating the animal advantageously with regard to light and shade. The paired eyes of most vertebrates are set in a lateral position in the head, permitting an almost panoramic view of the environment. Such *panoramic vision*, coupled with a system of muscles, by which the eye is reflexly rotated towards any object of significance—such as the movement of a predator—is characteristic of most mammals, and clearly provides a valuable 'early-warning' system. In limited groups of mammals, and some raptorial or predatory birds, the position of the orbits has changed, so that the two uniocular fields subtended by each eye overlap to a greater or lesser extent. This entails that the part of the environment in front of the animal is focused by both eyes. By a gradual refinement of the neural control of the ocular muscles, constantly provided with a feedback from the retinae, the eye movements become sufficiently concerted to 'fuse' the two slightly dissimilar images falling on the retinae, leading to the establishment of *binocular vision*. This advance is characteristic of carnivorous mammals, who may track down their prey in part by smell, but must rely upon the much more accurately directional nature of vision to carry out the final attack. Primates also possess forward-looking eyes and hence binocular vision; but in their evolution the effect of an arboreal phase of existence is generally regarded as the operative factor in the elaboration of not merely binocular, but *stereoscopic vision*, which is characterized by a more highly evolved motor 'understanding' of the three-dimensional nature of space. Olfaction is less useful in trees, and the acquisition of great skill in not merely climbing but in swinging or leaping from branch to branch could only occur with the development of stereoscopic vision. The same habitat undoubtedly favoured the retention and elaboration of pentadactyl and grasping extremities; and although man, and perhaps his immediate ancestors, is not an arboreal primate, the terrestrial specialization of his feet has not occurred in his hands. Left free of locomotor influences by the adoption of bipedal gait, the hands have in man formed a highly significant partnership. This, coupled with the development of a particularly large brain, able to process with increasing intricacy the highly detailed information from the eyes, and to control both the eyes and hands in increasingly skilful and subtle tasks, can be regarded as the major factors in the extraordinary evolution of human abilities.

The eye, therefore, is not to be regarded in isolation. Its array of modalities—sensitivity to very small changes in luminosity, particularly in dark-adapted or *scotopic vision*, high discriminativeness as to form and movement and to colour in light-adapted or *photopic vision*—do not merely provide interesting information. The information is vital; it is doubtful whether a blind individual could long survive outside human society. The eyes provide a continuous monitoring of all we do, especially in manual tasks. Visual means of communication have proved more valuable and lasting even than auditory. The gradual evolution of visual signs, reacting with auditory communication, has led to the formation of language in all its permutations. Through language, with all its potentialities for communication of increasingly precise information and conceptual influences, it becomes possible for generation after generation to profit from recorded knowledge and skill. The results of this in human culture have become the mainstream of man's evolution. It is against this background that the structure of the visual apparatus should be studied, as we must now proceed to do.

THE PERIPHERAL VISUAL APPARATUS

The eyeball, the peripheral organ of sight, is situated in the cavity of the orbit, the walls of which serve to protect it from injury. The protection is perhaps adventitious, for other considerations, more basic to the function of vision, are more pertinent. It is difficult to imagine how the ocular movements could be concerted in the absence of a socket; nor would the spatial relationship between the two eyes be so precisely preserved in the absence of rigid sockets, a factor of prime importance in animals with binocular vision. Certain accessory structures—the muscles, fasciae, eyebrows, eyelids, conjunctiva and lacrimal apparatus—are intimately associated with the eyeball and will be described in this section.

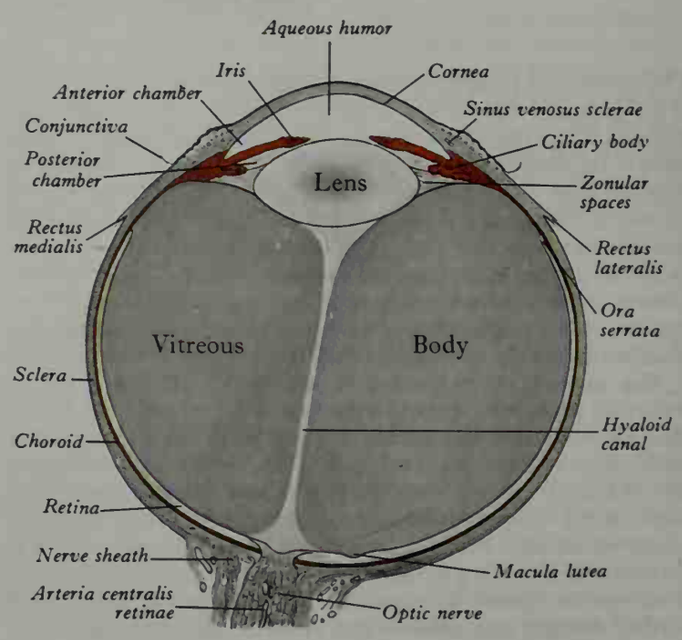
The eyeball is embedded in the fat of the orbit, but is separated from it by a thin membranous sac, termed the *fascial sheath of the eyeball* (capsule of Tenon) (p. 1181). It is composed of segments of two spheres of different sizes. The anterior segment is one of a small sphere; it is transparent, and it forms about one-sixth of the eyeball. It is more prominent than the posterior segment, which is one of a larger sphere, and is opaque, and it forms about five-sixth of the whole circumference of the eyeball. The *anterior segment* is bounded by the cornea and lens, and is further divided into *anterior* and *posterior chambers*, which are incompletely separated by the iris, being continuous through the pupil. Anteriorly, the periphery of the anterior chamber is overlapped by the sclera; the angle between the iris and cornea (p. 1152) forming an annulus which is of greater diameter than that of the *limbus*, the junction between sclera and cornea. The difference varies from 1 to 2 mm, the 'angle' being deeper above and below than at the sides. The posterior chamber, between the posterior surface of the iris and the anterior aspect of the lens and its supporting ligament, the zonule (p. 1176), is triangular in section, the apex of the triangle being where the iris touches the lens. Its base, the zonular region, is not, strictly speaking, the zonule itself, since the posterior chamber is regarded as extending among the collagenous bundles of the zonule and even into a *retrozonular space*, the canal of Petit, between the zonule and the vitreous humor in the *posterior segment*, which comprises the parts of the eyeball posterior to the zonule and lens. The term *anterior pole* is applied to the central point of the anterior curvature of the eyeball, and that of *posterior pole* to the central point of its posterior curvature; a line joining the two poles forms the *optic axis*. (By the same convention, the eyeball is considered to have an *equator*, equidistant between the poles; any circumferential line joining the poles is a *meridian*.) The primary axes of the two eyeballs are nearly parallel, and therefore do *not* correspond with the axes of the orbits, which are directed forwards and laterally. The optic nerves follow the direction of the axes of the orbits, and

therefore are not parallel; each nerve enters its eyeball about 3 mm to the nasal side of the posterior pole. The vertical diameter (23·5 mm) of the eyeball is rather less than the transverse and anteroposterior diameters (24 mm); the anteroposterior diameter at birth is about 17·5 mm and at puberty from 20 to 21 mm; it may vary considerably from this in *myopia* (29 mm) and *hypermetropia* (20 mm). In the female all three diameters are rather less than in the male. (*See* Stenström 1946, Sorsby and Sheridan 1960.)

The eyeball comprises three tunics, and the contents enclosed by them. From without inwards the three tunics are: (1) the fibrous tunic, consisting of the *sclera* behind and the *cornea* in front; (2) the vascular, pigmented tunic, comprising, from behind forwards, the *choroid*, *ciliary body* and *iris*, forming together the *uveal tract*; and (3) the nervous layer, termed the *retina*.

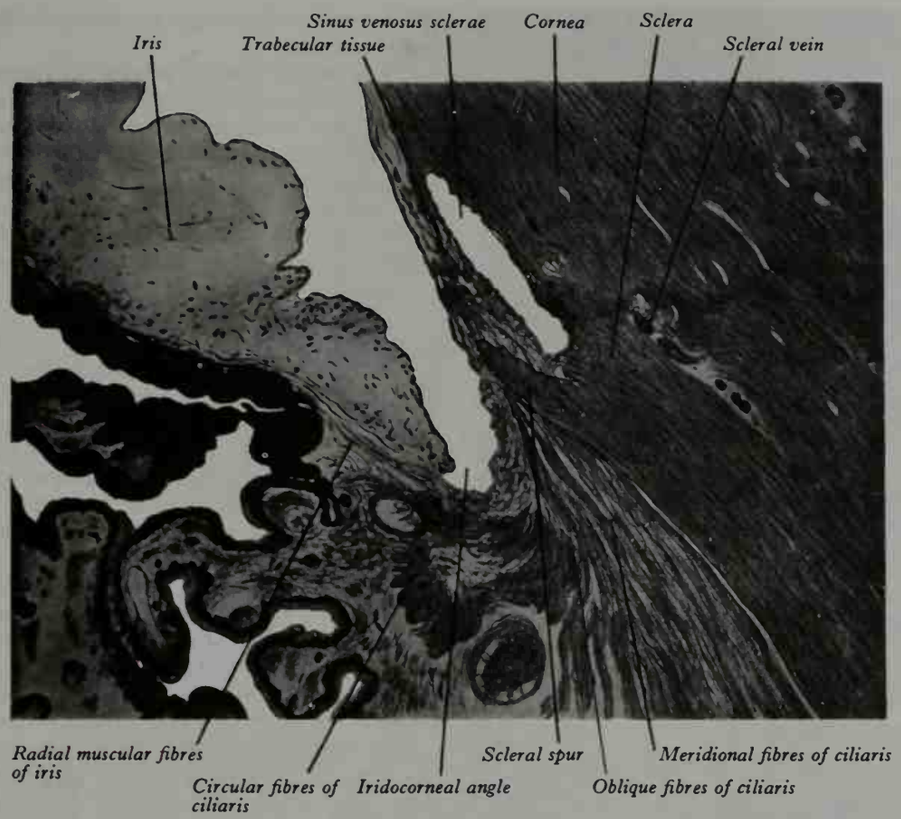
The Ocular Fibrous Tunic

The fibrous layer of the eyeball (7.247) consists of an opaque, posterior part, the *tunica sclera*, and a transparent, anterior part, the *tunica cornea*.



THE SCLERA (TUNICA SCLERA)

The sclera, so named from its density and hardness, is a firm membrane which, when distended by the intraocular pressure, serves to maintain the form of the eyeball. It is thickest (about 1 mm) behind, near the entrance of the optic nerve, and thinnest (0·4 mm) at a distance of about 6 mm behind the sclerocorneal junction, in the region of attachment of the recti (p. 1178). Its *external surface* is white, and is in contact with the inner surface of the fascial sheath of the eyeball (p. 1181)— it is smooth, except where the tendons of the orbital muscles are attached to it; its anterior part is covered by the conjunctival epithelium, reflected on to it from the deep surfaces of the eyelids and continuous anteriorly with that covering the cornea. Its *internal surface* is brown, and is marked by grooves in which the ciliary nerves and vessels ramify; it is separated from the external surface of the choroid by an extensive *perichoroidal space*, which is traversed by an exceedingly delicate cellular tissue, termed the *suprachoroid lamina* (or *lamina fusca of the sclera*). Posteriorly, the sclera is pierced by the optic nerve, and is continuous through the fibrous sheath of this nerve with the dura mater. Where the optic nerve pierces the sclera, the latter has the appearance of a cribriform plate and is named the *lamina cribrosa sclerae* (7.258); the minute orifices in this lamina transmit the nerve bundles. One opening, larger than the rest, and occupying the centre of the lamina, transmits the central artery and vein of the retina. The lamina cribrosa is the weakest part of the sclera; if the intraocular pressure be raised for some time, as in cases of chronic glaucoma, the lamina cribrosa becomes bulged outwards producing the condition of 'cupped disc'. Around the lamina cribrosa numerous small apertures are present which transmit the ciliary vessels and nerves, and about midway between these and the sclerocorneal junction there are four or five large apertures for the transmission of veins (*venae vorticosae*). In front, the sclera is directly continuous with the cornea, the line of union being termed the *sclerocorneal junction* (or *limbus*). In the substance of the sclera close to this junction is a canal lined with endothelium running circularly, termed the *sinus venosus sclerae*, which in section presents the appearance of an oval cleft. The outer wall of the cleft is formed by a groove in the sclera. Posteriorly the cleft extends as far as a projecting rim of scleral tissue termed the *scleral spur*, which in section is triangular with the apex directed forwards and inwards. The sinus may be double in parts of its course. The inner wall of the scleral sinus, that is, the aspect of the sinus adjoining the aqueous chamber, is formed by a loose trabecular tissue continuous anteriorly with the posterior limiting lamina of the cornea. Between the fibres of this tissue are spaces through which the aqueous humour in the anterior chamber filters into the sinus (7.250), from which it then passes into the bloodstream, since the scleral sinus drains externally into the anterior ciliary veins. Normally the sinus contains no blood; although the communicating channels between the sinus and the anterior ciliary veins contain no valves, these channels are oblique and flattened and may prevent reflux of blood into the sinus. Such a valvular mechanism is dubious, pressure gradients being more likely to prevent reflux of blood, since under conditions of venous congestion blood may pass into the sinus. The anterior and outer side of the scleral spur gives attachment to most of the fibres of the trabecular tissue mentioned above and the posterior and inner side to the meridional fibres of the ciliaris. The *iridocorneal angle* (7.248) of the anterior chamber lies between the trabecular tissue and scleral spur anteriorly and outwards and the periphery of the iris posteriorly and inwards.



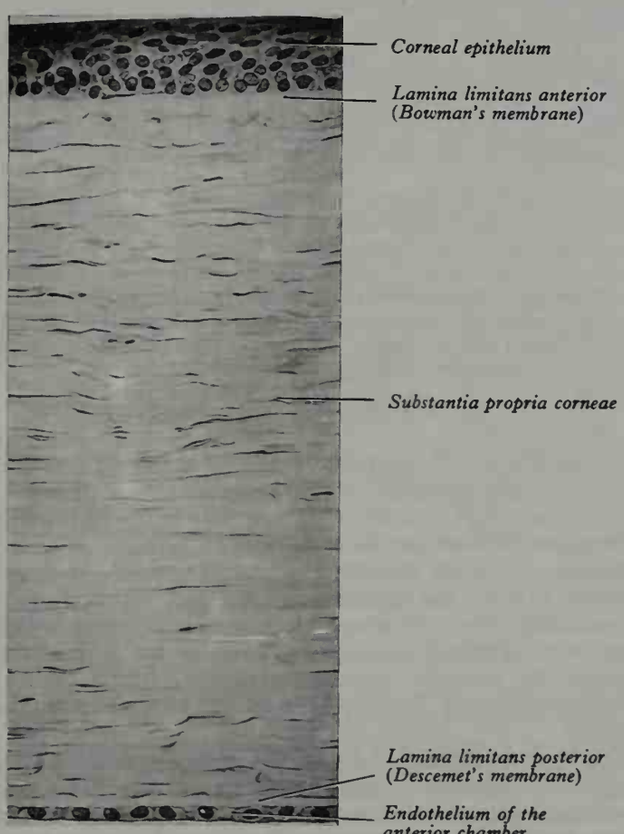
Structurally, the sclera is formed of white fibrous tissue intermixed with fine elastic fibres; flattened connective tissue cells, some of which are pigmented, are contained in lacunae between the fibres. The fibres are aggregated into bundles arranged in characteristic patterns in different parts of the sclera. Thus they are circumferential with respect to the optic papilla, but become reticular in arrangement anterior to this, and markedly meridional near the attachments of the four recti (Kokott 1934). The individual fibrils vary in diameter from 28 to 280 nm with periodicities of 80 and 21 μm. Collagen accounts for 75 per cent of the dry weight of the sclera. The sclera acts as a viscoelastic structure—an important factor in relation to intraocular circulation and pressure (Gloster *et al.* 1957; Helen and McEwen 1961). Its *vessels* are scanty; its capillaries are small, and unite at wide intervals. Its *nerves* are derived from the ciliary nerves.

THE CORNEA

The cornea (7.247) is the anterior, projecting and transparent part of the external tunic, to which is due the major part of the refraction of the rays of light entering the eye. It is convex anteriorly, and projects as a flattened dome in front of the sclera. Its degree of curvature varies in different individuals, and in the same individual at different periods of life, being more pronounced in youth than in old age. As the curvature of the cornea is greater than that of the rest of the eyeball, a slight furrow, called the *sulcus sclerae*, marks the junction of the cornea and sclera. The cornea is dense and about 1·2 mm thick round its periphery and 0·5–0·6 mm at its centre. Its anterior surface is somewhat elliptical, the transverse diameter being slightly greater than the vertical. Its posterior surface is circular and, because the corneoscleral junction is slightly oblique superiorly and inferiorly, is more extensive than the anterior surface in the vertical axis. The diameter of the cornea is about 11·7 mm on its

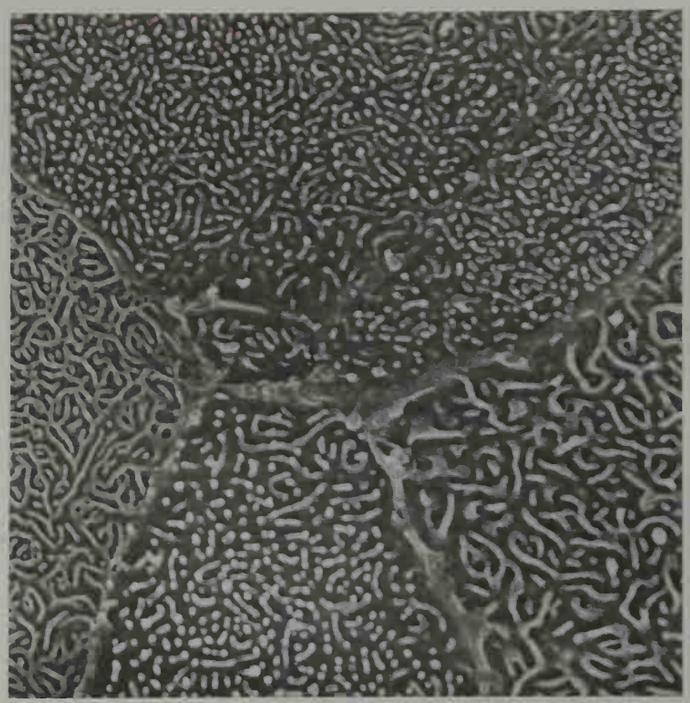
7.247 A horizontal section through a right human eyeball. Superior aspect.

7.248 A general view of a meridional section through the iridocorneal angle.



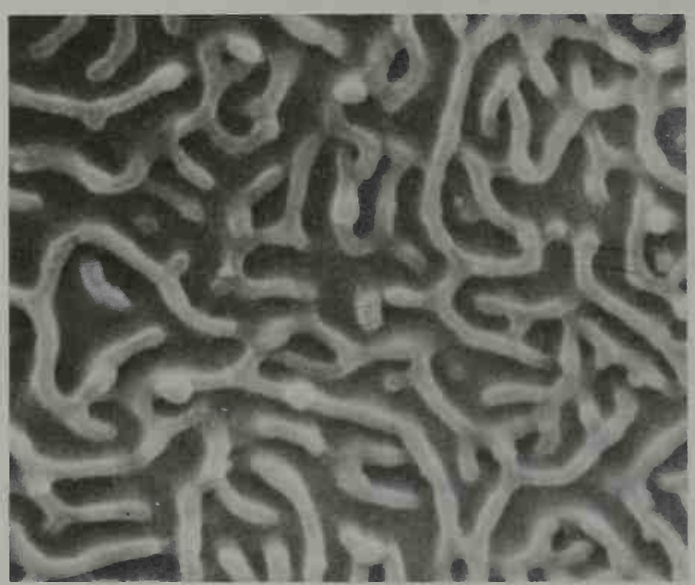
posterior aspect; anteriorly it is 11·7 mm horizontally but only 10·6 mm in the vertical.

Structurally (7.249), the cornea consists from before backwards of five layers—(1) the corneal epithelium, continuous with that of the conjunctiva; (2) the anterior limiting membrane (of Bowman); (3) the substantia propria; (4) the posterior limiting lamina (of Descemet); (5) the endothelium of the anterior chamber.



The *corneal epithelium* covers the front of the cornea and generally consists of five layers of cells. The deepest cells are columnar; their basal surfaces are flat and their outer surfaces rounded, and they contain large round or oval nuclei. The cells of the second layer are polyhedral, with oval nuclei. In the superficial layers the cells become progressively flattened, but, unlike the superficial cells of the epidermis, they contain flattened nuclei and they do not normally become keratinized. Most of the cells of the corneal epithelium are 'prickle' cells, similar to those of the germinative zone of the epidermis (p. 1218). At the sclerocorneal junction (or limbus), the epithelium becomes thicker (up to ten or more layers of cells) and is continuous with the conjunctiva covering the sclera. The surface cells of the corneal epithelium display, as do those of the conjunctiva elsewhere, microvilli and microplicae (Dohlman 1971). The latter are considered (Andrews 1975) to be concerned in the retention of an unbroken film of surface secretion, which is essential to what is, of course, the primary refractive surface of the eye.

Scanning electron microscopy of the external surfaces of the corneal epithelial cells has confirmed these interesting features (Pfister 1973; Pfister and Burstein 1977). As is shown in illustration 7.249B, C a pattern of fine irregularities (microvilli) is intermixed with more common, fine, sinuous, intercommunicating ridges. The two types of ultrastructural detail appear to predominate in different cells, giving them a light or dark appearance, the first displaying microvilli, the second microplicae. Some epithelial cells display both features in varying proportions, and a few cells present microprojections merely in the central region of their exposed surfaces. All these observers agree in regarding these projections as helping to maintain the superficial film of tear fluid.



The *substantia propria* is fibrous, compact, unyielding and perfectly transparent. It is composed of about 200–250 flattened, superimposed lamellae which are made up of bundles of modified connective tissue, the fibres of which are continuous with those of the sclera. Each lamella is about 2 μm thick and of very variable width (10–250 μm). The fibres of each lamella are mostly parallel, but at obtuse angles to those of adjacent lamellae. Fibres frequently pass from one lamella to the next. The dimensions of

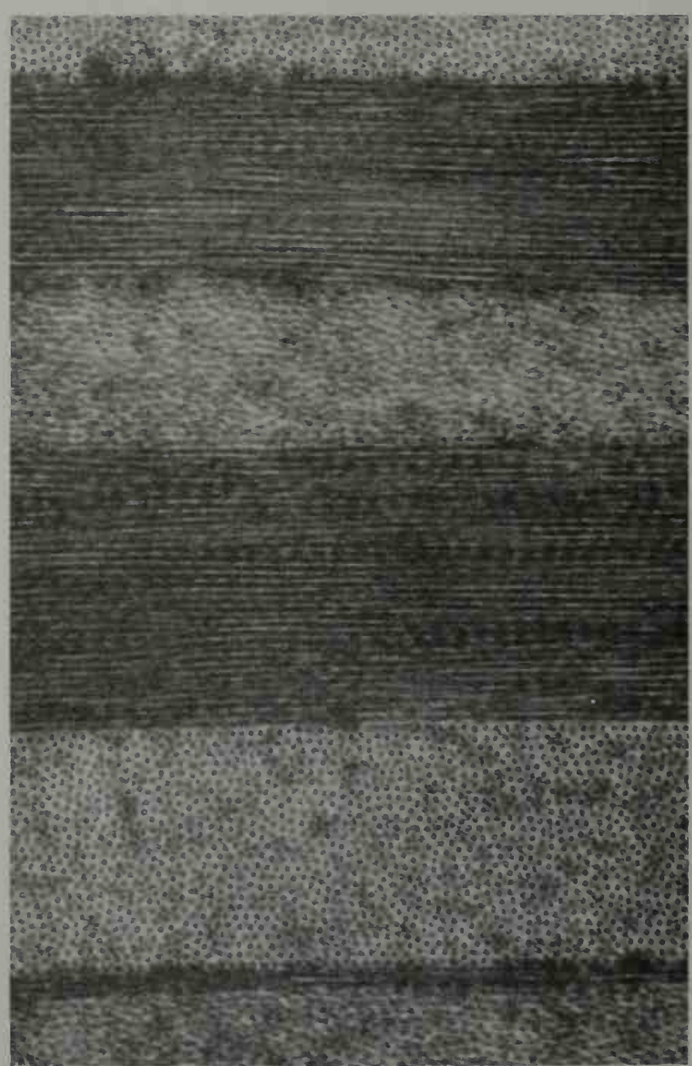
B

C

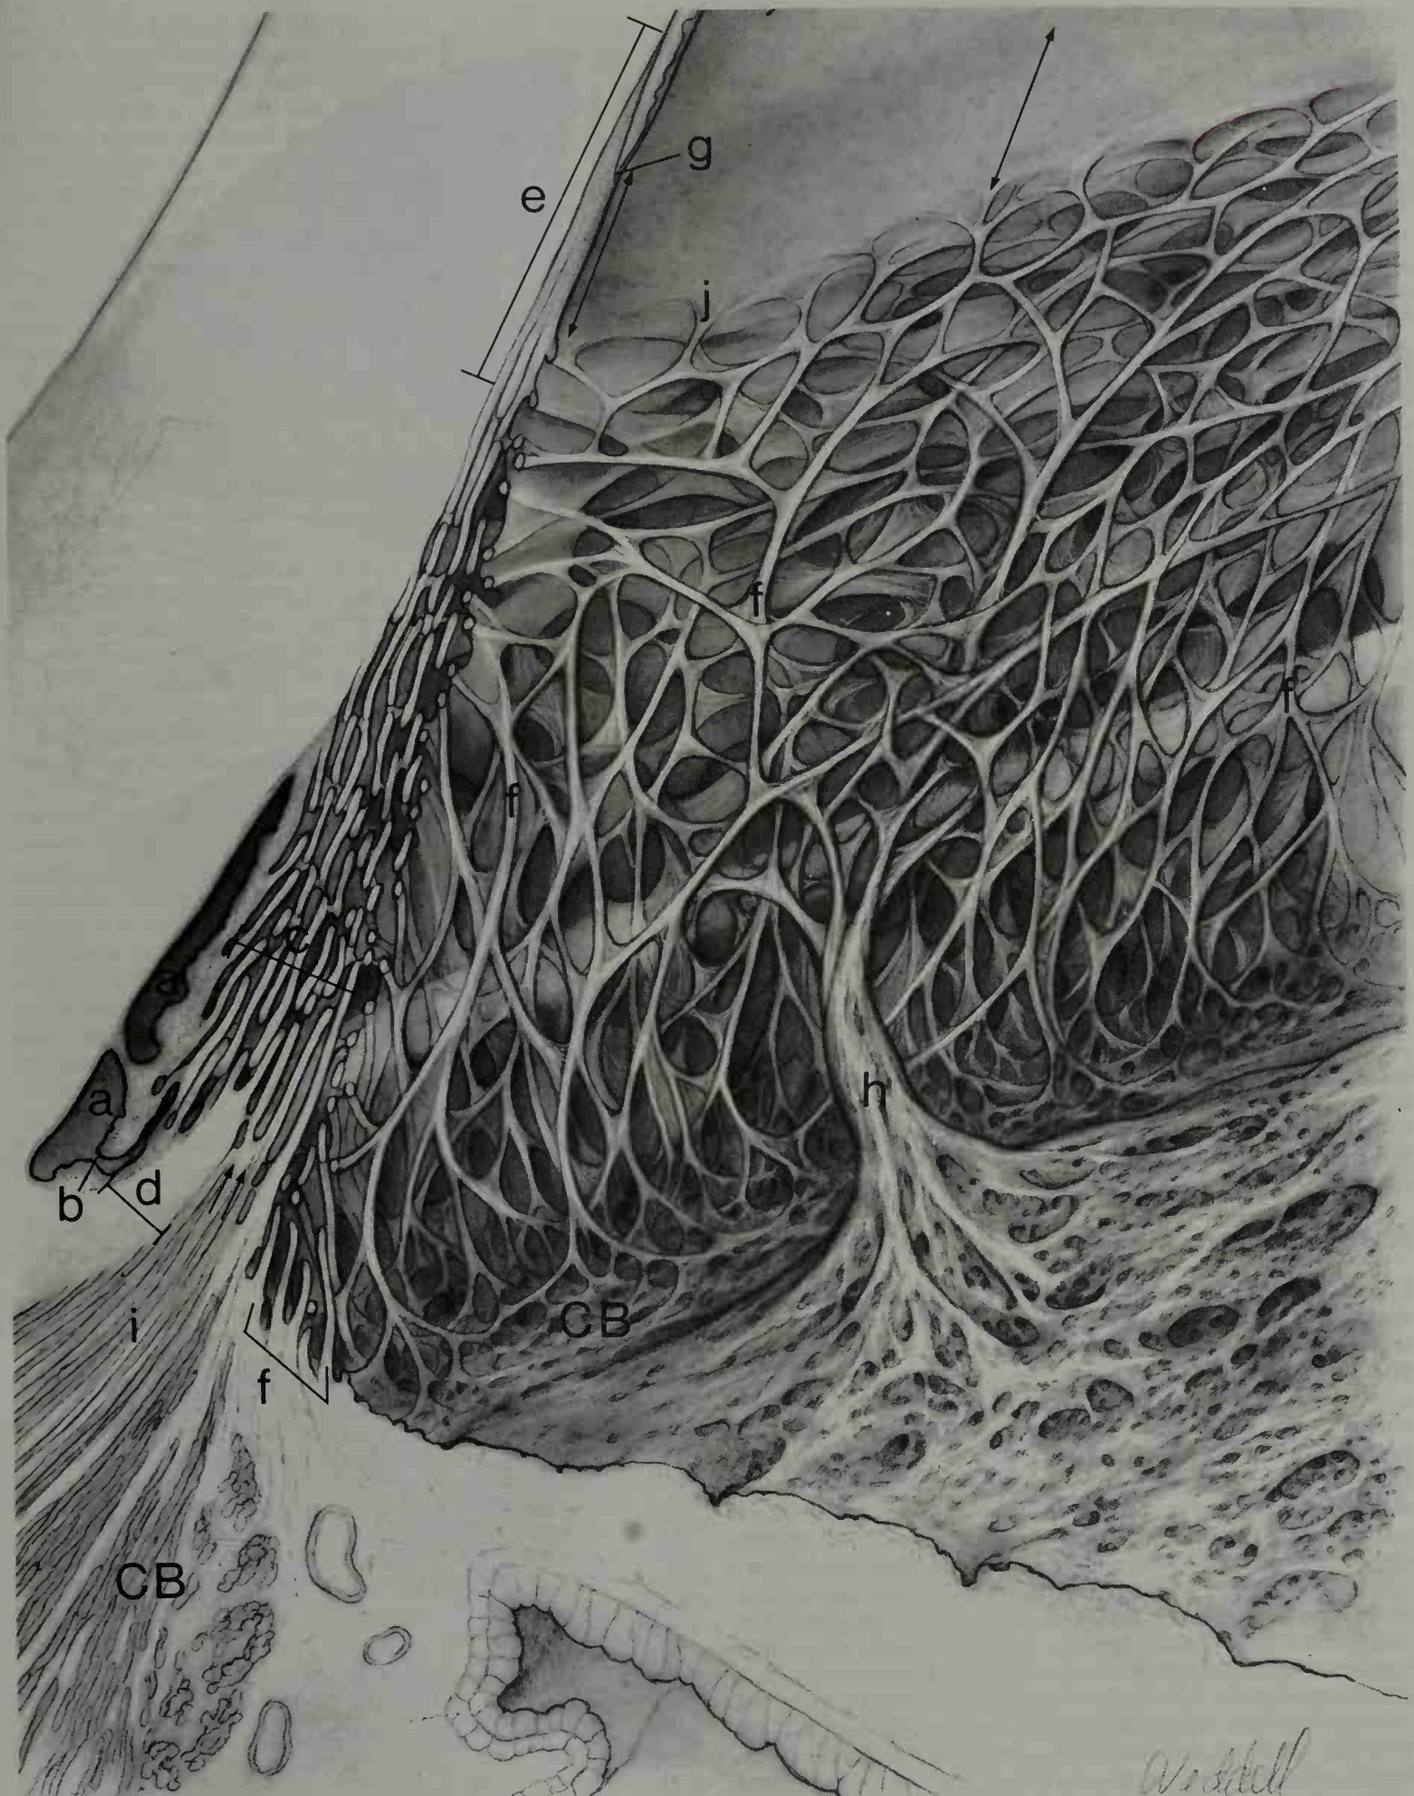
7.249B, C Scanning electron micrographs of normal human corneal epithelial cells. In B (magnification × 5000) parts of the outlines of several cells are visible; in the upper and lower cells, microvilli predominate, but some microplicae are seen. The cells at the right and left of the field display predominantly microplicae, with only a few microvilli. In C (magnification × 30,000) a small number of microvilli are scattered amongst abundant microplicae. (By kind permission of Drs. R. R. Pfister and N. L. Burstein, *Investigative Ophthalmology* and *Visual Science*.)



the fibres vary in different parts of the cornea, being larger in the vicinity of the posterior limiting membrane. Estimates of diameter vary from 21 to 65 nm with periodicities of 63 and 6 nm.

Between the lamellae there is a small amount of ground substance, in which fibroblasts occur. These are stellate or dendritic in shape and appear to communicate with one another by numerous offsets. However, electron microscopy shows that there is no syncytial arrangement amongst the corneal cells. Occasionally nomadic cells, macrophages, lymphocytes, or polymorphonuclear leucocytes may invade the substantia propria.

The layer immediately beneath the corneal epithelium is the *anterior limiting lamina* (Bowman's membrane). It consists of fine closely interwoven fibrils structurally similar to those found in the substantia propria, but contains no fibroblasts. It is about 8 μm in thickness and its collagen fibres are random in arrangement; views on their width vary from 14 to 36 nm—much less than those of the corneal stroma.



The *posterior limiting lamina* (Descemet's membrane) covers the posterior surface of the substantia propria, and is a thin, transparent, homogenous membrane. Ultraviolet and polarization microscopy show that it has a stratified, probably fibrillar arrangement, confirmed by electron microscopy. It is considerably thicker than the endothelium to which it is subjacent and of which it is now regarded to be the basement membrane. It separates easily from both the endothelium and the corneal stroma. At the margin of the cornea it breaks up into fibres which form the trabecular tissue on the inner wall of the sinus venosus sclerae (7.250), the spaces between the trabeculae being termed the *spaces of the iridocorneal angle*; they communicate with the sinus venosus sclerae and with the anterior chamber. Some of the fibres of this trabecular tissue pass on to the internal surface of the scleral spur and are continued into the substance of the iris, forming the *pectinate ligament of the iris*; others are connected with the sloping external surface of the scleral spur and a few reach the anterior part of the choroid. The relationships of the trabecular spaces, anterior chamber, and scleral venous sinus, both in structural and functional terms, are still topics of controversy. *See* Davson (1976) for recent views and discussion.

The *endothelium of the anterior chamber* covers the posterior surface of the posterior elastic lamina, is reflected on to the front of the iris, and also lines the spaces of the iridocorneal angle; it consists of a layer of polygonal, flattened, nucleated cells. Electron microscopy reveals that these have no basement membrane. At their borders these polygonal cells display highly complex,

D

7.249D Transmission electron micrograph of the subtantia propria of the human cornea; note the geometric precision of the alternation in direction of adjacent layers of collagen fibres. (Preparation by Dr. John Marshall—*see* 7.251B.) Magnification × 48,000.

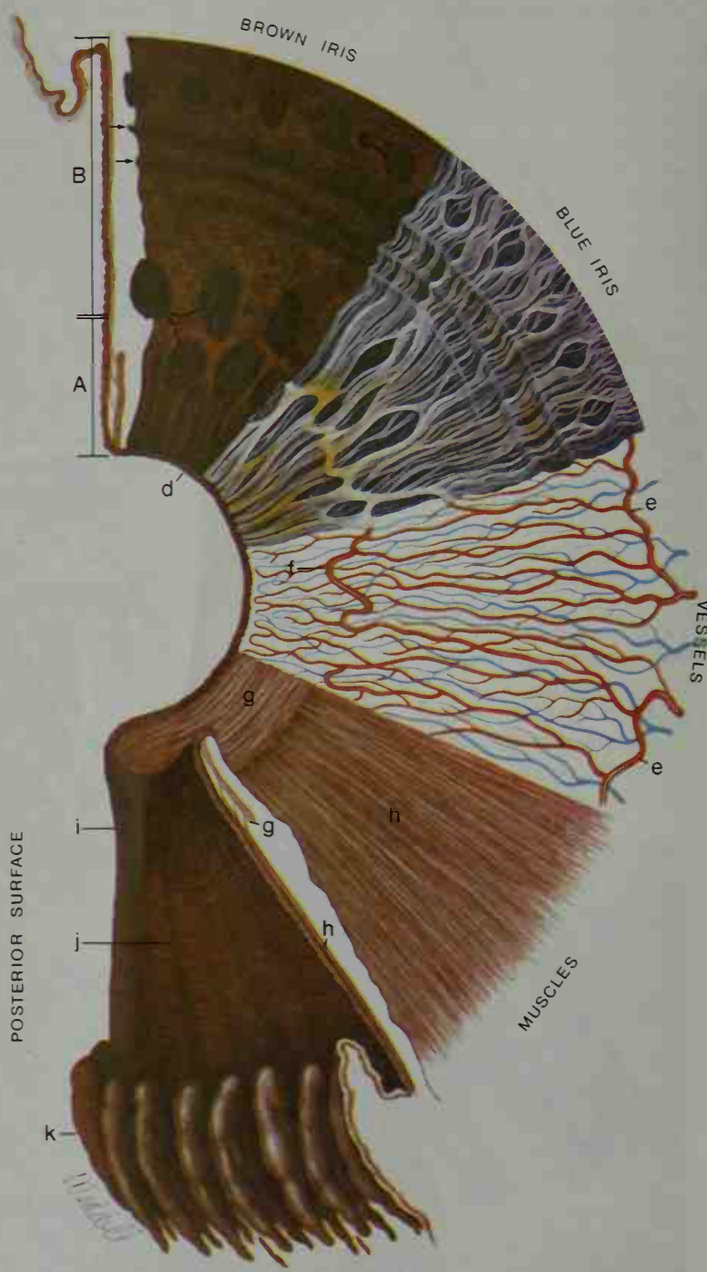
7.250 The iridocorneal angle and adjoining structures, showing the proximity of the scleral venous sinus (*aa*) to the pectinate ligament (*ff*). The trabecular meshwork of the latter is partly uveal, being continuous with the iris (*h*) and ciliary body (CB) and muscle (*i*). Anterior to the scleral spur (*d*) scleral trabecular tissue (*c*) is even closer to the scleral venous sinus. Aqueous fluid percolates through this trabecular region, reaching the lumen of the sinus through small apertures (*b*). The pectinate ligament diminishes as it approaches the corneal limbus (*e*), and in this junctional zone the posterior limiting membrane (of Descemet) also terminates (*g*). The endothelium of the anterior chamber (posterior corneal epithelium) is continuous with the endothelium of the trabeculae (*j*) at the limbus. (From *Histology of the Human Eye*, by Drs. Michael J. Hogan and Jorge A. Alvarado, illustrated by Mrs. Joan E. Weddell, published by W. B. Saunders, Philadelphia, 1971—by kind permission of the authors, artist and publishers. 7.251, 253, 254, 255, 262, and 265 are from the same source.)

interdigitating profiles when seen by scanning electron microscopy, and their free surfaces show sparsely distributed microvilli.

Vessels and Nerves. The cornea is a non-vascular structure, the capillary vessels of the conjunctiva and sclera ending in loops at its circumference. Lymph vessels do not occur in the cornea. The *nerves* are numerous and are branches of the ophthalmic nerve, and particularly the long ciliary nerves. Around the periphery of the cornea they form an *annular plexus*, from which fibres enter the substantia propria in a radial pattern. They lose their myelin sheaths and ramify throughout the substantia propria in a delicate network, and their terminal filaments form an intricate plexus beneath the corneal epithelium. This is termed the *subepithelial plexus*, and from it fine, varicose fibrils are given off which pass through the anterior limiting membrane to ramify between the epithelial cells, forming an *intra-epithelial plexus*. Ultrastructural studies (Matsuda 1968) of human corneal nerve fibres show that the endoneurium and myelin sheaths are gradually lost as the fibres enter the cornea. There are no specialized end organs, and in their epithelial course the nerve fibres are devoid of Schwann cells; they do not arborize. Electron microscopic studies of the simian corneal nerves suggest that nerves entering the stroma do not pass to the corneal epithelium, whose nerves enter it directly from the limbus (Lim and Ruskell 1978).

The fibrous tunic of the eye is usually dismissed as being merely protective, but its common and continuous functions are to provide a smooth translatable external surface (*vide infra*), a suitable attachment for muscles and a resistance to the intraocular pressure. In this manner the optical shape and dimensions of the eyeball are maintained. For further details of the physiology of the cornea and sclera *see* Jakus (1964), Laugham (1969), Davson and Graham (1974).

The Vascular Tunic



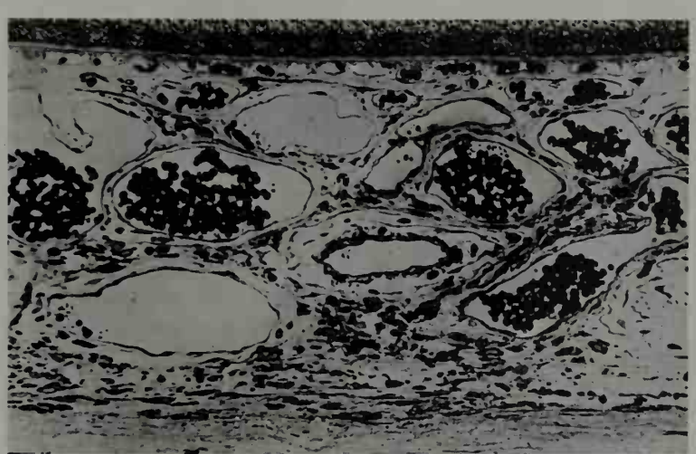
The vascular tunic or *uveal tract* of the eye consists of the choroid, the ciliary body and the iris (7.247), forming, of course, a continuous structure.

The choroid covers the inner surface of the sclera, and extends as far forwards as the ora serrata of the retina. The ciliary body continues from the anterior edge of the choroid into the circumference of the iris. This iris is a circular diaphragm behind the cornea, and presents near its centre the rounded aperture of the *pupil*.

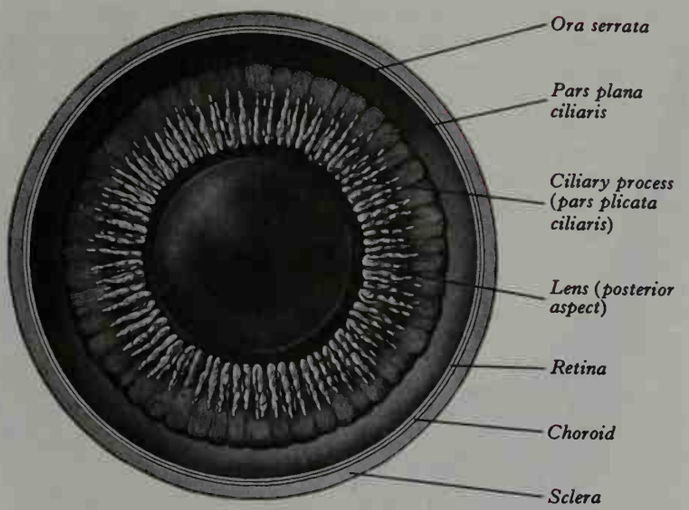
THE CHOROID

The choroid is a thin, highly vascular membrane, of a dark brown or chocolate colour, lining somewhat less than the posterior five-sixths of the eyeball; it is pierced behind by the optic nerve, and in this situation is firmly adherent to the sclera. It is thicker posteriorly. Its external surface is loosely connected with the sclera by the *suprachoroid lamina* (lamina fusca); its internal surface is firmly attached to the pigmented layer of the retina. At the optic disc it is continuous with pial and arachnoid tissues around the optic nerve.

Structurally, the choroid consists mainly of a dense capillary plexus, and of small arteries and veins carrying blood to and from it. (In accord with its high vascularity, the blood flow through the choroid is also high, but this is probably to be associated with the effect of the intra-ocular pressure, some 15–20 mm Hg, which requires a high venous pressure, above 20 mm Hg, if circulation is to be maintained. Metabolic demand is relatively low—the venous blood loses only 3 per cent of its oxygen (Bill 1970). The warming effect of the choroidal circulation may have some importance.) On its external surface is the thin *suprachoroid lamina*, about 30 μm thick, which is composed of delicate non-vascular lamellae, each consisting of a network of fine collagen and elastic fibres, among which are branched cells containing dark-brown pigment granules. Ganglionic neurons and plexuses of nerve fibres are enmeshed in the connective tissue. The mesothelium-lined interstices, sometimes described, are not supported by modern observations; pathological accumulations of fluid may split the lamellae of the suprachoroid. All such potentially weak connective tissue zones are a great attraction to those in search of lymph spaces in the eye.



7.251 A Composite view of the surfaces and internal strata of the iris. In a clockwise direction from above the pupillary (A) and ciliary (B) zones are shown in successive segments. The first (brown iris) shows the anterior border layer and the openings of crypts (*c*). In the second segment (blue iris), the layer is much less prominent, and the trabeculae of the stroma are more visible. The third segment shows the iridial vessels, including the major arterial circle (*ee*) and the incomplete minor arterial circle (*f*). The fourth segment shows the muscle stratum, including the sphincter (*g*) and dilatator (*h*) of the pupil. The everted 'pupillary ruff' of the epithelium on the posterior aspect of the iris (*d*) appears in all segments. The final segment depicts this aspect of the iris, showing radial folds (*i* and *j*) and the adjoining ciliary processes (*k*). (From *Histology of the Human Eye*—see 7.250.)



The choroid proper (7.251B, 225) is internal to the suprachoroid lamina (which is in part derived from scleral connective tissue). Its layers are variously described, but generally recognized are (*a*) an external *vascular lamina* composed of small arteries and veins and loose supporting connective tissue, in which are scattered pigment cells, (*b*) an intermediate *capillary lamina* (choroidocapillaris), and (*c*) a thin, apparently structureless, *basal lamina* (the membrane of Bruch). The vascular lamina is itself sometimes divided on the basis of the calibre of its vessels, which naturally decreases towards the capillary layer. In general, however, these vessels are relatively small and the capillaries

large, and the latter, in any case, dominate the scene. The vascular lamina contains the branches of the short posterior ciliary arteries (p. 689), extending anteriorly in a meridional direction from their entry through the sclera near the optic disc. The veins of the vascular lamina are much larger, and they converge in whorls or vortices upon four or five principal *vorticose veins*, which pass through the sclera to drain into the ophthalmic veins of the orbit. The capillary or choroidocapillary layer, separated from the retina only by the choroidal basal lamina, is almost certainly responsible for the maintenance of the outer layers of the retina, at least in part. It forms a finely meshed network, especially in the posterior region of the eyeball; but the meshes become larger as they approach the ciliary body, where they link up with the capillaries of the ciliary processes. The basal lamina was until recently considered to be a glassy, homogenous layer (lamina vitrea); it is only 2–4 μm in thickness, but electron microscopy has revealed much intimate detail. It consists essentially of a middle stratum of elastic tissue between internal and external collagenous layers, united externally to the basement membrane of the choroidocapillary lamina and internally to the basement membrane of the pigment cells of the retina (Lerche 1965; Nakaizumi 1964). Its exact functional significance is not certain, but it is obviously related to the passage of fluid and solutes from the choroidal capillaries to the retina, and it is said to provide a smooth surface for the precise orientation of the pigment cells and receptors of the retina, a factor important to precise vision. In its development (Takei and Ozanics 1955) the basal lamina is derived from retina and choroid, the former contributing its most internal layer which is in fact the basement membrane of the retinal pigment epithelium. Its most external stratum is closely associated with, and perhaps identical with, the basement membrane of the choroidal capillary endothelium. The functions of the pigment cells of the choroid are speculative. Clearly it is plausable to assume that they prevent the passage of light from the exterior of the sclera; but it seems more probable that they absorb light which has passed through the retina, thus preventing reflexion. In many animals, especially in those of nocturnal habit, specialized cells in the choroid form a reflecting structure, the *tapetum*, which is responsible for the greenish glare visible in the eyes of such animals at night (Walls 1963). The significance of this arrangment is uncertain; it may be a mechanism of aggression or it may bring about increased stimulation of the retinal receptors.

Although there is some clinical evidence of a nerve supply to the choroid, direct anatomical evidence is sparse. In a recent study of the results of crush lesions of the ophthalmic nerves in monkeys (Bergmanson 1977), no evidence of fibres from the ciliary nerves, in the suprachoroidal part of their courses, was found; none of their degenerating fibres terminated in the choroid.

7.251B Light micrograph of a section of human eyeball showing full thickness of the choroid coat and adjacent parts of the retina (above) and sclera (below). Note, from above downwards, rod and cone processes projecting among pigment cells, the basal lamina (membrane of Bruch), layer of capillaries (choriocapillaris), layer of larger vessels, and loose connective tissue merging into the sclera. Numerous pigment cells are scattered throughout the choroid. Magnification × 350. (Kindly provided by Dr. John Marshall, Institute of Ophthalmology, London.)

7.252 The interior aspect of the anterior half of the eyeball.

THE CILIARY BODY

The ciliary body is a direct anterior continuation of the choroid, and the iris is a further extension of the ciliary body itself. All three regions of the uveal tract evince certain common features and regional differences dependent on variations in function. The ciliary body is specifically concerned with the suspension of the lens and with the mechanism of accommodation, and this accounts for the accumulation of muscle which causes it to bulge towards the interior of the eyeball (7.253). It is also involved as the major producer of aqueous fluid entering the anterior segment of the eye, with which its anterior aspect is related. More posteriorly it is directly contiguous with the vitreous humor, and it is probable that it secretes some of the vitreous glycosaminoglycans. The anterior and the long and short posterior ciliary arteries all meet in the ciliary body (7.255), and it is hence a highly vascular region. This rich circulation is concerned not only with the secretory and muscular activities of the body, but also with the supply of the iris and the limbal region. The ciliary body is also traversed by the major nerves supplying all the anterior ocular tissues.

Externally, the ciliary body extends from a point about 1·5 mm posterior to the corneal limbus (which corresponds also to the scleral spur) to a point 7·5 to 8 mm posterior to this on the temporal side of the eyeball and 6·5 to 7 mm on the medial or nasal side. The body is hence a slightly eccentric structure, extending posteriorly from the scleral spur, to which it is attached, with a meridional width varying from about 5·5 to 6·5 mm. As seen from the interior of the eyeball it presents a posterior periphery, where it is continuous with the choroid, which is crenated or scalloped—the *ora serrata*. Its anterior extremity is confluent with the periphery of the iris, and lateral to this it bounds the iridocorneal angle of the anterior chamber. The internal aspect of the ciliary body is grey in colour, due to the pigment in the deeper layer of its epithelium. It is divisible into an anterior ridged or plicated part, the *corona ciliaris* (pars plicata), which surrounds the base of the iris in an annular manner, and posterior to this a relatively smooth annular strip, the *orbiculus ciliaris* (pars plana, ciliary ring). The orbiculus accounts for more than half of the meridional width of the ciliary body, being 3·5 to 4 mm across. The peripheral rim of the orbiculus is the ora serrata, a dentate limit at which the fully developed *optical* or sensory part of the retina is suddenly reduced to two layers of epithelial cells, prolonged over the whole of the ciliary body as the *pars ciliaris retinae* and beyond this on to the posterior surface of the iris. The corona ciliaris, forming a smaller annular region within the orbiculus, is ridged by seventy to eighty *ciliary processes* which radiate in a meridional direction from the base of the iris towards the orbiculus ciliaris (7.252). Branching

7.253 A magnified view of the ciliary region seen from the ocular interior. Above is the periphery of the lens, attached by the fibres of the *zonule* (suspensory ligament) to the processes of the *corona ciliaris* (pars plicata) of the ciliary body (a). The *orbiculus ciliaris* or pars plana ciliaris (b) has a scalloped boundary, the *ora serrata* (c), which separates it from the retina (d). Flanking the 'bays' (c) of this are the *dentate* processes (f), with which linear ridges or *striae* (g) are continuous. These striae extend forwards between the main ciliary processes, providing an attachment for the longer zonular fibres. The posterior aspect of the iris shows radial (h) and circumferential (i) sulci. (See 7.250 for acknowledgement.)

from the sides of these processes into the valleys between them are numerous minor ridges, the *ciliary plicae*, forming a complex pattern which, in microscopic preparations, presents highly intricate profiles (7.253). Into the valleys between the ciliary processes groups of fibres of the *zonule* (suspensory ligament) of the lens extend, passing beyond the processes to establish continuity with the basement mebrane of the superficial layer of epithelial cells covering the orbiculus ciliaris. The sites of these attachments are marked by striae which pass posteriorly from the valleys of the corona across the orbiculus almost to the apices of the dentate processes of the ora serrata (7.253).

For description it is convenient, if arbitrary, to treat the intimate structure of the ciliary body under three headings: (1) the ciliary epithelium; (2) the ciliary connective tissue and vessels; and (3) the ciliary muscle.

The ciliary epithelium is bilaminar, consisting of two layers of simple epithelium superimposed one upon another and representing the two layers of the optic cup. The *superficial lamina* is formed of cells which are columnar over the orbiculus and cuboidal where they cover the ciliary processes, becoming irregular and more flattened in the intervals between the processes. They contain little or no pigment and are the sole anterior continuation of the neural layers of the retina; this excludes the pigment epithelium of the retina, which is itself continuous with the *deeper layer* of the ciliary epithelium. The cells of the latter are also approximately cuboidal and are loaded with pigment granules. The two layers are firmly united, but pathological accumulations of fluid may separate them, just as the retina detaches from its own pigment epithelium. A basement membrane intervenes between the two epithelia, and the basal aspects of the superficial cells are much infolded, as in the case of other secretory epithelia. These superficial cells exhibit junctions of the desmosomal type, and in their cytoplasm mitochondria are numerous and the endoplasmic reticulum is well developed, the latter often forming stacked arrays in the peri-nuclear zone. The Golgi apparatus is not well developed. Lipid and melanin granules are often present but not prominent.

The pigment epithelium is united to the stroma of the ciliary body by its own basement membrane, which is continued posteriorly into the basal lamina of the choroid tunic (p. 1156). The cytoplasm of these cells contains very numerous round or oval granules containing abundant melanin and measuring about 0·6 to 0·8 μm in diameter. The cells are linked laterally to each other by relatively few desmosomes, these being more numerous between cells in the two strata of the epithelium, despite the intervention of a basement membrane.

The ciliary stroma is composed largely of loosely arranged fasciculi of collagen fibres, and these are aggregated into a considerable mass between the ciliary muscle and the overlying ciliary processes, into both of which the connective tissue extends. In this inner stratum of connective tissue are numerous larger branches of the ciliary arteries and veins with a rich interconnecting network of capillaries of comparatively large calibre; the majority of these are adjacent to the epithelium, and are especially concentrated in the ciliary processes. In these sites capillaries are chiefly of fenestrated type; numerous vessels also enter the ciliary muscle, but the capillaries there evince much less frequent fenestration. Anteriorly, near to the periphery of the iris, is the major arterial circle (7.251, 255), formed chiefly by the long posterior ciliary arteries, branches of the ophthalmic (p. 689), which enter the eye well posterior to the equator and pass anteriorly between the choroid and the sclera to reach the ciliary body. The veins of the body, into which those of the iris drain, pass posteriorly to join the vorticose veins of the choroid.

The ciliary muscle has been variously described by different authorities, their main divergencies being in the number of divisions or parts recognized in this small annular mass of nonstriated muscle. In most descriptions three parts are usually named—*meridional*, *radial* or oblique, and *circular* or sphincteric—but other views have occasionally been stated (*see* Calasans 1953; Rohen 1964). Most and perhaps almost all of the ciliary muscle fibres are attached to the scleral spur (7.254), from which they pass in a variety of directions. It is upon these variations that a somewhat arbitrary division of the whole muscle into parts is dependent. The most external fibres extend in a meridional or longitudinal direction, passing posteriorly into the stroma of the choroid, where many exhibit terminal branchings or *epichoroidal stars*. The most internal fibres swerve acutely as they leave the scleral spur (7.254) and run circumferentially to form a circular or sphincteric element in the muscle, in close proximity to the periphery of the lens. Between these two muscular strata are fibres which cross obliquely from one to the other, often crossing each other in a lattice of interweaving fibres. This part of the muscle is often referred to as radial in disposition. In its ultramicroscopic features the ciliary muscle exhibits some differences from other nonstriated muscle masses. The fibres show distinct cell walls and possess basement membranes, but they contain an unusual abundance of mitochondria and endoplasmic reticulum. A small bundle of fibres is usually surrounded by a common fibroblastic sheath, forming units not encountered in other nonstriated muscles. Junctions between the fibres within a bundle are described, but their precise nature is still uncertain; they are said to resemble intercalated discs. Three types of nerve ending have been observed, the most common being an indirect contact of synaptic membranes with an interposed basement membrane; contact without a basement membrane also occurs, and most rarely larger and more intimate contacts in depressions in the muscle fibre substance.

Both myelinated and nonmyelinated nerve fibres abound in the ciliary muscle and elsewhere in the ciliary body. The latter are postganglionic fibres derived from the ciliary ganglion, where they link with the parasympathetic outflow of the oculomotor nerve; but there is considerable evidence that some of these fibres are sympathetic. While it is clear that the former supply stimulates the fibres of the ciliary muscle to contract, the role of the sympathetic supply is still unsettled. Cervical sympathetic stimulation in some experimental animals leads to flattening of the lens, which is tantamount to relaxation of accommodation, but the mechanism of this is uncertain. It may be due to an inhibitory effect on the ciliary muscle; but it has also been suggested that the volume of the ciliary body may be reduced by vasoconstriction, thus resulting in tension on the zonule and through this on the periphery of the lens—the reverse of the slackening effect on the zonule of ciliary contraction (Morgan 1944). For a recent critique of this topic consult Alpern (1969). An electron microscopic study of the autonomic plexus in the ciliary muscles of rhesus monkeys has revealed, according to Townes-Anderson and Raviola (1979), a cycle of degeneration and regeneration which becomes more marked in older animals.

THE IRIS

The iris is the delicate and adjustable diaphragm which surrounds the *pupil*, its central orifice (slightly medial to the true centre), which exerts a considerable control over the amount of light entering the eye. The pupil may vary in diameter over a range of at least 1 to 8 mm, and even more under the influence of drugs. This represents an effective aperture range in excess of *f* 20 to *f* 2·5, and a ratio of 32:1 in the amount of light permitted to enter the eye. While this is obviously not enough to save the retina from the effects of very intense illumination, it is a factor in smoothing out the wide range of luminosities encountered in ordinary use and in thus preserving useful vision in highly variable conditions. The pupillary diameters noted above and an average diameter of the iris of about 12 mm are, of course, taken as measured through the cornea, whose dioptric power introduces a magnification factor of about 12 per cent. *Constriction* and *dilatation* of the pupil are self-explanatory terms, for which meiosis and mydriasis are also used clinically, though these are more properly reserved for the extreme limits of contraction and dilation. For a most crudite discussion of the immense literature on the pupil and its responses, and an account of iris activity *see* Loewenfeld (1958) and Loewenstein and Loewenfeld (1970).

Though the iris is named after the rainbow, its range of colour is somewhat less, extending from light blue to a very dark brown. The hue may vary in the two eyes and through the same iris. The colour is due to the combined effects of the iridial connective tissue and pigment cells in absorbing or reflecting different

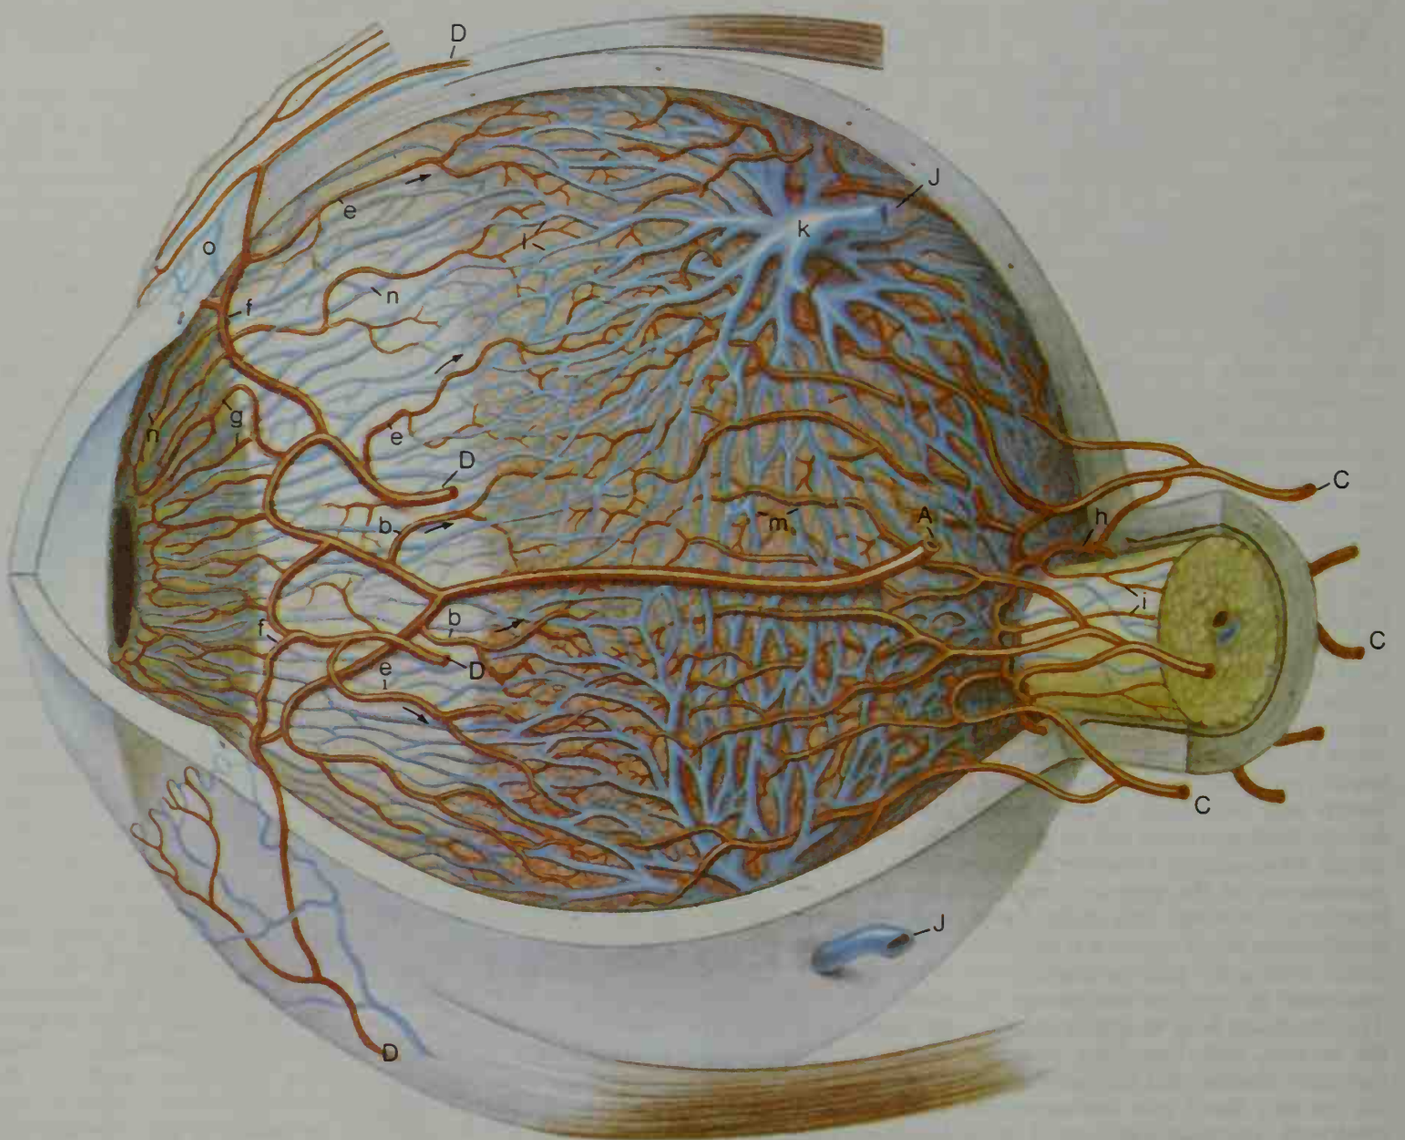
7.254 The ciliary muscle and its components. The meridional or longitudinal (1), radial or oblique (2), and circular or sphincteric (3) layers of muscle fibres are displayed by successive removal towards the ocular interior. The cornea and sclera have been removed, leaving the pectinate ligament (*a*), the scleral venous sinus (*b*), collecting venules (*c*) and scleral spur (*d*). The meridional fibres often display acutely angled junctions (*e*) and terminate in epichoroidal stars (*f*). The radial fibres meet at obtuse angles (*g*), and similar junctions, at even wider angles (*h*), occur in the circular stratum of the ciliaris. (See 7.250 for acknowledgement.)

frequencies of light energy in a selective manner. In the absence of significant amounts of pigment, as in the iris of the newborn, the colour is light blue; some degree of pigmentation is necessary to confine light transmission to the pupil and to the centre of the lens, where optical aberrations are least. The concentration of melanocytes is the predominant factor in iris hue, but their distribution is often irregular and may produce in this manner a flecked or maculated appearance.

In shape the iris is not a discoid diaphragm; the anterior convexity of the lens bulges it a little, so that it is more accurately described as a very shallow cone, truncated by the pupillary aperture. It is sited between the cornea and the lens (7.247), immersed in the *aqueous fluid* or humor, and it partially divides the *anterior segment* of the eye into an *anterior chamber*, enclosed by the cornea and iris (which meet at the *iridocorneal angle*) and an unfortunately termed *posterior chamber*, between the iris and the lens. Peripherally, in the latter cavity, the ciliary processes protrude a little between the divisions of the zonular ligament of the lens; and it is here that most of the aqueous fluid is produced, finding its way through the pupil into the anterior chamber and finally to its exit into the scleral venous sinus (p. 1152) at the iridocorneal angle—the 'filtration angle' of clinical parlance.

The microscopic structure of the iris displays a number of unusual features (7.251). Its anterior surface, forming the posterior boundary of the anterior chamber, is not covered by a distinct epithelium, despite frequent statements to the contrary; this surface is merely a modified 'anterior border layer' of the general *stroma*, which forms the bulk of the iris. The stroma contains the vessels and nerves of the region and, near the periphery of the pupil, an aggregation of nonstriated muscle fibres forming an annular contractile structure, the *sphincter pupillae*. The posterior aspect of the iris consists of a continuation of the same two layers of epithelium which cover the ciliary body and which represent the internal and external strata of the optic cup. The pupil, through which this epithelium turns round for a short distance on to the *anterior* surface of the iris as the pigment ruff, or 'border', therefore corresponds with the opening of the optic cup. The deeper, and hence in the iris the more anterior of these epithelial layers, is commonly termed, a little confusingly, the *anterior epithelium* of the iris. It should be emphasized to avoid confusion, that this anterior epithelium is immediately *posterior* to the stroma of the iris. Its cells are pigmented, like those of the same layer in the ciliary epithelium; closely associated with them are the radially arranged nonstriated fibres of the dilatator pupillae, which like the sphincter has a most unusual embryological origin in being derived from the neural ectoderm of the optic cup. Superficial and posterior to this layer of cells is a stratum of heavily pigmented cells, forming the so-called *posterior epithelium*. The layer is continuous with the *non-pigmented*, retinal layer of the ciliary epithelium.

The *anterior border layer* or anterior surface of the iris has been much studied at low magnification by slit-lamp microscopy, with which it is seen to display a somewhat fluffy appearance, except in heavily pigmented irides. Depressions or *crypts*, through which vessels may be visible in the stroma, and various radial and circular folds and striae can be observed, but details of this kind should be sought in a suitable authority (e.g. Vogt 1942). The constituents of the anterior border lamina are chiefly much branched fibroblasts and melanocytes, with no vestige of the endothelium which covers it at birth, and to a rapidly decreasing extent during the early postnatal years (Vrabec 1952). This is confirmed by electron microscopy (Tousimis and Fine 1959). The fibroblasts form an approximately single continuous layer on the surface, with branching processes which form no actual junctions (Smelser and Ishikawa 1966). At the peripheral base of the iris they blend with the connective tissue of the trabecular meshwork (pectinate ligament) at the iridocorneal angle. At the pupillary border they come into contact, but again without specialized junctions, with the pigment epithelium of the posterior surface of the iris. The melanocytes also exhibit intricately branched processes, and again no special junctions have been observed between them. Some capillaries invade the border layer. Macular junctions have recently been reported in the anterior border layer of the iris in monkey and rabbits, occurring chiefly between fibroblasts. Naked axons were also observed in close apposition to melanocytes and fibroblasts. The nerve fibres were presumed to be sympathetic and it is hypothecated that the cells and axons may release transmitter substances into the anterior chamber (Ringvold 1975).

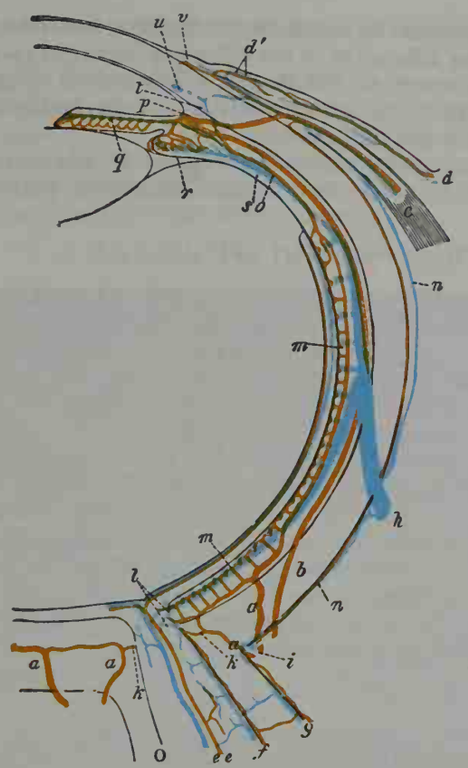


The *stroma of the iris*, which is derived like the anterior border layer from the mesoderm between the developing lens and optic cup, is also formed by fibroblasts and melanocytes; but in this region there is, in addition, a considerable amount of loose collagenous tissue, whose spaces are filled with fluid and a mucopolysaccharide ground substance. These spaces are apparently in fairly free communication with the fluid in the anterior chamber of the eyeball, and the interchange of fluid between the chamber and the iridial stroma may explain the large changes of volume which appear to accompany contraction and relaxation of the iris diaphragm. The mesodermal stroma also contains not only an abundance of blood vessels and nerves, but also the ectodermal sphincter and dilatator muscles. There is no elastic tissue, and any of the elastic recoil which has been attributed to the iris, and sometimes suggested as a dilatation force when the sphincter is relaxed, must reside in other structures, if it in fact exists. The collagen fibrils, which have a diameter of about 60 nm, and a periodicity of 50 to 60 nm, are very loosely arranged, many describing incomplete circumferential loops around the pupil as centre. 'Clump' cells, mast cells, macrophages and lymphocytes are said to occur in the stroma, but the reader is referred to larger monographs quoted at the end of this account for fuller details.

The sphincter pupillae is an annular flattened band of nonstriated muscle about 0·75 mm in width and 0·15 mm in thickness. Its fusiform cells are closely packed and are often arranged in small groups, as in the ciliary muscle; in accordance with the effect of the muscle on the pupil these fibres are orientated parallel to its margin. Stromal collagen tissue encloses the muscle anteriorly and posteriorly and is particularly dense in the latter situation, where it binds the sphincter pupillae to the pupillary extremity of the dilatator muscle. Ultramicroscopy shows that the muscle fibre groups noted above are not entered by nerve fibres, only one fibre of the group usually being innervated. It is presumed that the depolarizing current of contraction spreads to the rest of the fibres through gap junctions. In other details of cytoplasmic organelles, densities resembling Z-bands, and basement membranes, the muscle fibres are like those of nonstriated muscles elsewhere. Small nerves ramify in the connective tissue between the fibre bundles; most of their fibres are nonmyelinated and they are often enclosed as groups of several axons in the same Schwann cell sheath. They do not approach the surfaces of muscle cells more closely than 0·1 μm.

The dilatator pupillae, a muscle whose existence has been the subject of a prolonged, vexed and at times almost ridiculous controversy, is now a well-established entity, on microscopic, physiological and pharmacological grounds (Alphen 1963; Loewenfeld 1958). It is a thin stratum immediately anterior to the deeper, anterior layer of the epithelium of the posterior aspect of the iris. Its fibres are indeed muscular processes of this anterior layer, whose cells are therefore myoepithelial in character. Their apical processes form the epithelium itself (*supra*). Myofilaments appear in both parts of these cells, but are much more numerous in their basal, muscular processes. The latter are about 4 μm thick, 7 μm wide, and 60 μm in length. They are fusiform and form a stratum 3 to 5 elements thick through most of the iris, from its periphery to a point near the outer perimeter of the sphincters, which it overlaps a little. Towards this perimeter the dilatator rapidly peters out, sending spurs of muscle processes to blend with it. These processes, unlike the apical parts of the myoepithelial cells of the anterior epithelium, show a clear basement membrane, and they are joined by gap junctions like those in the fibres of the sphincter which probably also serve as points of electrical coupling. Their myofilaments are about 3 nm in diameter and numerous densities resembling Z-discs are evident. Nonmyelinated nerve fibres have been described in relation to the muscular processes or 'fibres', and these terminate very close to the cell membrane, the interval being of the order of 20 nm.

The arteries of the iris (7.251, 255, 256) are derived from the long posterior and the anterior ciliary arteries, and from the vessels of the ciliary processes. Each of the two long ciliary arteries, on reaching the attached margin of the iris, divides into an upper and a lower branch; these anastomose with corresponding branches of the artery from the opposite side and with the anterior ciliary arteries, and form a vascular circle (*circulus arteriosus major*). From this circle vessels converge to the free margin of the iris, and there communicate to form a second circle (*circulus arteriosus minor*). This minor circle is incomplete, and some observers regard these vessels as venous. The smaller arteries and veins are very similar in the structure of their walls, and they also share certain peculiarities. Thus, they are often slightly helical—perhaps an adaptation to the great changes in the shape of the iris which occur as the pupil varies in size. Perhaps also to be ascribed to this is the peculiar structure of the vascular wall. All the vessels, including the capillaries, have a non-fenestrated endothelium, with a well-marked and often thick basement membrane. Outside this, in the arteries and veins, there is no elastic lamina, and nonstriated muscle fibres are few, especially in the veins. The connective tissue of the media is loose, and external to this is a remarkably dense collagenous adventitia, which appears to form almost a separate tube outside the endothelium. The loose stratum of the media has been regarded as a lymph space, but this is improbable; it is about 7 μm in width, and contains a matrix probably derived from the basement membrane of the endothelium (Hogan *et al.* 1971).



The nerves of the iris, like those of the choroid, are chiefly derived from the branches of the long ciliary rami of the nasociliary nerve and from the short ciliary branches of the ciliary ganglion. The latter contain postganglionic but thinly myelinated fibres which innervate the sphincter pupillae. The dilatator pupillae is supplied by postganglionic nonmyelinated fibres derived from the superior cervical ganglion of the sympathetic trunk, but the routes by which these reach the muscle are not precisely established, and they may vary in different species of mammals and may be multiple in man. The sympathetic plexus around the internal carotid artery is said to send a branch through the ciliary ganglion, and these postganglionic fibres reach the eyeball through the short ciliary nerves; but some sympathetic fibres may travel to the eye through the long ciliary nerves. (For details of other routes in monkeys, see p. 1064.) The innervation of the muscles of the iris, as that of the ciliaris, is probably more complex, and both the sphincter and dilatator may possess a double autonomic innervation. Histochemical stains for acetylcholine-esterase and fluorescent techniques have de-

7.255 The vascular arrangements of the uveal tract. The long posterior ciliary arteries, one of which is visible (A), branch at the ora serrata (*bb*) and feed the capillaries of the anterior part of the choroid. Short posteriorly ciliary arteries (CC) divide rapidly to form the posterior part of the choriocapillaris. Anterior ciliary arteries (DD) send recurrent branches to the choriocapillaris (*ee*) and anterior rami to the major arterial circle (*ff*). Branches from the circle extend into the iris (*g*) and to the limbus. Branches of the short posterior ciliary arteries (CC) form an anastomotic circle (*h*) (of Zinn) round the optic disc, and twigs (*i*) from this join an arterial network on the optic nerve. The vorticose veins (*jj*) are formed by the junctions (*k*) of suprachoroidal tributaries (*l*). Smaller tributaries are also shown (*m*, *n*). The veins draining the scleral venous sinus (*o*) join anterior ciliary veins and vorticose tributaries. (From *Histology of the Human Eye*—see 7.250.)

monstrated both cholinergic and adrenergic activity in both iridial muscles (Ehinger and Falck 1966; Lowenstein and Locwenfeld 1970). Although ganglion cells have occasionally been reported in the iris, it is most likely that all, or almost all the fibres are postganglionic in type, and almost all are also nonmyelinated. They form a plexus at the base of the iris, and from this small nerves and individual fibres extend not only to the two muscles, but to the vessels and to the anterior border layer and the anterior epithelium (but not the pigment layer) of the posterior surface of the iris. Some fibres may be afferent and some are vasomotor, but little is known of either. For details of the occurrrence and distribution of the nonmyelinated sympathetic and parasympathetic nerve fibres in the choroid consult Ruskell (1971). For a discussion of the difficulties in identifying 'free' afferent nerve endings in the iris and ciliary body (and of the uncertainty in distinguishing them from efferent autonomic endings), consult Bergmanson (1978), who has described such endings in the monkey, using the accumulation of mitochondria usually regarded as a criterion of sensory terminals (Cauna 1966; Macintosh 1974). He found that not only did trigeminal (ophthalmic division) terminals display this characteristic, but that it was also observable in autonomic endings in these sites.

Pupillary membrane. In the fetus, the pupil is closed by a delicate, vascular membrane, termed the *pupillary membrane* (p. 177). The vessels of this membrane are partly derived from those of the margin of the iris and partly from those of the capsule of the lens; they end in loops a short distance from the centre of the membrane, which is thus left free from blood vessels. About the sixth month of intrauterine life the membrane begins to disappear by absorption from the centre towards the circumference, and at birth only scattered fragments are present; in exceptional cases it persists and may interfere with vision.

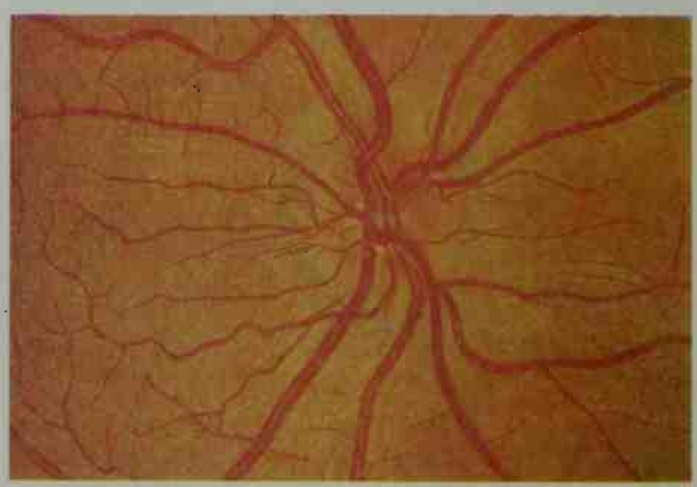
The Retina

The retina (7.247) is the neural, sensory stratum of the eyeball. It is very thin, varying from 0·56 mm near the optic disc to 0·1 mm anterior to the equator of the eyeball, continuing at this thickness to the ora serrata. It is, of course, much thinner at the optic disc and the fovea of the macula (Spence *et al.* 1969). Its external surface is in contact with the choroid, its internal with the hyaloid membrane of the vitreous body. Posteriorly it is continuous with the optic nerve; it gradually diminishes in thickness from the optic disc to the ciliary body; it presents a crenated margin named the *ora serrata* (7.252, 253). Here the nervous tissues of the retina end, but a thin prolongation of the membrane extends forwards over the back of the ciliary processes and iris, forming the *ciliary* and *iridial parts of the retina*. This forward prolongation consists of the pigmented layer of the retina together with a deeper stratum of columnar epithelium; in the iridial part of the retina both layers of epithelium are cubical and pigmented. The part of the retina extending from the optic disc to the ora serrata is known as the *optic part of the retina*. The retina is soft, translucent, and of a purple tint in the fresh, unbleached state, owing to the presence of a colouring material, named *rhodopsin*, or *visual purple*; but it soon becomes clouded, opaque, and bleached when exposed to light. (It is, in fact, difficult to prepare an eye in such a way as to demonstrate the purple pigment. In the preserved eyes usually dissected, the *fixed* retina has a cloudy white colour.) Near the centre of the posterior part of the retina there is an oval, yellowish area, named the *macula lutea* (7.257); it shows a central depression, termed the *fovea centralis*, where visual resolution is highest. At the fovea centralis the retina is exceedingly thin, some of its layers being absent here, and the dark colour of the choroid is distinctly seen through it. About 3 mm to the nasal side of the macula lutea the optic nerve pierces the retina at the *optic disc*, which has a diameter of about 1·5 mm. The circumference of the disc is slightly raised, while the central part presents a slight depression. The centre of the disc is pierced by the central artery and vein of the retina (7.257, 258). The optic disc is insensitive to light, and is termed the 'blind spot'. On ophthalmoscopic examination the normal disc is seen to be pink; it is, however, much paler than the retina and may be grey or almost white. In cases of optic atrophy the capillary vessels disappear and the disc appears white. The name 'optic papilla' applied to the disc is misleading since almost all of the normal disc lies in the same plane as the surrounding retina.

The Structure of the Retina

As has already been stated (pp. 169 and 176), the retina is derived from the two layers of the invaginated optic vesicle, the outer of which becomes the *pigment cell* lamina, the inner developing into the far more complex multilaminar structure containing the *photoreceptors* (rod and cone cells), their *first order neurons* (bipolar cells), the somata and beginnings of the axons of their *second order neurons* (ganglion cells), and *interneurons* arranged across these centripetal pathways (horizontal and amacrine cells). In addition, the retina contains *neuroglial elements* (Müller cells, or sustentacular gliocytes) and a *vascular system* composed chiefly of capillaries. In some descriptions the region of the retina posterior to the ora serrata (*pars optica retinae*)—the region which functions as a sense organ—is separated from its pigment epithelium as 'the retina proper'; but since the epithelium is functionally integrated with the rest of the retina, this arbitrary division into a *stratum pigmentosum* and a *stratum nervosum* will not be followed here. The description will, however, be limited to the sensory region of the retina, whose ciliary and iridial parts have already been considered (pp. 1157, 1159. (The potential space between pigment cells and photoreceptors has been equated with the ventricular cavities of the brain since it is developmentally a hollow outgrowth—*see* p. 176.)

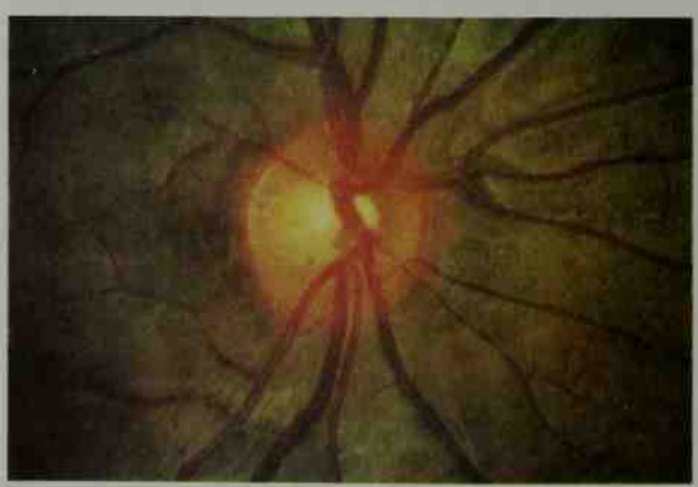


It is customary to recognize ten layers in the retina, and this plan will be adhered to in the following pages (7.259–262). It is hardly necessary to add that this is merely a morphological convenience in the primary analysis of the highly integrated nervous elements of the retina.

For a concise comparative review of the anatomy and physiology of the vertebrate retina *see* Boycott (1974).

THE RETINAL PIGMENT EPITHELIUM

This is a single lamina of cells arranged with marked regularity and extending from the periphery of the optic disc to the ora serrata, anterior to which they continue into the ciliary epithelium (p. 1157). They are approximately flat rectangles in radial sections and hexagonal when seen in tangential aspect. They number about 4 to 6 million in the human eye, becoming more numerous in more aged eyes. Near the macula they measure about 10 and 14 μm in their radial and tangential dimensions, but become much flattened near the ora serrata (Ts'o and Friedman 1967, 1968). Their nuclei are in the basal part of the cytoplasm, adjacent to the basal lamina (Bruch's membrane) of the choroid (p. 1156), from which the cells are separated by their own basement membrane. The latter is much infolded into the cytoplasm of the basal aspects of the cells. Their apical regions project between the rod and cone processes as microvilli of 5 to 7 μm in length. The intermediate cytoplasmic region contains numerous mitochondria and pigment granules. The pigment is melanin, and various other organelles, associated with the formation of this, have been identified in retinal epithelium, including well-developed granular and agranular endoplasmic reticulum in stacked arrays, premelanosomes and melanosomes (Breathnach and Wylie 1966; Seÿi 1967). Lipofuscin also occurs (Feeney *et al.* 1965), probably as a residue representing the end of a phagosomal process. Additional autoradiographic and ultramicroscopic studies (Young and Bok 1969; Spitznas and Hogan 1970), suggest that the microvilli of the pigment epithelium cells are concerned in a continuous erosion of the external ends of the rod and cone processes. Lamellar inclusions in the cytoplasm of the microvilli closely resemble the lamellar structures in the outer segments of the photoreceptors; they have been termed phagosomes, and they evince progressive disintegration as they pass deeper into the cytoplasm of the cell (Marshall and Ansell 1971).



A typical cell membrane of 'unit' structure encloses the pigment cells. Basally, as stated earlier, this is much infolded by the basement membrane. The latter has a fibrillar structure, and some of its fibrils join the basal membrane of the choroid, a junction which may explain the adherence of the pigment lamina to the choroid rather than to the rest of the retina. Laterally the

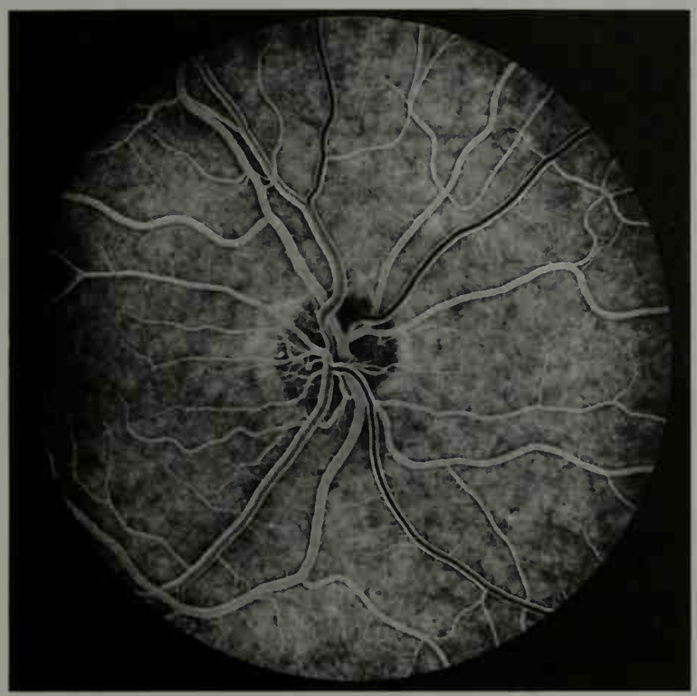
D

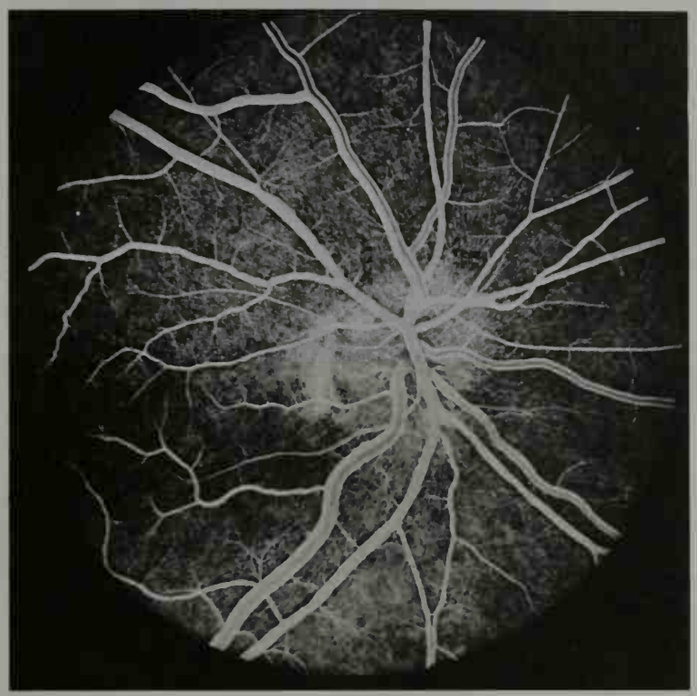
7.257A–D Ophthalmoscopic photographs of the right human retina.

A Note dichotomous branching of vessels, arteries being brighter red and showing a more pronounced 'reflex' to light, as a pale stria along their length. The veins are also larger in calibre; more of them cross arteries superficially than is usual. The optic disc, around the entry of the vessels, is a light pink, with a surrounding zone of heavier pigmentation. Compare with 7.257E, from the same Caucasian adult.



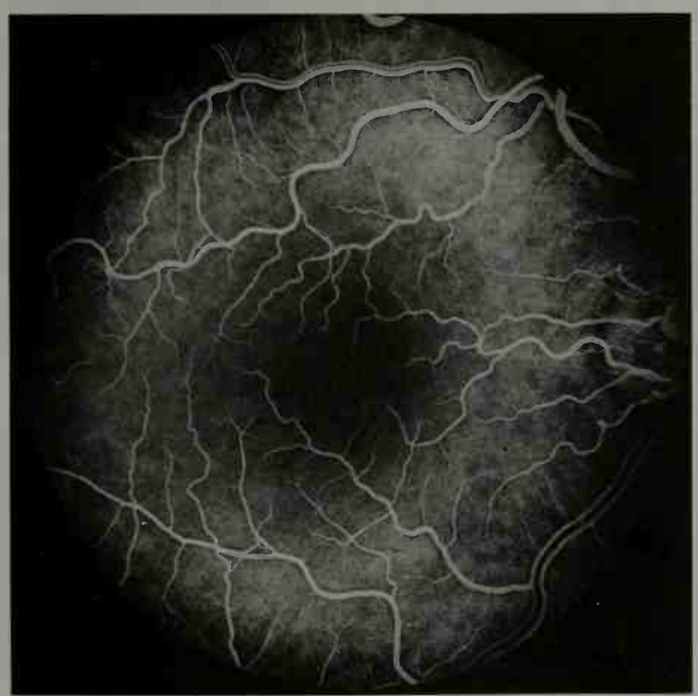
B Appearances in a heavily pigmented individual, with a paler optic disc than in 7.257A. Note accentuation of the edge of the disc by retinal and choroidal pigmentation. The arteries cross the veins superficially in this retina. Negroid adult.

C Normal macula of a young Caucasian subject. Note the fovea, showing as a central, paler, circular area. The macular branches of the central retinal artery are approaching from the right. The macula is largely free of vessels of macroscopic size, but the capillaries here form a particularly close network, except at the fovea.



D The region of the optic disc in an eye with poorly developed pigmentation. Three cilioretinal arteries are curving round the edge of the disc, two on the left, one on the right. Between the two cilioretinal arteries a single macular artery is apparent. Due to the depressed pigmentation choroidal vessels are also visible, especially veins; and on the left of the photograph two large vorticose venous tributaries can be seen.

membranes of the pigment cells do not interdigitate markedly, and the variable space between them is sealed off from the apical space (between the microvilli and the photoreceptors) by zonulae occludentes. Other forms of junction also occur. Miki *et al.* (1975) have described retino-choroidal attachment sites in various mammals, including mankind. These include reciprocal interdigitations, as noted above, and also junctions resembling desmosomes. A viscous, mucopolysaccharide substance occupies the space, which is embryologically derived from the cerebral ventricles.



Although the functions of the pigment epithelium of the retina are still far from elucidated, their ultramicroscopic features strongly suggest a phagocytic activity, possibly a nutritive role, to which may be added a contribution to the spacing and mechanical support of the photoreceptors, and an optical function in absorbing light and preventing back reflexion.

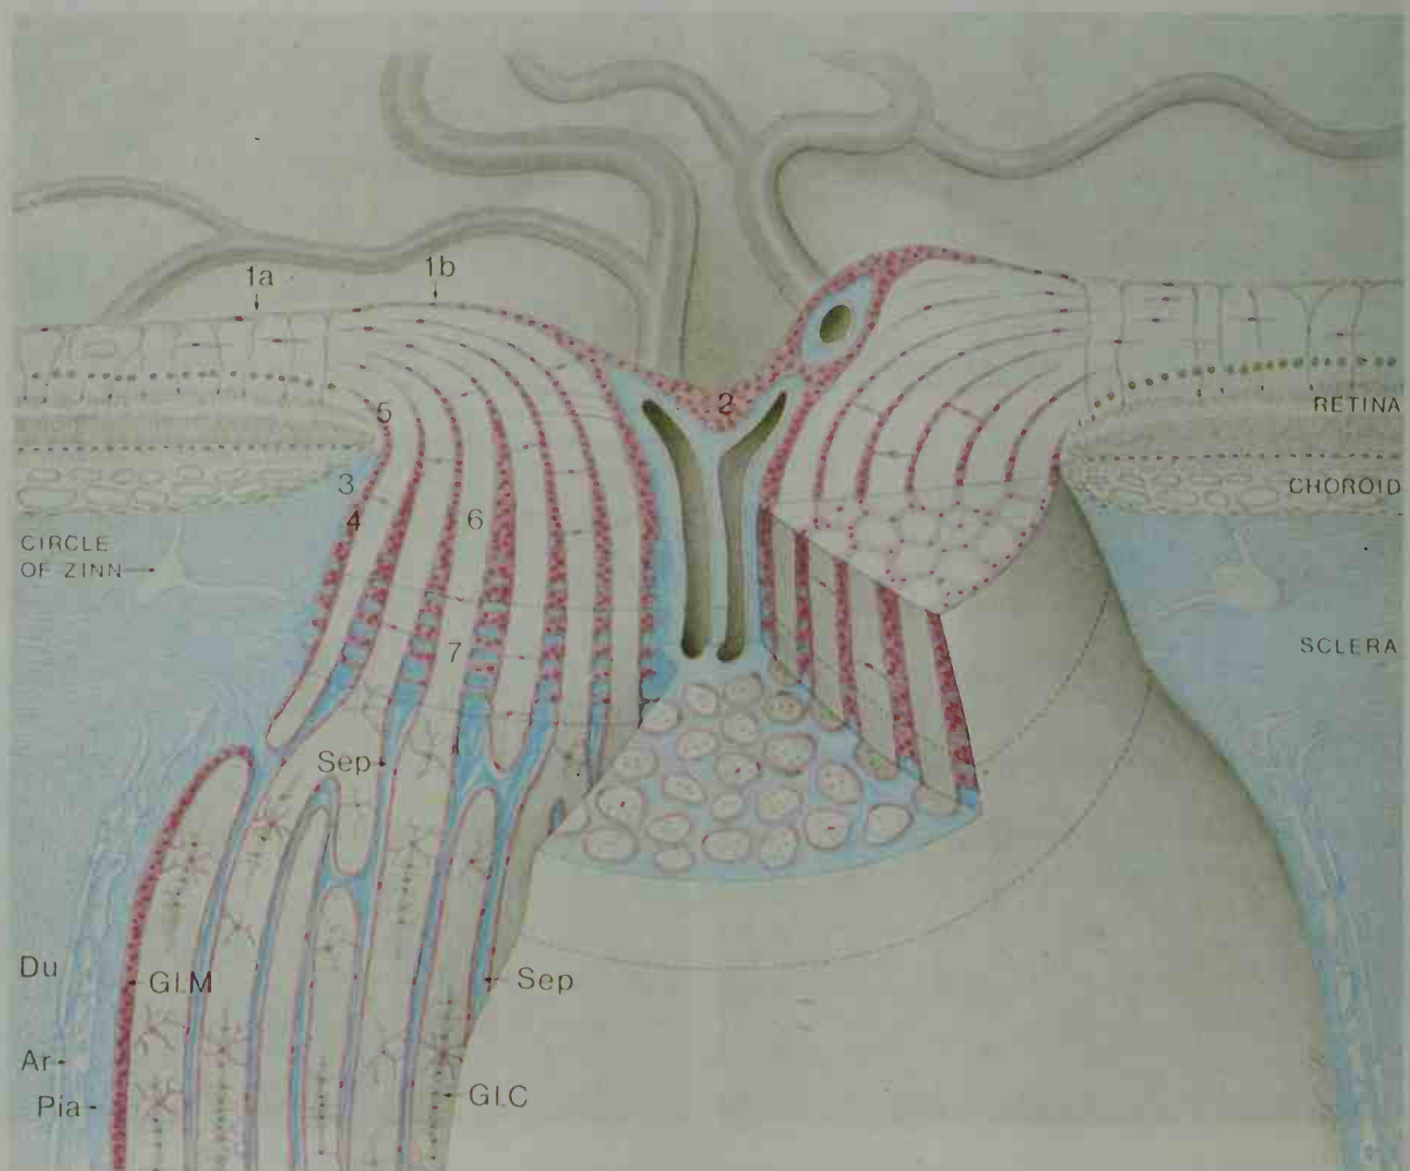
7.257E–H Fluorescence angiograms of the retina. These are produced by photography with a fundus camera at known periods of time following introduction of fluorescein into the circulation. (For details of the technique consult *Fluorescence Photography of the Eye*, by Emanuel S. Rosen, Butterworths, London, 1969, to whom we are indebted for all the colour photographs and angiograms in this illustration.)

E Angiogram of the same retina as that appearing in 7.257A, taken in 'mid-venous' phase. The arteries display an even fluorescence, but the veins appear striped, due to laminar flow. This appearance is the reverse of, and not to be compared with the arterial 'reflex' seen in 7.257A. The background mottling is due to fluorescence from the choroidal vessels.

F Angiogram of the left optic disc, showing the major arteries and veins and also their smaller branches. Note particularly the radial pattern in the retinal capillaries. The laminar flow in the veins is less obvious than in 7.257E.

G Angiogram showing the macular region of a right eye. The main macular vessels are approaching from the right. The subject was an elderly person with considerable macular pigmentation, which masks fluorescence from the choroidal circulation. Compare with 7.257H.



H Angiogram of the macula of a young subject showing the macular capillaries in detail. Note the central avascular fovea. Left eye. Compare with 7.257G.

7.258A A horizontal section through the optic nerve at its point of exit from the human eyeball.

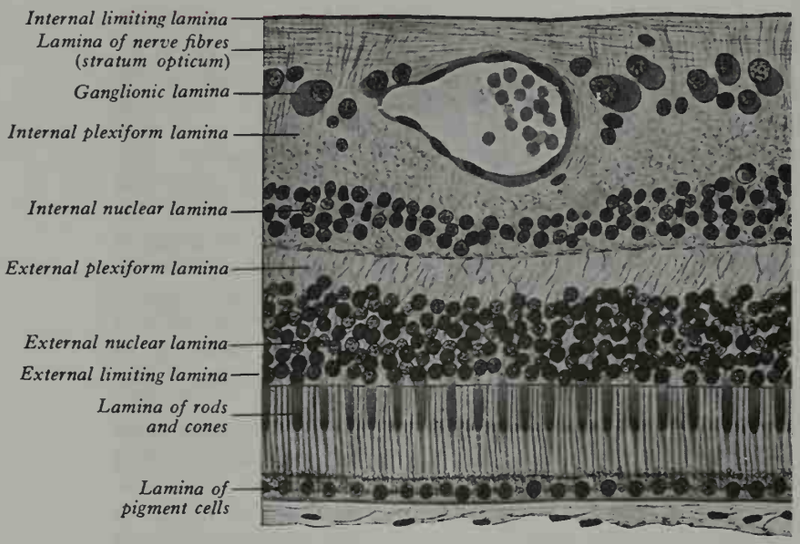
THE PROCESSES OF THE ROD AND CONE CELLS

The retinal photoreceptor cells (7.259, 260) consist of a cell body containing the nucleus, which will be described in lamina 4 (*vide infra*), an axonal centripetal process which forms synapses with the retinal neurons in lamina 5, and a photosensitive centrifugal or external process which will be the subject of this section. Although intermediate forms exist in various vertebrates, the great majority of these processes, and hence the cells of which they are a part, fall into two categories, *rods* and *cones*, differentiated principally by the cylindrical and conical form of their processes, but also by the existence of a constricted *outer fibre* connecting the rod process to the soma of its cell (7.260B), a feature absent from cone cells, though in these a small constriction or waist may be apparent. At the junction of the rod processes with their outer fibres and of the cone processes with their cell bodies is the external limiting membrane, through which the photoreceptor process appear to be thrust (7.260B), as if

7.258B Schematic representation of the exit of the human optic nerve from the eyeball, showing the distribution of collagenous (blue) and neuroglial (magenta) tissues. Sep=septa of collagenous connective tissue carried into the nerve from the pia mater and dividing the nerve fibres into numerous fascicles. Gl.M=astroglial membrane separating nerve fibres from connective tissue. Gl.C=astrocytes and oligodendrocytes among the fibres in their fascicles. Du, Ar, Pia=dura, arachnoid and pia maters respectively. *1a* is the internal limiting lamina of the retina, which is continuous with an astroglial membrane (of Elschnig) covering the optic disc (*1b*). An accumulation of astrocytes forms a central meniscus (of Kuhnt) in the centre of the disc (2). The anterior or so-called 'choroidal part' of the lamina cribrosa (6) is separated from the choroid by a spur of collagenous tissue (3). The 'border tissue of Jacoby' (4), which is largely astroglia, frequently extends beyond the choroid (5) to separate much of the retina from the 'retinal part' of the optic nerve head. The posterior part of the lamina cribrosa (7) contains collagenous tissue derived from the optic nerve septa and fenestrated sheets of collagen fibres continuous with those of the sclera. (Reproduced by kind permission of Dr. Douglas K. Anderson and Dr. W. F. Hoyt, *Arch. Ophthal.*, **82**(4), 506–530, 1969. Copyright 1969, American Medical Association.)

through a sieve; the nature of this structure will be discussed below (see the external limiting lamina).

The rod and cone processes are closely packed in a highly ordered array, but the density of this diminishes throughout the neuroretina to the ora serrata, where they abruptly cease. In the human retina they are most numerous in and near the *macula*, the region at the optical centre of the retina where vision is most discriminative as to form and colour, though least adapted to functioning in low luminosities. They are entirely absent over the whole of the *optic disc*, where the centrifugal fibres of the retina leave the eyeball to form the optic nerve. The *central area* of the retina is a region 5 to 6 mm in diameter, which contains the *macula lutea*, measuring about 2 mm horizontally and 1 mm vertically, its yellow colour being due either to the presence of xanthophyll, a great reduction in the capillary bed, or perhaps to cell inclusions (other than xanthophyll) in the bipolar and ganglion cells. Approximately at the centre of the macula is the *fovea centralis*, a deep conical depression in the retina, where almost all elements



7.258C A transverse section of the optic nerve and its meningeal coverings posterior or proximal to the entry of the central retinal artery, which is visible at the side of the nerve. The dural and pial sheaths are stained green, the subarachnoid pink. Note the fasciculation of the nerve. (Material stained by Masson's trichrome technique and kindly provided by Dr. N. A. Locket, Institute of Ophthalmology, University of London.)

except cones are absent, on its floor at least, the diameter of this being said to be no more than 0·4 mm. This *foveola*, as it is sometimes called, is about 4 mm lateral and 1 mm inferior to the centre of the optic disc; the latter corresponds to the 'blind spot' in the uniocular visual field. The extremely small size of the foveola accounts for the accuracy with which the visual axis must be directed to achieve the most discriminative vision. The macula has been further divided into peri- and para-foveal areas, but for such details recent monographs should be consulted. (*See* also Yamada 1969.) The macula and central fovea will be considered further when the general structure of the retina has been described (p. 1174).

The total number of rods in the human retina has been estimated at 110 to 125 million and of the cones at 6·3 to 6·8 million (Østerberg 1935). Other similar figures have been stated. The distribution of the two types of receptors differs; the cones, which have their densest arrangement at the rod-free foveola (about 147,000 per square millimetre), fall off in numbers very rapidly from this point to a 10-degree circle round the macula to a density of about 5,000 per square millimetre, maintaining this to the ora serrata. The rods, on the other hand, exhibit an almost opposite density, rising from zero at the foveola to an even greater figure than cones at the 10-degree circle (160,000 per square millimetre), and then slowly diminishing in frequency to the periphery of the retina, where there are still estimated to be approximately 30,000 per square millimetre—rods being thus six to thirty times more numerous in the peripheral part of the retina outside the 10-degree circle. This distribution accords well with the phenomena of photopic (cone) and scotopic (rod) vision. Even with light microscopy it is clear that the neurons in the retina are much less numerous than the rod and cone cells; the ganglion cells (*vide infra*, p. 1172), whose axons form the optic nerve, are probably in the region of a million in number in the entire human retina. It is hence obvious that large numbers of rod and cone cells must activate a single axonal pathway in the optic nerve and beyond. This correlation of rod and cone distribution with photopic and scotopic vision is well illustrated by the retina of cats, which are nocturnal. In the area centralis the concentration of cones, though greater than elsewhere in the feline retina, is about one sixth of the human figure. In contrast the rods, at 275,000 per mm² in the area centralis, reach a maximum of 460,000 per mm² peripheral to this, both concentrations being much greater than anywhere in the human retina.

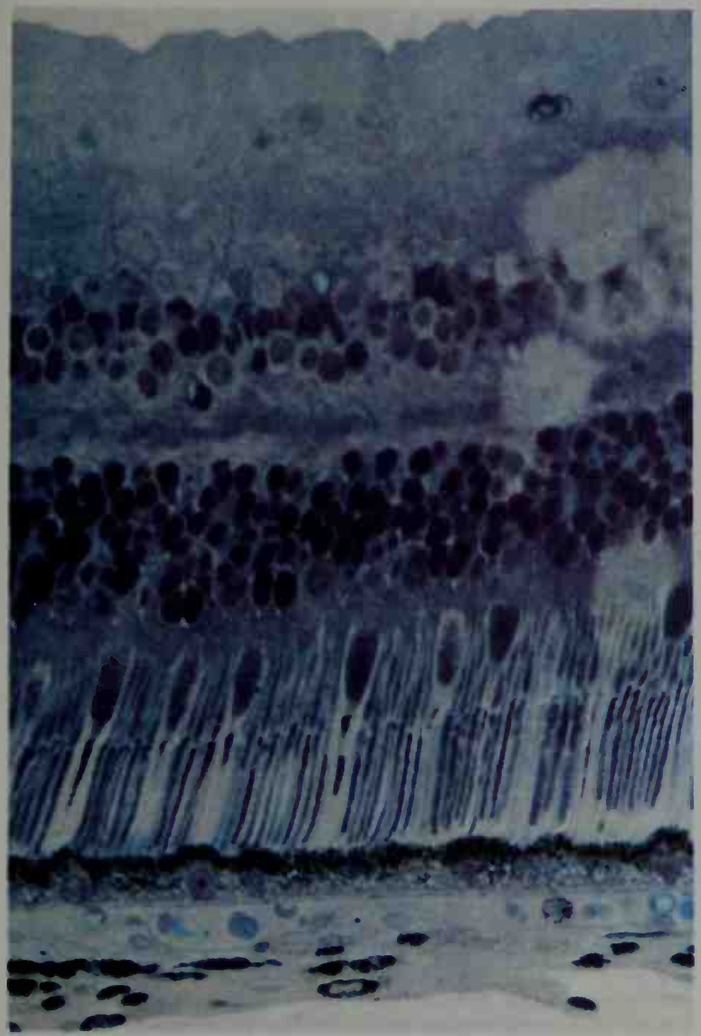
The rod and cone processes exhibit greater differences with light microscopy than with the electron microscope. Even with the former technique both forms of process show an external or peripheral segment, which with ordinary stains is refractile, positively birefringent and PAS-positive, and an internal segment which stains deeply and has a fibrillar structure. The combined segments of the rod process measure about 100 to 120 μm in the freshly fixed human retina, the cone processes being about 65 to 75 μm (Eichner 1957). These dimensions diminish towards the ora serrata, especially in the cones, which are in addition much narrower at the fovea, where they closely resemble rods in their dimensions. The outer segment of rods contains the photosensitive pigments named *rhodopsins* (visual purple), and in the cones (Rushton 1962, Pirenne 1967, Dowthall and Knowles 1977) similar pigments have been detected. These substances display different absorption characteristics, and these account for the different behaviour of rods and cones in conditions of high and low luminosity. Different absorption maxima have also been observed amongst cones themselves in the primate retina, and there is at least some degree of accord between these findings and the trichromatic theory of colour vision. (For a survey of vertebrate photoreceptors and their pigments consult Crescitelli 1972.)

In their *ultrastructural details* the rods and cones are very similar and will be considered together; the rod processes have been more extensively studied (Sjöstrand 1953, 1961; Villegas 1964; Misotten 1962; Dowling 1965; Cohen 1965; Boycott 1974). The rod *outer segment* consists of a remarkably regular series of discoid structures, stacked like thin coins and surrounded by a cell membrane, to the external aspect of which are applied the microvilli of the pigment epithelial cells (*vide supra*, p. 1164). The electron microscope shows that these *discs*, which number from 600 to 1,000 in various species of vertebrate, are flattened sac-like structures, consisting of two unit membranes continuous at the periphery of the disc and separated by a less electron-dense *intradisc space*, except near the periphery, where the space becomes an annular interval of greater width (7.260B). In some vertebrates the discs are infoldings of the cell's membrane, but in the human retina this continuity is lost. The dimensions of these discs have been reported in detail in many species, including primates, and details may be sought in the papers quoted. The discontinuity of the saccular 'discs' in rod outer processes (more recently supported by Cohen 1970, also by Laties and Liebman 1970) provides a distinct *qualitative* difference between these and the discs in cone cells (see also Ripps and Weale 1976), for in the latter the discs do preserve, at part of their periphery, a continuity with the plasma membrane of the outer process. Moreover, as seen in transverse section the cone discs are circular, whereas those of the rod cells display a scalloped profile and are totally separated from the plasma membrane (Cohen 1972). The discoid saccules of cone cells are more flattened than those in rod processes, but are separated by a slightly greater interval. Consequently the number of discs in a unit length is about the same in both types of cell, there being about 30 discs per μm. There is now considerable evidence that the discs of both types of receptor, which develop originally in the vicinity of the cilium (*vide infra*), are progressively pushed away from the basal part of the cell, so that the oldest discs are at the distal end of a rod or cone process and closely related to the pigment epithelial cells. As has

7.259A Section through the primate retina, from its vitreous aspect (above) to the choroid tunic (below), showing its layered structure some little distance from the macular region. Diagram to illustrate the customarily recognized strata.

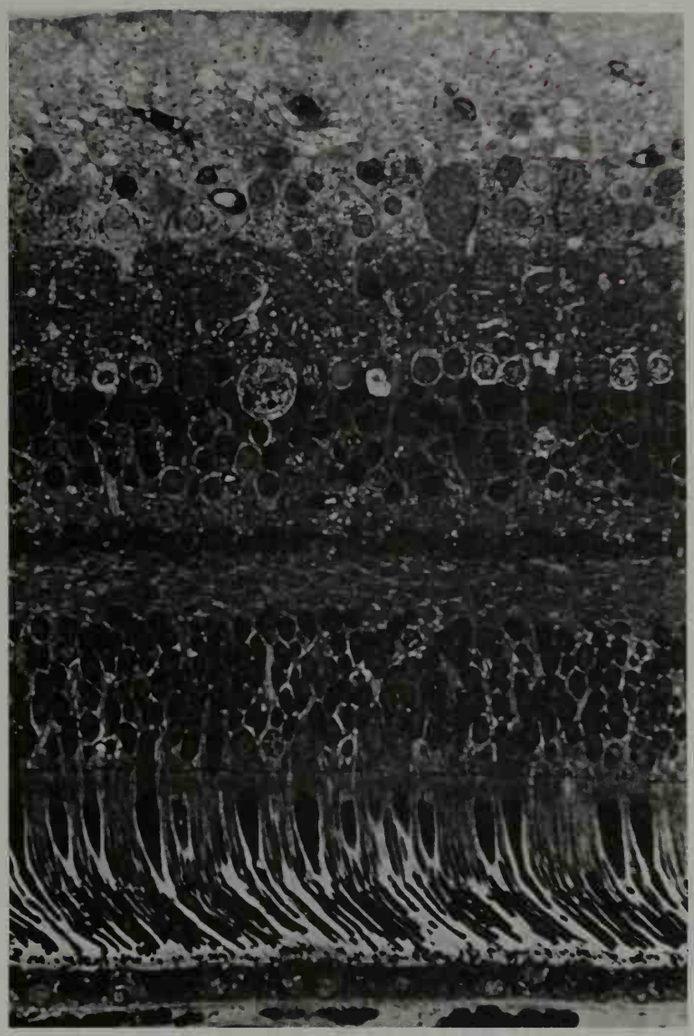
already been mentioned (p. 1164) the epithelial cells are concerned with the phagocytosis of degenerating discs. Young (1971) has shown that in the rhesus monkey almost 1,000 discs are thus removed peripherally and generated proximally in a rod outer segment in the surprisingly short period of 11 days. Since each pigment cell may interdigitate with 24–45 rod segments, the voracious 'appetite' of the former may lead to the destruction of 2,000–4,000 discs *per diem*! These renewal processes have been established by the observed progression of radioactive tracers, introduced into mature animals (rat, mouse, and monkey) by a technique introduced by Droz (1968). There is no such clear evidence for a renewal progress in the outer processes of cones, though Hogan (1972) has described a similar phagocytic process in connexion with the cones of the human fovea. The significance of such a high turnover of a complex intracellular structure as photoreceptor discs has not yet been clarified. The molecular structure of the disc membrane is now considered to consist of a regular arrangement of rhodopsin molecules orientated transversely to the photoreceptor process and embedded in a lipid bilayer, whose molecules extend in the long axis of the process (Schmidt 1938; Weale 1970). Cone (1972) has shown that the orientation of the rhodopsin molecules is labile. Since proteins act as ionic gates for the transference of substances across phospholipid bilayers, the behaviour of rhodopsin molecules during photochemical activity is a problem urgently requiring solution. Despite much hypothecation in the form of molecular models, the problem remains (*see* Ripps and Weale 1976, for a discussion).

7.259B Colour photograph of unstained retinal pigment epithelium seen in surface view. (Human, aged 40 years.) Magnification ×3,500. (Preparation kindly loaned by Dr. John Marshall, Institute of Ophthalmology, London.)



The rod *inner segments* are longer than the outer and somewhat greater in diameter, both differences being even more accentuated in the inner segments of the cones. The inner segment is itself divisible into two regions—an outer *ellipsoid*, which is acidophilic, contains some glycogen, and displays a large number of mitochondria, and an inner *myoid*, adjacent to the soma of the cell, and containing much randomly arranged agranular endoplasmic reticulum and free ribosomes. The myoid is basophilic, and it contains much more glycogen than the ellipsoid. Extending from the inner to the outer segment are bands of the cytoplasm of the ellipsoid, covered with cell membrane, which are closely applied to the outer segment. Another cytoplasmic process connects the ellipsoid to the outer segment, but in this case there is cytoplasmic continuity. This process, the *cilium*, originates in a basal body and has a similar internal structure to a motile cilium (De Robertis 1960). The cone processes have a very similar structure to that of the rods, the differences being largely dimensional. (For further details *see* Dieterich and Rohen 1970.)

Although the structure of the rod and cone processes has now been described in most extensive detail, it is not yet possible to equate these highly remarkable features to functional studies with any degree of confidence. Their stacked discs have been likened to photomultiplier tubes, intensifying the electrical energy derived from photochemical processes, but this is merely an attractive analogy.



Despite the physiological demonstration of at least three types of human cone cell, each with a characteristic range of sensitivity to the light spectrum, no means of distinguishing these structurally has yet been found. Variations in colour sensitivity of different parts of the retina have not been correlated with regional variations in cone shape or dimensions; and the known sensitivity variations (e.g. achromatism of the extreme periphery) are possibly due to differences in neuronal connexions rather than dimensional or distributional variations. For the same reason the duplicity theory of vision may itself be in part explicable to such factors, as well as the widely accepted equation of photopic and scotopic vision with cones and rods.

THE EXTERNAL LIMITING LAMINA

At the level of the junctions between rod and cone processes with the outer fibres of the rods and the somata of the cone cells light microscopy shows what appears to be a thin membrane, which is commonly regarded as being fenestrated by the above continuities. It extends throughout the neural retina and has been considered for many decades to consist of the fused terminal expansions of the 'fibres of Müller'. These are elaborate neuroglial elements, with cell bodies in the internal nuclear layer (lamina 6, *vide infra*), and from them long processes stretch radially through almost the whole thickness of the retina, from its vitreal surface almost to the pigment epithelium. From these vertical fibres large numbers of subsidiary processes spread out horizontally in a dendriform manner into the plexiform layers (laminae 5 and 7) and form meshworks embracing the somata of cells in the nuclear and ganglion cell layers (laminae 4, 6 and 8). Similar 'fibre baskets' also surround the proximal segments of the photoreceptors. This structural arrangement has naturally suggested that these *retinal gliocytes* or *Müller cells* supply a physical support to the retina, like neuroglia elsewhere in the central nervous system. Moreover, the processes of these cells form a similar *internal limiting membrane* (lamina 10) on the vitreal aspect of the retina, and hence it is not unreasonable to ascribe a stabilizing role to these glial elements. As long ago as 1932 the external limiting membrane was described by Arey as a series of unions between the cell membranes of the rods and cones on the one hand and the 'fibres of Müller' on the other. Ultrastructurally this view has been corroborated (*see* Fine and Zimmerman 1962, for a summary of the earlier literature on this topic), but there is much variation in the types of junction described. They occur between the glial processes and the rod and cone inner segments; a

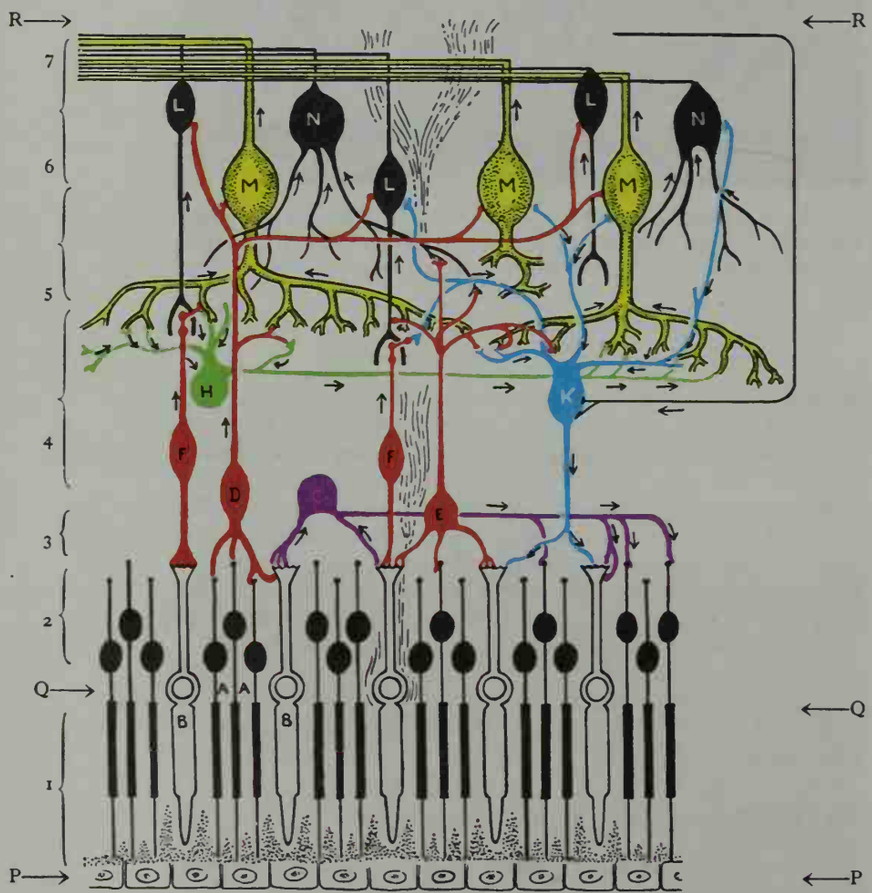
more recent study of them in the human retina describes them as zonulae adherentes, which also sometimes unite adjoining glial fibres (the classical view) and adjacent photoreceptor processes to each other (Spitznas 1970).

In the plexiform layers the horizontal branches of Müller's cells are closely related to the dendrites and axons of the retinal neurons, and may at times form helical lamellae around individual neurites, without, however, the production of myelin. Like other neuroglial cells they also make extensive contacts with blood vessels, especially capillaries; their basement membranes are at these sites fused with those of nonstriated muscle cells in the media of the vessel or with the basement membrane of the endothelium in the case of capillaries. With their very extensive ramifications and widespread contacts with other retinal elements, these gliocytes take up much of the total volume of the retina, also reducing the extracellular space to exiguous proportions. All the glial processes are, of course, cytoplasmic extensions of the cell body, and it is not surprising, therefore, that other than supportive functions have been ascribed to the retinal gliocytes. There is physiological evidence, for example, that they are concerned in the transport of glucose to retinal neurons, and they are able to synthesize and store glycogen (Cogan and Kuwabara 1967; Radnot and Lovas 1968).

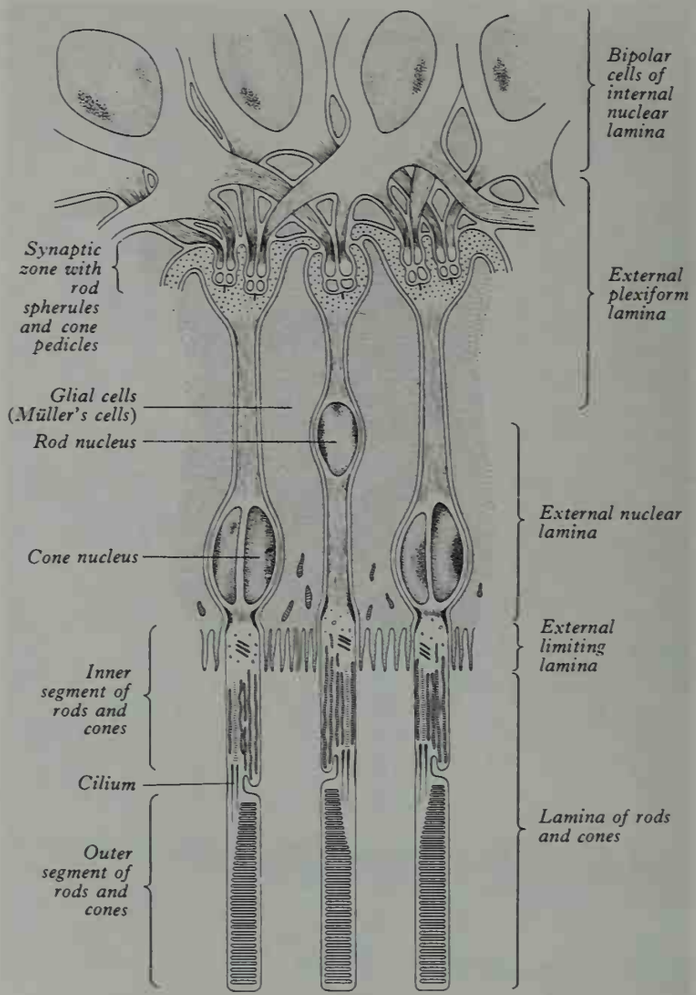
THE EXTERNAL NUCLEAR LAMINA

This retinal lamina contains the parts of the rod and cone cells which are not external to the external limiting membrane or in the external plexiform layer, and this implies in particular the somata of these cells. As they traverse the membrane the photoreceptor processes become the narrower 'outer fibres' of the rods and cones, those of the rods being much more slender and elongated (7.260A). The outer fibres of the cone cells are not much more than a short 'waist' between the process and soma of the cell. The cytoplasm of both types of fibre contains long mitochondria, vesicular agranular endoplasmic reticulum, and many free ribosomes; as it merges into the cell body and spreads round its nucleus, aggregations of microtubules are apparent. The thickness of the external nuclear lamina—and the number of rows of cells in it—varies from 27 μm in the peripheral retina to 50 μm in the fovea (p. 1174), representing in the former a single row of cones with four of rod nuclei, and in the latter about ten rows of cone nuclei.



THE EXTERNAL PLEXIFORM LAMINA

The 'inner fibres' of the rod and cone cells pass centrally (towards the vitreous) and form a most intricate zone of synapses (7.260B) with the dendrites and axons of the bipolar and horizontal neurons of the internal nuclear layer (lamina 6). The inner fibres of the photoreceptors resemble axons, containing a few mitochondria and vesicles, free ribosomes, microfilaments and microtubules. The rod axons are 15 to 25 nm in diameter and 1 μm or even more in length, those of the cones being much thicker and containing more microtubules. Rod axons end in an oval, invaginated *rod spherule*, cone axons as conical or pyramidal *cone pedicles*. These terminations form complex multiple junctions with the bipolar and horizontal neurons, the neurites of which



approach them from the internal nuclear layer. The external plexiform layer is sometimes regarded as displaying *three sublaminae*—an outer one of rod and cone inner fibres or axons, an intermediate one of spherules and pedicles, and an internal sublamina of bipolar and horizontal cell processes. (For reviews of this complex subject consult Dowling and Boycott 1966, Misotten and Van den Dooring 1966, Boycott and Dowling 1969, Boycott 1974.)

The rod spherule (7.261) is part of a synaptic complex consisting of three elements—*presynaptic* (the spherule itself), *synaptic* (contacts of the spherular membrane with those of bipolar dendrites and the neurites of horizontal cells), and *postsynaptic* (bipolar and horizontal cell neurites). The spherule is infolded to form a double-walled structure enclosing in its hollow the terminations of two to seven dendrites or processes. The dendrites are derived from *rod bipolar cells* (*vide infra*) and the processes from horizontal neurons; the latter are probably not polarized, conducting impulses in either direction, and hence their neurites cannot properly be termed axons or dendrites. The cytoplasm of the rod spherule contains many presynaptic vesicles and a peculiar osmiophilic lamellar structure, the *synaptic ribbon* (7.261). Microtubules have been described in close association with synaptic ribbons and vesicles in the photoreceptor cells of amphibia (Gray 1976) and primates (Glees and Spoerri 1977). The presynaptic (rod) and postsynaptic (bipolar and horizontal cell) membranes are not thickened as in typical synapses, nor does the 15 nm synaptic cleft contain fibrils or other features. Postsynaptic vesicles may also be present.

The cone pedicle also displays an invaginated pattern, but of a more complex design (7.261). Its cytoplasmic organelles are like those of the rod spherule. A much larger number of neurites make contacts with it. These contacts are of three types: (1) deeply infolded synapses, containing three neurite terminals, two more deeply situated than the other, form *triads*, there being about twenty-five such groups to each cone pedicle; (2) slightly depressed contacts, also on the basal aspect of the pedicle, number as many as 500; and (3) interreceptor contacts connect the periphery of the cone pedicle to adjoining pedicles or rod spherules. The triads contain two 'axon' terminals from horizontal cells and one dendritic terminal from a *midget bipolar neuron* (*vide infra*) or from a horizontal process. (As noted above, some observers consider that the horizontal cell processes cannot be distinguished as axonal or dendritic.) The surface contacts of cone pedicles are synapses with the dendrites of 'flat' bipolar cells (*vide infra*). The interreceptor contacts are devoid of synaptic vesicles, in contrast with other cone pedicle contacts, but they do contain neurotubules. Each pedicle displays six to twelve such contacts. Interreceptor contacts are particularly frequent among the cones of the fovea; elsewhere the contacts are usually between rod and cone cells. In view of the high resolution mediated at the fovea, such contacts have been accepted with reluctance as synapses. However, high resolution microscopy and freeze-fracture techniques (Raviola and Gilula 1973; Witkovsky *et al.* 1974) indicate that they are gap junctions, and that they may provide low resistance routes for the propagation of electrotonic excitation. If this is so, there is at photoreceptor level a separate mechanism of interactions, in parallel with that exercised by horizontal and amacrine cells elsewhere in the retina (*vide infra*).

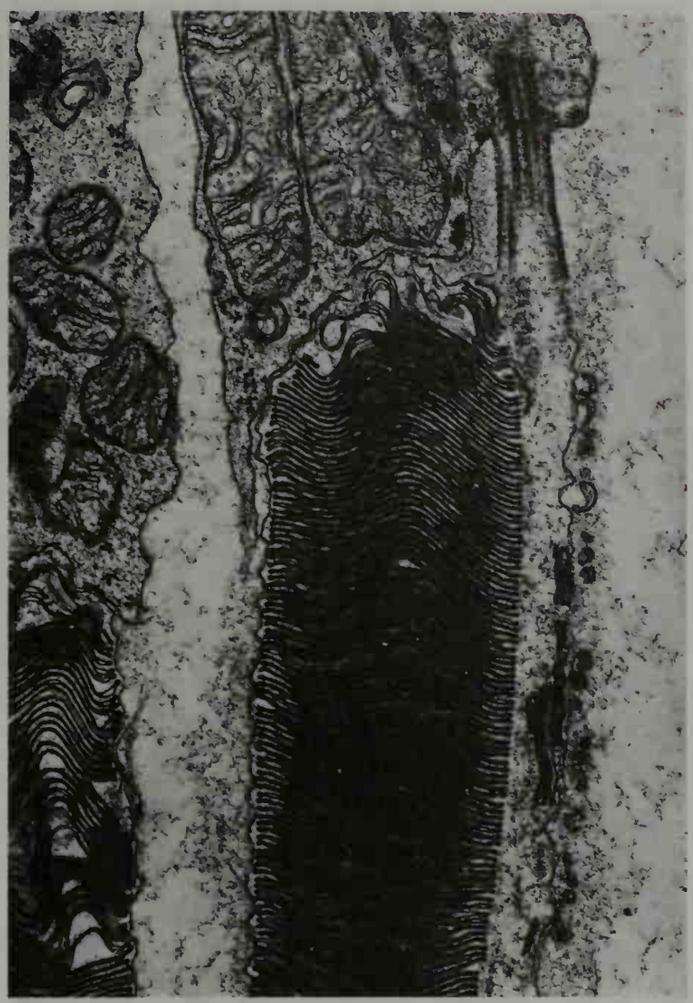
Sjöstrand, in: *The Structure of the Eye*, ed. G. K. Smelser, Academic Press, New York, 1961.)

From this brief description it is clear that each rod cell has direct connexions with two bipolar and perhaps several cone cells, and also with a horizontal neuron. Cone cells display much more complex and numerous contacts, probably between 575 and 600 in number, and involving midget and flat bipolar cells, horizontal, rod and cone cells. The possible pathways for convergence of activities and interactions between the photoreceptors are obviously numerous, but the precise physiological significance of these complex pathways of intercommunication is uncertain. Ultrastructural studies of freeze-fractured material (Raviola 1967) have added somewhat to the structural details of intercellular junctions. The interphotoreceptor contacts have been confirmed as gap junctions, but these and other details do not yet explain the retinal *modus operandi*.

THE INTERNAL NUCLEAR LAMINA



This layer is perhaps unfortunately named. In light microscopic preparations the retina contains *three* tiers of 'nuclei' or cell somata; for the ganglion cells provide the most internal, the 'internal' nuclear layer being thus *intermediate* between this and the layer of rod and cone cells. The layer contains the cell bodies of the *retinal gliocytes* (fibres of Müller) and those of the bipolar, horizontal and amacrine neurons. These cellular components of the inner nuclear layer are arranged in orderly strata. Most external are the cell bodies of the *horizontal cells*, whose processes extend into the adjacent external plexiform layer to form synapses with rod spherules and cone pedicles, as already stated above. Internal to this is a stratum of *bipolar neurons*, which are the primary sensory neurons of the retino-geniculate pathway (p. 977); their dendrites connect with the rod and cone cells, and their axons pass centrally into the internal plexiform layer (lamina 7) to form synapses with the ganglion cells (lamina 8). Internal again to the bipolar cells are the somata of the retinal gliocytes, which have been considered earlier (p. 1168). The most internal stratum of the internal nuclear layer consists of the cell bodies of the *amacrine neurons*, with neurites which spread into the adjacent internal plexiform layer to interconnect with the dendrites of ganglion and the axons of bipolar neurons.

Each of the three categories of neurons in the internal nuclear layer—horizontal, bipolar and amacrine—consists of several types, which are distinguished more by the pattern of their connexions than by their cytological differences, which are not easily defined by light or electron microscopy.

The horizontal neurons are usually divided into two types—*rod* and *cone horizontal cells*. They have multipolar somata, from the angles of which extend a single long process and several short ones (seven in cone and ten to twelve in rod horizontals). Their cytoplasm is like that of bipolars (*vide infra*), except that they contain an organelle rich in ribosomes (Kolmer's crystalloid), which is peculiar to them. The long processes may be up to 1 mm in length—a very long neurite by retinal standards—and their branches make contacts with both rod spherules and cone pedicles. The short neurites of the *cone* horizontal neurons form synaptic junctions with seven cone pedicles, taking part in the formation of several of the triads of each (p. 1170). The short processes of the *rod* horizontal cells establish synapses with ten to twelve rod spherules. The long and short neurites of horizontal neurons are not usually classed as either axons or dendrites, and probably transmit impulses in both directions (7.262).

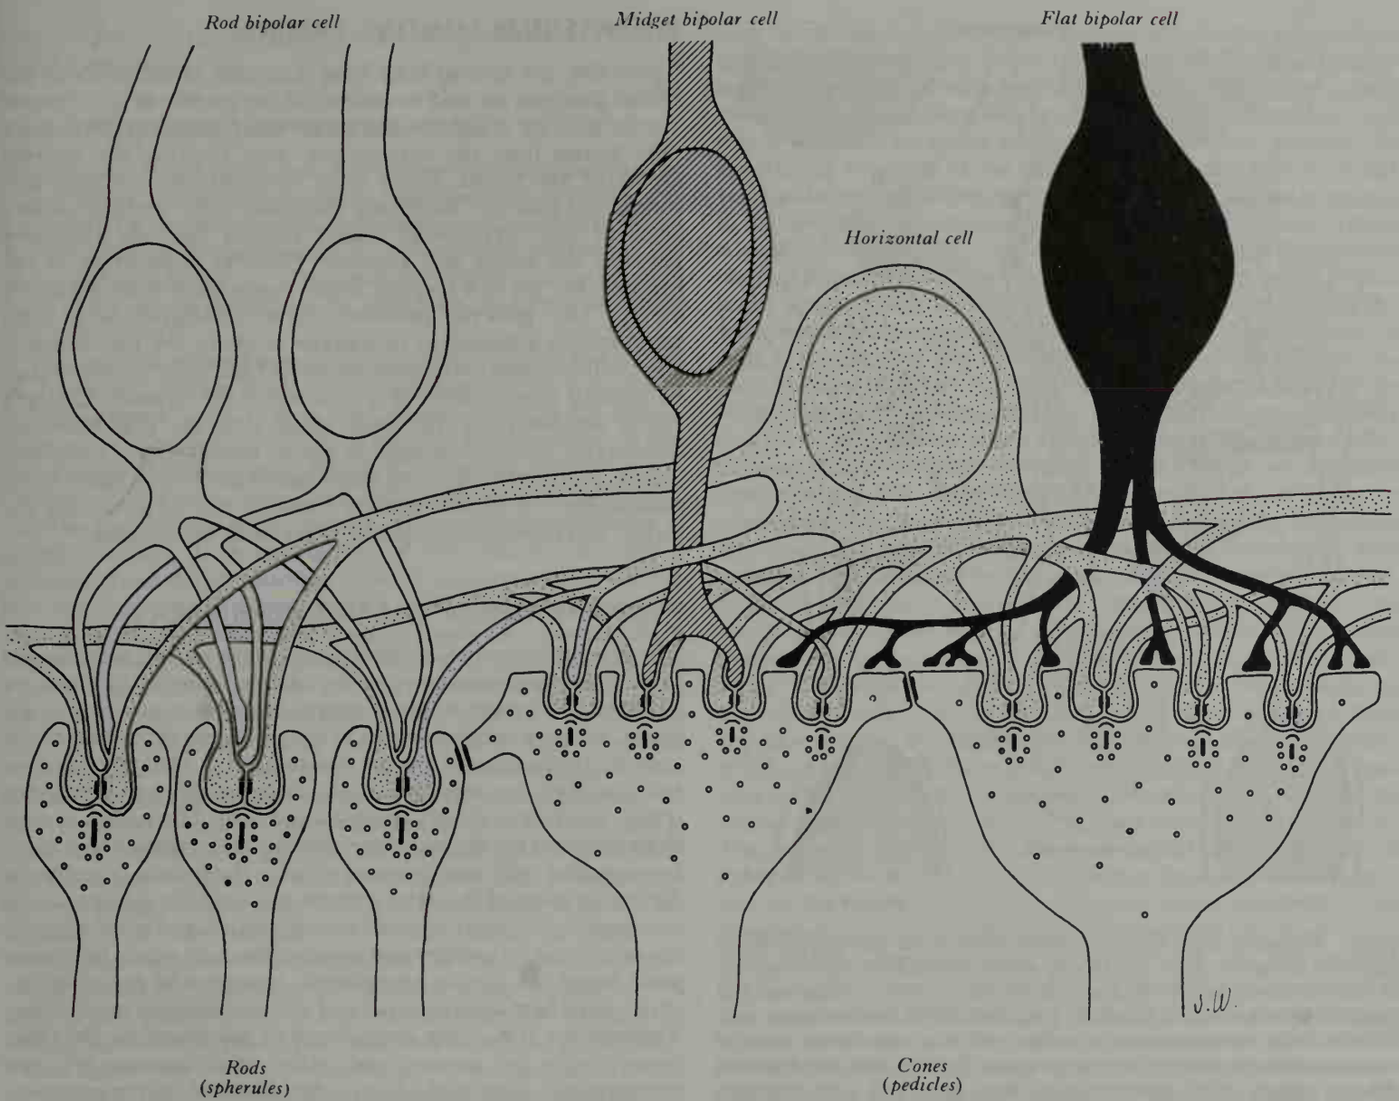
The bipolar neurons may be classified as *rod bipolar cells*, forming synapses with a variable number of rod spherules, and *midget* or *cone bipolar cells*, which take part in the triad synapses of cone pedicles (7.261). The axon of each rod bipolar connects with up to four ganglion cells while the midget bipolars connect each with but a single midget ganglion cell (*vide infra*). A third type, the *flat bipolar neuron*, connects by its dendrites with many cone pedicles, and through its axon with all types of ganglion cell. Even with electron microscopy the somata of these three kinds of bipolar neuron are difficult to identify and distinguish. They vary somewhat in size and shape, but all are very similar in their organelles—abundant mitochondria, free ribosomes, agranular endoplasmic reticulum, and microtubules.

The amacrine neurons (7.262) are so named because of their lack of a large axonal neurite. All their processes resemble dendrites, but are said to show the cytoplasmic features of both axons and dendrites; the direction of conduction in any process at a particular time will be determined by the polarization of the synapses which are active. Each cell has one or two thick processes from which dendritic trees of variable complexity branch out. It is upon the basis of these patterns that five types of amacrine neuron have been differentiated, though their somata cannot as yet be distinguished by ultrastructural features. They contain an indented nucleus, many cisternae of granular endoplasmic reticulum, free ribosomes, microtubules and occasionally cytoplasmic crystalline bodies, and surface cilia. Subsurface cisterns have been described recently in the amacrine, and also bipolar and ganglionic, neurons of the monkey's retina (Spoerri and Glees 1977). Their significance is uncertain, but some resemblances to synaptic specializations suggests a role in intercellular communication. The processes of amacrine neurons display aggregations of synaptic vesicles at scattered sites, which are presumably points of synaptic contact with bipolar axons and ganglion cell dendrites. *Stratified* and *diffuse* amacrine cell types have been defined on the basis of their dendritic deployment as observed in silver-stained sections; both these types have been further subdivided. Recently Kolb and West (1977) have confirmed the occurrence of a type of amacrine cell (first demonstrated in the teleost retina by Ehinger *et al.* 1969) which has processes extending into both internal and external plexiform layers, in the cat. In the internal layer it makes presynaptic connexions with bipolar neurons and pre- and post-synaptic junctions with other amacrine neurons. Since it also has

7.260C An electron micrograph of a section of a human retinal rod, showing the junction between the outer and inner segments. The outer segment is made up largely of photoreceptive lamellae (or discs), connected by a short cilium (top right) to the inner segment containing large mitochondria. (Kindly provided by Dr. N. A. Locket, Institute of Ophthalmology, London.) Magnification × 50,000.

presynaptic connexions with rod and cone bipolar neurons, it apparently mediates feedback between the two plexiform layers, but whether this is excitatory or inhibitory is not yet clear. Similar neurons have been described in the retina of the goldfish by Dowling *et al.* (1976), in which it is considered to be excitatory.

THE INTERNAL PLEXIFORM LAMINA



Between the internal nuclear layer and the lamina of ganglion cells there is a dense neuropil composed of the interconnecting neurites of bipolar, amacrine and ganglionic neurons; it may also contain occasional displaced somata of the latter two categories. It is also traversed, like most of the retinal laminae, by the processes of the retinal gliocytes, which fill the spaces between the neurites, coming into close apposition with them. Even in electron microscrope studies (Allen 1969) the details of the layer are difficult to interpret, but the bipolar axons, amacrine processes, and ganglion cell dendrites can be differentiated, and a wide variety of synaptic contacts can be identified (7.262). The bipolar axons form axodendritic and axosomatic synapses with ganglion cells, and axosomatic contacts with amacrine cells. Amacrine cell neurites make synaptic contacts with bipolar cell axons and with the somata of ganglionic cells. These synapses are extremely numerous; in the region of the fovea they are as dense as 2 million per square millimetre.

THE GANGLIONIC CELL LAMINA

The ganglion cells are the second neurons in the visual pathway. Their dendrites are connected with the processes of bipolar and amacrine cells in the internal plexiform layer, while their axons pass into the layer of nerve fibres (lamina 9), which they form. Here they turn tangentially to approach the optic disc, through which they leave the eyeball as the constituent fibres of the optic nerve. Ganglion cells are arranged in a single stratum through most of the retina, but they are progressively more densely packed from its periphery to the macula. In the vicinity of this they are ranked in about ten rows, diminishing again towards the fovea, in which they are largely absent. They are multipolar nerve cells and vary from 10 to 30 μm in diameter; they contain a relatively large nucleus. Ganglion cell dendrites are variable in number and in their patterns of spread and branching; they usually emerge at the opposite pole of the cell with respect to its axon. On the basis of their dendritic patterns ganglion cells have been classified into at least six types (midget, stratified, diffuse, etc.). *See* Cajal (1911); Polyak (1941); Boycott and Dowling (1969); Boycott (1974).

The midget ganglion cells are monosynaptic in their connexions, and have relatively simple dendrites: They are the commonest form in the central area of the retina. They make synaptic contact with the axon terminals of the midget bipolar neurons (7.260, 261). Since the latter are usually each connected to a single midget ganglion cell centrally, and to a single cone pedicle by their dendrites—especially in the foveal area—these arrangements provide relatively specific pathways for individual cone processes. However, as reference to the connexions of cone cells will show (p. 1170 and 7.261), this does not entail that a cone cell discharges exclusively through the midget bipolar and midget ganglion cell associated with it. **Polysynaptic ganglion cells** (rod and flat ganglion cells) include all the other types of ganglionic neuron, for details of which the authorities quoted above should be consulted. They have one or two large dendrites which spread much more widely than those of the midget ganglion cells; and they synapse with the axon terminals of many bipolar neurons—probably with hundreds as a rule. Since it is clear, by light microscopy, that the bipolar neurons are more numerous than ganglion cells (though not by two orders of

7.260D Tangential sections through the primate retina to show the variations in distribution of rod and cone processes in the foveola (top), fovea (middle), and peripheral macula (below). Note the *small* cone processes in the foveola, from which rods are absent. The cones, which are elsewhere larger than the rods, predominate in the fovea, rods becoming more numerous towards the periphery. 7.261A A scheme of the synaptic arrangements involving the rod spherules and cone pedicles of the retina. For details consult text.

magnitude), it is obvious that many bipolars must transmit to the same ganglion cell; there is also evidence that the reverse relationship obtains. Such intricate interconnexions at least suggest a structural basis for the summation and lateral inhibition long established in general physiological terms, and more recently explored in detail by unit recording techniques.

The cytoplasm of the ganglion cells contains many fibrils and chromatin granules, the latter appearing as aggregations of cisternae of granular endoplasmic reticulum under the electron microscope. Subsurface cisternae also occur (*see* p. 1171). Free ribosomes and agranular reticulum are also abundant, as are microtubules. It is not possible, nevertheless, to distinguish the types of ganglion cell by their ultrastructure. Their axons are the main component of the nerve fibre lamina which will now be considered.

THE NERVE FIBRE LAMINA

The axons of the ganglion cells converge towards the optic disc from all parts of the retina, forming a lamina of nerve fibres (stratum opticum) which is consequently thickest (20–30 μm) at the periphery of the disc. The axons converge in a simple radial pattern from the medial (nasal) half of the retina, whereas the position of the macular area, inferolateral to the optic disc, somewhat complicates the course of the lateral (temporal) axons. Those from the macula form a *papillomacular fasciculus* which passes directly to the disc, while the more peripheral temporal fibres swerve circumferentially above and below the macula to reach the disc.

7.261B An electron micrograph of a part of the outer plexiform layer of the retina (monkey), showing synapses at the pedicle base of a cone (centre) and adjacent rod spherules. Note the presence of mitochondria and of synaptic ribbons surrounded by synaptic vesicles in the cone pedicle. The neuropil composed of interweaving dendritic processes of bipolar, horizontal and other cells is shown below. Kindly supplied by Dr. N. A. Lecket, Institute of Ophthalmology, London.)

7.262 A scheme of the synaptic arrangements in the internal plexiform lamina of the retina. Note that bipolar axonal terminals of three types are shown—*axodendritic* (A) in *dyads* involving neurites of amacrine and ganglion cells, *axosomatic* involving ganglion cells (B) and amacrine cells (C). Similarly the neurites of amacrine cells also make three types of contact—with the axons of bipolar neurons (D), and with the dendrites (E) and somata (F) of ganglion cells. (Both 7.261 and 7.262 are from *Histology of the Human Eye*—see 7.250. Modified from J. E. Dowling and B. B. Boycott, *Proc. R. Soc. B.*, **166**, 1966.)

Ganglion cell retinal axons are non-myelinated—an obvious optical advantage—myelin is highly refractile. The myelin sheaths commence as the axons pass into the optic disc to form the optic nerve. Occasionally, small myelinated fibres have been observed in the human retina; myelination is usual in parts of the retina in many other mammals. The axons in the nerve fibre layers are surrounded by processes of retinal gliocytes and of other neuroglial elements, such as astrocytes and microglial cells (Wolter 1959). Like the somata of the ganglion cells, their axons vary in diameter, ranging from 0·6 to 2·0 μm. They have the ultrastructural appearances typical of axons elsewhere (p. 844).

Centrifugal axons have often been described as present in the retina, but this has almost as often been denied. A considerable literature exists on this topic (Bowin 1895; Mukai 1970), but the existence of such efferent terminals in the human retina is still an open issue. Various sources for efferent retinal fibres have been suggested, including the lateral geniculate nucleus (p. 977), superior colliculus, hypothalamus, and others. They may be vasomotor in nature, but since efferent terminals have been described in relation to amacrine cells by Cajal and others, it is tempting to assume in the visual pathway an efferent analogue to the cortico-olivo-cochlear connexions of the auditory apparatus (pp. 910 and 1204). The majority of studies of this problem have, however, been carried out in birds (Cajal), or mammals remote from man, though this is rarely made plain in textbooks and monographs. There is, nevertheless, good evidence of a corticogeniculate pathway which exerts a modifying influence on the afferent visual pathway (p. 1174), and it may be that a so far ill-defined connexion of this kind extends into the retina itself.

THE INTERNAL LIMITING LAMINA

Classically, the conical branching terminals of the fibres of the retinal gliocytes are said to coalesce at the surface of the vitreous humor to form a continuous membrane, separating the nerve fibre lamina from the vitreous gel, thus 'limiting' the internal aspect of the retina. Some early observers denied this, and considered that the '*membrana hyaloidea*'—the limiting surface layer of the vitreous—in reality formed the sole boundary between the retina and vitreous. Electron microscopy of the junction has led to a concept which compounds both the above views. The gliocyte processes have associated with their terminations a basement membrane of about 0·5 μm, which is sinuously adapted to the glial processes externally but smooth on its internal aspect, where it is adjacent to the vitreous. Collagen fibrils derived from the latter blend with the glial basement membrane, which consequently can be said to have a composite origin. The internal limiting membrane is an obvious factor in the mechanisms of fluid exchange between the vitreous and the retina, and perhaps through the latter, with the choroid.

PECULIARITIES OF THE MACULAR AREA

The general formation and dimensions of the central, macular and foveal areas have been noted earlier. All the layers of the retina are modified to a greater or lesser degree in this central region of the retina, and to a marked degree in the *fovea*, the central pit of the macula. In the floor of this pit (the *foveola*, p. 1167) there are no rod cells at all, but only about 2,500 closely arrayed and elongated cones, which here greatly resemble rod cells. The *somata* of even these elements are displaced peripherally to the sloping wall of the fovea, so that only cone *processes* occur in the foveola. Despite the distorting effect of this arrangement, the foveolar cone processes are nevertheless orientated in a strictly vertical and radial manner, the only other retinal element present (through which light must pass) being the fibrous cytoplasmic processes of the gliocytes, which even here form internal and external limiting membranes. Towards the rim of the conical wall of the foveal pit the other layers begin to appear, and other modifications are also characteristic. Most of the fovea is devoid of rod cells or processes, which only reach its periphery. The rod-free central part of the fovea contains approximately 35,000 cones, and in the whole foveal area (about 1·75 square millimetres) there are in the region of 100,000. Hence, in the fovea, where the cones are most slender and hence most densely aggregated—all other layers being absent—there exist the most favourable conditions for photopic vision. Moreover, the cones in this locality possess the most specific connexions (with individual midget bipolar and ganglion cells), and this accords with the highly discriminative nature of foveal vision.

Because of the general displacement of the outer nuclear lamina towards the periphery of the fovea, the internal fibres or 'axons' of the photoreceptors are stretched out in a tangential direction in the external plexiform layer, and hence no cone pedicles or rod spherules are apparent in the central fovea and foveola. The inner nuclear layer is displaced to the edge of the foveal depression, and the internal plexiform, ganglion cell, and nerve fibre layers are almost absent from the whole fovea. Therefore, even on the wall of the fovea the retina is thinner and more transparent. Capillaries approach as far as the foveal margin, invading only the ganglion cell layer at this circumference. The central fovea is normally devoid of all blood vessels.

The *parafoveal region*, extending for about 0·5 mm around the fovea (diameter ~1·5 mm), is the thickest part of the retina, in part due to heaping up of displaced bipolar and ganglion cells. Around the circumference of the parafoveal area another, *perifoveal region* is described. This is the zone in which the density of cones begins to diminish rapidly, and where the incidence of rods shows an opposite tendency.

The fovea is the last part of the primate retina to attain full development, which is not completed until about the fourth postnatal month in mankind. Prenatal development of the primate fovea has been chiefly studied in rhesus monkeys. Details are beyond the scope of this volume; for a résumé of the literature

consult Hollenberg and Spira (1973); Hendrickson and Kupfer (1976); *see* also p. 176.

THE OPTIC DISC AND RETINAL BLOOD VESSELS

The retina is interposed between two sets of arteries and veins, the ciliary vessels of the choroid and the branches of the central artery and vein. It is dependent upon both circulations, neither of which is alone sufficient to maintain full visual activity in the retina. The choroidal circulation (p. 1157) and the orbital and intraneural parts of the central retinal vessels have been described elsewhere (pp. 688 and 748).

The **central retinal artery** enters the optic nerve and travels in it to arrive at the 'head' of the nerve, where its constituent fascicles (about 1,000 in man) are passing through the lamina cribrosa—the representative of the sclera in this situation. In fact this region, where the neural tissues of the retina meet the neural elements of the optic nerve (including astrocytes and other glial cells) and also the connective tissues of the sclera and meninges, is highly complex. It is also the entry and exit for the retinal circulation and the only locality in which anastomoses with other arteries (the posterior ciliary arteries, *vide infra*) occur. It can be seen by ophthalmoscopy as the **optic disc** (7.257) or papilla, a region of much clinical interest, since it is here that the central vessels enter and leave the eye and can be inspected directly—the only vessels accessible in this way in the whole body. Oedema of the disc (papilloedema) may be the earliest sign of raised intracranial pressure, which is reflected in the subarachnoid space around the optic nerve and may hence compress and obstruct the central retinal vein where it crosses the space. The optic disc is somewhat medial and superior to the posterior pole of the eyeball and hence not on the visual axis. It is round or oval, being usually about 1·6 mm transversely and 1·8 mm in the vertical. Its appearance is very variable and details should be sought in suitable monographs (Duke-Elder and Wybar 1961). In light-skinned races the general retinal hue is a bright terracotta-red, and the pale pink of the optic disc contrasts sharply with this; its central part is usually even paler and may be a light grey colour. These differences are due to the degree of vascularization of the two regions—this being much less at the optic disc—and the total absence of choroidal and retinal pigment cells, these two ocular tunics being represented by little more than the internal limiting membrane of the retina. Even this does not pass far on to the disc, for the retinal gliocytes are here replaced by astrocytes which belong to the optic nerve (Anderson and Hoyt 1969). In individuals with considerable skin pigmentation both the retina and the disc display darker hues (7.257). The optic disc does not project at all in many eyes, and rarely enough to justify the term *papilla*. It is usually a little more elevated where the papillomacular fibres turn into the optic nerve on the lateral side; and where the retinal vessels pass through its centre there is usually a slight depression.

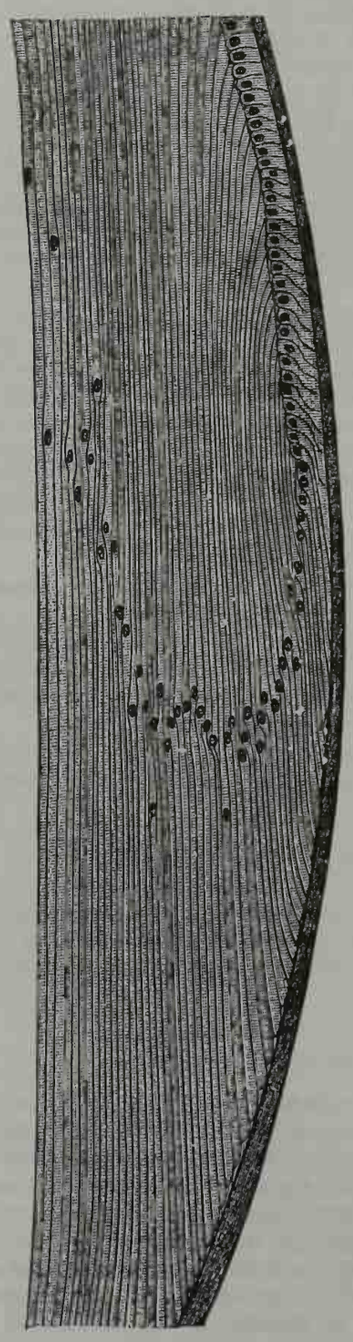
The *central retinal vessels* pass through individual apertures in the lamina cribrosa. While still at this level, usually just beyond the reach of the ophthalmoscope, the *central retinal artery* divides into two equal branches, superior and inferior; and these divide dichotomously again, after a course of a few millimetres, into superior and inferior nasal and temporal branches. Each of these four vessels supplies its own 'quadrant' of the retina, their territories being in fact rather more than quadrants, since they ramify beyond the equator as far as the ora serrata. A corresponding system of veins unites to form the central retinal vein, but the venous and arterial vessels do not correspond exactly, and the latter often cross the veins, usually lying superficial to them. At such crossings, in severe hypertension, the arteries may impress the veins and cause visible dilation of them, peripheral to the crossings. Pulsation is not visible in the arteries with a monocular ophthalmoscope but may be with instruments showing higher magnification. The branching of the central artery is usually dichotomous—two equal rami diverging from each other at an angle of 45–60°, but smaller branches may leave a larger one singly and at right angles to it. The arteries and veins ramify in the nerve fibre layer, close to the internal limiting membrane, which accounts for the clarity with which they can be seen by opthalmoscopy (7.257). Arteriolar branches pass deeper into the retina and may penetrate as far as the internal nuclear layer, from which venules return to the larger superficial retinal veins. A dense capillary bed extends between such vessels, and this is diffusely arranged and displays no laminar features. In general the structure of the vascular walls is like that of typical vessels of the same calibre, but an internal elastic lamina is lacking in the case of retinal arteries, and muscle cells may appear in their adventitious coat. The capillaries consist of a non-fenestrated endothelium and numerous mural cells or *pericytes*, which extend in the axis of the capillary external to the endothelium, sharing the same basement membrane. The cytoplasm of the two types of cells is similar, but the pericytes do not contain myofilaments; their function remains uncertain. For ultrastructural details of the retinal capillaries *see* Tominaga and Ikui (1964). Microcirculatory studies of the human retina in flat preparations stained after trypsin digestion have revealed many details of capillary arrangement. This resembles the deployment of capillaries in renal glomeruli, a network of capillaries connecting individual arterioles and venules with little or no interconnexion with neighbouring vessels. The distinction between capillaries is not, however, as exclusive as it is in the vessels which feed them. The whole of the retinal arterial and arteriolar tree is for practical purposes devoid of anastomoses, nor do arteriovenous shunts occur. The territories of the quadrantic arteries, for example, do not overlap, nor do the branches within a given quadrant show any anastomoses. For this reason, any blockage of a retinal artery is followed by loss of vision in the corresponding part of the visual field of that eye; the only exception to the endarterial nature of the retinal arterial system is limited to the vicinity of the optic disc. The posterior ciliary arteries enter the eyeball close to the entry of the optic nerve (7.255), and in addition to branches which supply the adjoining region of the choroid, other rami form an anastomotic circle (of Zinn) in the sclera around the 'head' of the optic nerve. Branches from the circle join the pial arteries supplying the nerve (Hayreh 1969), and from any of the arteries in this region small rami may pass into the eyeball to anastomose with a retinal artery (7.257). Such a connexion is called a *cilio-retinal artery*; similarly, small retino-ciliary venous anastomotic channels may sometimes be detected. For other details consult Singh and Dass (1960), in which anastomoses between the central retinal artery and pial branches of the ophthalmic artery within the optic nerve are discussed.

The retinal capillaries, which do not pass beyond the external boundary of the internal nuclear lamina, show regional differences in their density. They are especially numerous in the macula, but absent from the central part of the fovea; they become less numerous in the peripheral retina and are absent from a zone about 1·5 mm wide adjoining the ora serrata.

The central artery is innervated by sympathetic fibres and probably also has a parasympathetic supply (Ruskell 1970).

The Ocular Refractive Media

The contents of the eyeball are the aqueous humor, the vitreous body and the lens. All play a part in refracting the rays entering the eye, and the refracting power of the lens can be varied for near or far vision.



THE AQUEOUS HUMOR

The aqueous humor fills the anterior and posterior chambers. It is small in quantity and is formed by active transport and diffusion from the capillaries of the ciliary processes, from which it passes into the posterior chamber. Thence it passes into the anterior chamber through the pupillary aperture and escapes from the iridocorneal angle into the anterior ciliary veins, through the spaces of the angle and the sinus venosus sclerae. Interference with the resorption of the aqueous humor into the sinus venosus sclerae results in increase of the intraocular pressure—the condition known as *glaucoma*. The optic disc becomes cupped and resultant degenerative changes in the nervous and vascular elements of the retina produced by pressure lead to blindness.

The operation of iridectomy may re-establish the flow of the aqueous humor from the posterior chamber to the anterior in cases where the disease is due to adhesions between the iris and the lens. The aqueous humor is not only a metabolic avenue for the avascular tissues, the lens and cornea, but is also chiefly responsible for maintenance of the intraocular pressure, and hence the constancy of the optical dimensions of the eyeball. It carries glucose and amino acids and mediates the exchange of respiratory gases. It contains a high concentration of ascorbic acid.

7.263 The human lens, hardened and divided. Enlarged view.

7.264 A section through the margin of the lens, showing the transition of the columnar epithelium into the lens fibres. Note that the lens cells retain their nuclei long after they have assumed the form of a fibre.

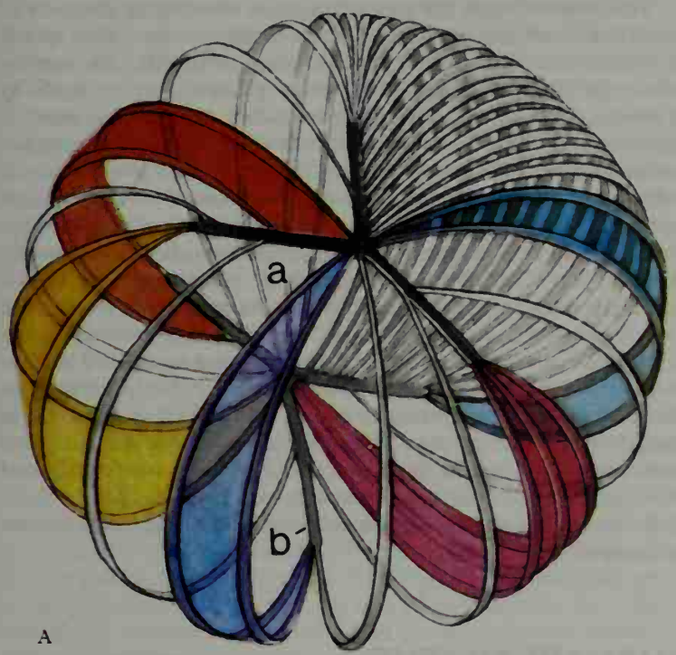
THE VITREOUS BODY

The vitreous body occupies the vitreous chamber, which constitutes about four-fifths of the eyeball. It fills the concavity of the retina, and is hollowed in front, forming a deep concavity, the *hyaloid fossa*, adjacent to the lens. A colourless, apparently structureless, transparent gel, consisting of about 99 per cent of water, some salts and a little glycoprotein and hyaluronate (but *v. infra*). Fibrils of about 16 nm diameter, and a periodicity of 22 nm, and an interfibrillary substance (*vitreous humor*) may be distinguished by electron microscopy (Schwarz 1961). At its periphery the gel is condensed to form the so-called *vitreous (hyaloid) membrane*. A narrow canal, called the *hyaloid canal*, runs from the optic disc to the centre of the posterior surface of the lens. In the fetus the canal is occupied by the hyaloid artery (p. 176), which normally disappears about six weeks before birth. The vitreous membrane is attached to the ciliary epithelium and processes, and to the edge of the optic disc. Anterior to the ora serrata it is thickened by the accession of radial fibres and is termed the *ciliary zonule*. Here the membrane presents a series of radially arranged furrows, in which the ciliary processes are accommodated and to which they adhere, as is shown by the fact that when they are removed some of their pigment remains attached to the zonule. The ciliary zonule splits into two layers, one of which is thin and lines the hyaloid fossa of the vitreous body; the other, forming a system of *zonular fibres* which collectively comprises the *suspensory ligament of the lens*, is thicker and passes over the ciliary body to be attached to the capsule of the lens a short distance in front of its equator; some of the fibres of the suspensory ligament are attached behind the equator of the lens (7.253). Scattered and delicate fibres are also attached to the region of the equator itself. This ligament retains the lens in position, and is relaxed by the contraction of the meridional fibres of the ciliaris, so that the lens is allowed to become more convex (p. 1184).

The structure of the vitreous body has been studied in much detail, both by light and electron microscopy, and by X-ray diffraction (Suguira 1957; Fine and Tousimis 1961; Brini *et al.* 1968). It contains collagen fibrils of 6–15 nm diameter, the arrangement of which shows regional differences, in particular a cortical condensation. Rounded cells can be identified by phase contrast microscopy; for details of such *hyalocytes*, consult (Hogan 1963). No blood vessels penetrate the vitreous body; so that its nutrition must be mediated by the vessels of the retina and ciliary processes, situated upon its exterior.

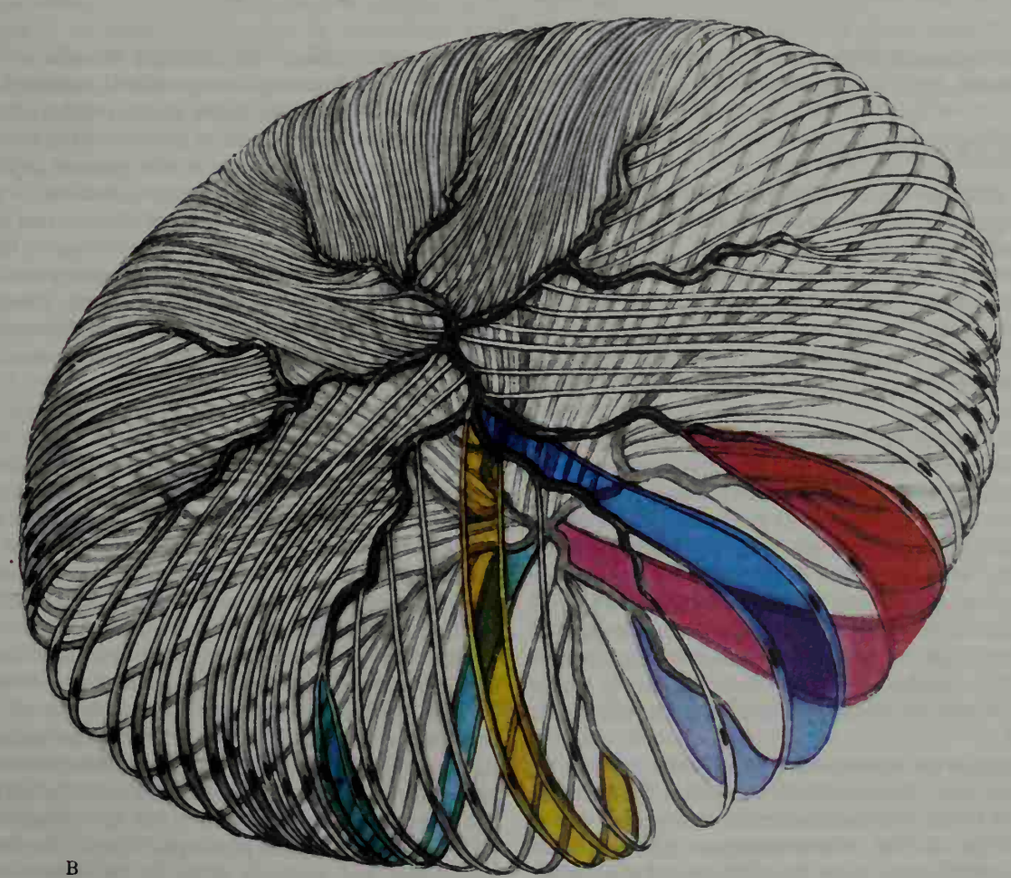
THE LENS

The lens (7.263–265), enclosed in its capsule, is situated immediately behind the iris, in front of the vitreous body, and is encircled by the ciliary processes, which slightly overlap its margin or equator.



The *capsule of the lens* is a transparent, elastic membrane which closely surrounds the lens, and is thicker in front than behind. It contains no true elastic tissue, and its elasticity may reside in the disposition of the fine fibrils of which it is formed. It has been described as a very thick basement membrane, which is PAS positive. Its fibrils have a periodicity of 60 nm, which differ from those of the zonule, with which they are continuous at the periphery of the lens. The lens rests, posteriorly, in the hyaloid fossa of the vitreous body; anteriorly, it is in contact with the free border of the iris, but recedes from it at the circumference, thus forming the posterior chamber of the eye; it is retained in its position chiefly by the suspensory ligament already described.

The *lens* is a transparent, biconvex body, the convexity of its anterior being less than that of its posterior surface. the central points of these surfaces are termed respectively the *anterior* and *posterior poles*; a line connecting the poles constitutes the *axis* of the lens, while the marginal circumference is termed the *equator*. Its dioptric power is much less than that of the cornea. All the



optical media of the eye have a refractive index not much removed from that of water (1·33), but the corneal surface is in contact with air, and the majority of the 58 dioptres of which the eye is capable is effective here. The advantage of the lens is its potentiality of varying its dioptric power, and this is partly dependent upon a variation in its refractive index from 1·386 in its periphery to 1·406 at its core. The lens contributes about 15 dioptres to the total dioptric power of the eye. The *range* in dioptric power of the lens does not quite reach this, even at birth; most young children show minor refractive errors (Sorsby *et al.* 1961), and available dioptric range decreases with age, being halved by the age of forty and reduced to 1 or 2 dioptres by sixty. For further information on physiological optics consult Bennett and Francis (1962); Duke-Elder (1969).

THE STRUCTURE OF THE LENS

The lens is made up of soft cortical substance and a firm, central part, the so-called nucleus (7.263). Faint sutural lines (radii lentis) radiate from the poles to the equator. In the adult there may be six or more of these lines, but in the fetus there are only three, and these diverge in a Y-shaped manner at angles of 120°; on the anterior surface the Y is upright; on the posterior surface it is inverted (Mann 1924). These lines correspond with the free edges of septa—composed of an amorphous substance, which dip into the substance of the lens. When the lens has been hardened it is seen to consist of a series of concentrically arranged laminae, each of which is interrupted at the septa. Each lamina is built up of a number of ribbon-like lens fibres, the edges of which are more or less serrated—the serrations interdigitating with those of adjacent fibres, which are in part connected by desmosomes (Wanko and Gavin 1961), while the ends of the fibres come into apposition at the sutures. The ultrastructural characteristics of specialized contacts between lental fibres have been described (in the mouse) by Rafferty and Esson (1974); they regard these as gap junctions, a finding confirmed by Philipson *et al.* (1975) in human and bovine lenses. Kuwabara (1975), on the other hand, considers that the cortical cells of the lens are held together by reciprocal 'knob and socket' junctions and by fine ridges in the deeper parts of the lens. The fibres run in a curved manner from the sutures on the anterior surface to those on the posterior surface (7.265). No

A

B

7.265A and B The structure of the fetal (A) and adult (B) human lens, showing the major details of arrangement of the lens cells or fibres. The anterior (*a*) and posterior (*b*) triradiate sutures are shown in the fetal lens, and it is clear that fibres pass from the apex of an arm of one suture to the angle between two arms at the opposite pole, as shown in the coloured segments. Intermediate fibres show the same reciprocal behaviour, ending nearer to one pole, where they start further from the other, and so on. The suture pattern becomes much more complex as successive strata are added to the exterior of the growing lens, the original arms of each triradiate suture showing secondary and tertiary dichotomous branchings. (From *Histology of the Human Eye*—see 7.250.)

fibres pass from pole to pole; they are arranged in such a way that those which begin near the pole on one surface of the lens end near the peripheral extremity on the other, and vice versa. The fibres of the outer layers of the lens are nucleated, and together form a nuclear layer, most distinct towards the equator. The deeper fibres, which have lost their nuclei, are less flexible, and their contours are more deeply serrated. The superficial fibres, the more recently formed, are more flexible; in cross-section they are hexagonal, with two opposite sides longer than the rest. Adhesion along these sides is considered to be less firm, which may provide a basis for the moulding of the lens by its capsule in accommodation. The total number of lens cells or fibres is estimated to be about 2,000 in the adult lens. The anterior surface of the lens is covered by a layer of transparent, nucleated cuboidal epithelium. At the equator the cells become elongated, and their gradual transition into lens fibres can be traced (7.264). In tangential section or surface view these cells are polygonal, with a diameter of about 15 μm. In the central area of the lens they may be flattened and a mere 6 μm in depth. More peripherally they diminish in width but increase greatly in length, and mitoses are more frequent. At the equator of the lens mitotic activity is maximal. The lens 'fibres' retain their nuclei for a long period, but the oldest (and hence most deeply situated) fibres lose their nuclei. Despite the very slow growth of the lens, the epithelial cells are relatively active; experimental injuries in the mouse (Rafferty 1976) heal completely within 3 days.

In the fetus, the lens is nearly spherical and has a slightly reddish tint; it is soft and breaks down readily on the slightest pressure. A small branch (hyaloid artery) from the central artery of the retina runs forwards through the vitreous body to the posterior part of the capsule of the lens, where its branches radiate, forming a plexiform network which covers the posterior surface of the capsule, and is continuous round the margin of the capsule with the vessels of the pupillary membrane and with those of the iris. *In the adult*, the lens is colourless, transparent, firm in texture and devoid of vessels. *In old age*, it is more flattened on both surfaces, slightly opaque, of an amber tint and increased in density. In the condition termed cataract the lens gradually becomes opaque and blindness ensues. In such cases sight may be restored by extraction of the lens and the provision of suitable spectacles.

The dimensions of the lens are of some interest; its diameter at birth is 6·5 mm, increasing to 9·0 mm at fifteen years, after which it continues to grow very slowly throughout life. Its antero-posterior dimension increases from 3·5–4·0 mm at birth to 4·75–5·0 mm at 95(!). Its anterior radius (about 10·0 mm) is greater than the posterior (about 6·0 mm), but both these are reduced during accommodation. The continued growth of the lens is due to the continual slow production of new cells in its epithelium at the lental equator. The ultrastructural details of the lens capsule and its epithelium have been studied (Wanko and Gavin 1960; Cohen 1965). The capsule consists largely of fine filaments with a periodicity of 60 nm. As noted, the lens fibres, which develop from the epithelial cells, are at first nucleated, but their nuclei disappear as the fibre develops and extends. The fibre consists essentially of a fine fibrillary substance. In the adult there are 2,100–2,300 lens fibres; these may be as much as 8–12 mm in length in the cortical zone. The microfilaments of human lental cells are of 5–9 nm in diameter, and according to Rafferty and Goosens (1978) their arrangements, constitution, and sizes in different mammals may be associated with differing accommodative capacities.

THE ACCESSORY VISUAL APPARATUS

The accessory visual apparatus includes the extraocular muscles, the fasciae, the eyebrows, eyelids, conjunctiva and lacrimal gland.

THE EXTRAOCULAR MUSCLES

The extraocular or extrinsic ocular muscles (7.266–270) include an elevator of the upper eyelid, the *levator palpebrae superioris*, and six muscles capable of rotating the eyeball in any direction. The latter comprise the four *recti* (*superior*, *inferior*, *medialis* and *lateralis*), and the two *obliqui* (*superior* and *inferior*). This is an old pattern of muscles, extending—with slight modifications—through almost the entire vertebrate group, apart from the levator palpebrae superioris, which is a later delamination from the rectus superior.

In general details of structure the extraocular muscles resemble others, but differ in some features, particularly in details of innervation and pharmacological reactions (Bach-y-Rita *et al.* 1971; Hogan *et al.* 1971; Davson 1976). At least two forms of fibre occur: a slender (9–11 μm), slow-contracting type, and a thicker (11–15 μm), 'twitch' type of fibre. The former show motor endings of the 'en-grappe' category the latter motor end plates. More complex classifications, based on histological data, single or multiple innervation, and responses to different transmitter substances, have been advanced. The distribution of these categories of fibre has been also much studied. (*See* Davidowitz *et al.* 1977, for details.)

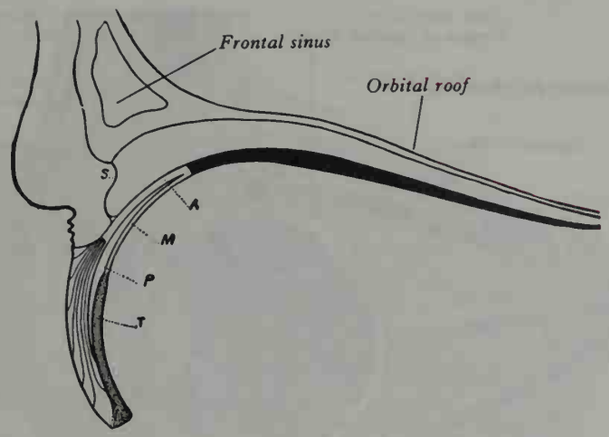
The levator palpebrae superioris (7.266–269) is thin and triangular in shape. It arises from the inferior surface of the lesser wing of the sphenoid bone, above and anterior to the optic canal, from which it is separated by the attachment of the rectus superior. At this posterior attachment it is narrow and tendinous, but soon becomes broad and fleshy, the medial margin of the muscle being almost straight, while the lateral is concave. The muscle ends anteriorly in a wide aponeurosis which splits into two lamellae. Some of the fibres of the superior lamella are attached to the anterior surface of the superior tarsus (p. 1185), while others radiate and pass through the overlying orbicularis oculi to the skin of the upper eyelid. The inferior lamella contains nonstriated muscle fibres forming the so-called *superior tarsal muscle*; it is attached directly to the upper margin of the superior tarsus and is covered by conjunctiva on its inferior surface. A less well-marked layer of nonstriated muscle is also present in the lower eyelid; it unites the inferior tarsus to the fascial sheath of the inferior rectus and its expansion to the sheath of the inferior oblique. A further thin layer of nonstriated muscle, the *orbitalis*, bridges the inferior orbital fissure; its precise function is uncertain. The *superior* and *inferior tarsal muscles*, just described, presumably assist in elevation of the upper and depression of the lower eyelid. All three nonstriated muscles receive a sympathetic innervation.

The connective tissue on the surfaces of the levator palpebrae superioris and rectus superior fuse. Where the two muscles separate to reach their insertions, the fascia between them forms a thick mass to which is attached the superior conjunctival fornix, and this is described as an additional insertion of the levator palpabrae superioris. When traced laterally the aponeurosis of the levator palpebrae superioris passes between the orbital and palpebral parts of the lacrimal gland and is fixed to a tubercle on the zygomatic bone, just within the orbital margin (p. 344). When traced medially the aponeurosis loses its tendinous nature as it passes over and comes into close contact with the reflected tendon of the obliquus superior, whence it can be followed towards the medial palpebral ligament in the form of loose strands of connective tissue. When the levator palpebrae contracts, the upper eyelid is raised, but the lateral and medial parts of the aponeurosis are stretched and thus limit the action of the muscle; the elevation of the upper eyelid is also considered to be checked by the orbital septum (p. 1185). ('Check' mechanisms abound in the orbit, but there is little or no direct evidence that the connective tissue structures thus implicated do in fact function in this manner. See also p. 1183.)

The four recti (7.267–270) are attached posteriorly to a fibrous ring which surrounds the superior, medial and inferior margins of the optic canal (7.268), and is termed the *common annular tendon*; this fibrous annulus is continued across the lower

and medial part of the superior orbital fissure and is attached to a tubercle on the margin of the greater wing of the sphenoid bone. The tendon is closely adherent to the dural sheath of the optic nerve and to the surrounding periosteum; within it are (1) the anterior aperture of the optic canal transmitting the optic nerve and ophthalmic artery, and (2) the medial part of the superior orbital fissure which transmits the two divisions of the oculomotor nerve, the nasociliary nerve and the abducent nerve. The superior ophthalmic vein may pass through, or above, the annular tendon, the inferior ophthalmic vein through or below it. Two specialized parts of this fibrous ring may be discerned: a lower, which gives origin to the rectus inferior, a part of the rectus medialis and the lower fibres of the rectus lateralis; and an upper, which gives origin to the rectus superior, the other part of the rectus medialis and the upper fibres of the rectus lateralis; a second small tendinous head of origin of the rectus lateralis arises from the orbital surface of the greater wing of the sphenoid bone, lateral to the tendinous ring. Each muscle passes forward in the position implied by its name, to be attached by a tendinous expansion into the sclera, posterior to the margin of the cornea. The average distances of the insertions of the recti from the margin of the cornea are: medialis, 5·5 mm; inferior, 6·5 mm; lateralis, 6·9 mm; superior, 7·7 mm.

The obliquus superior (7.267) is fusiform and occupies a superomedial position in the orbit. It arises from the body of the sphenoid superomedial to the optic canal and to the tendinous attachment of the rectus superior, and, passing forwards, ends in a round tendon, which plays in a fibrocartilaginous loop, the *trochlea*, attached to the trochlear fossa of the frontal bone. The contiguous surfaces of the tendon and the trochlea are separated by a delicate synovial sheath. After traversing the trochlea the tendon passes posterolaterally and inferior to the rectus superior to the lateral part of the eyeball, and is inserted into the sclera, *behind* the equator of the eyeball, in its superolateral posterior quadrant between the rectus superior and rectus lateralis

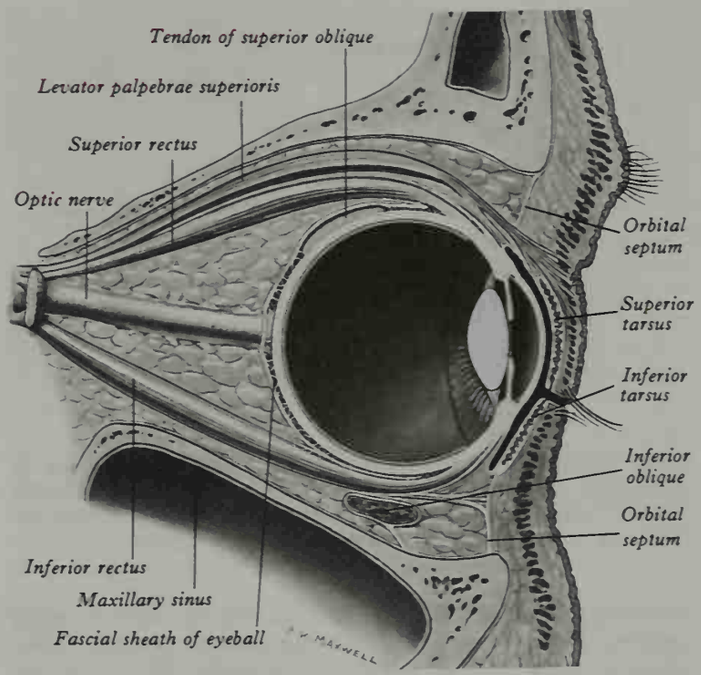


The obliquus inferior (7.267) is a thin, narrow muscle, near the anterior margin of the floor of the orbit. It arises from the orbital surface of the maxilla lateral to the nasolacrimal groove. Passing laterally, backwards and upwards, at first between the rectus inferior and the floor of the orbit, and then between the eyeball and the rectus lateralis, it is inserted into the lateral part of the sclera, *behind* the equator of the eyeball, in its inferolateral posterior quadrant between the rectus superior and rectus lateralis, near to, but somewhat behind, the insertion of the obliquus superior.

Nerve supply. The levator palpebrae superioris, the obliquus inferior, and the recti superior, inferior and medialis are supplied by the oculomotor nerve, the obliquus superior by the trochlear nerve, the rectus lateralis, by the abducent nerve.

ACTIONS OF THE EXTRAOCULAR MUSCLES

The *levator palpebrae superioris* elevates the upper eyelid, its antagonist being the orbicularis oculi. The degree of elevation—which, apart from blinking, is maintained for long periods of time during waking hours—is a compromise between adequate exposure of the optical media and control of light entering the eye. The amount of light, especially in conditions of very bright sunshine, can be reduced by lowering the upper eyelid, thus reducing glare. Although much is known of the physiology of blinking (McEwen and Goodner 1962), and its significance in the distribution of lacrimal secretions, little information is available concerning the continuous activity of the levator to keep the eyelid raised. The respective roles of the main, striated, voluntary part of the muscle and of the small, inferior stratum of nonstriated tissue (the superior palpebral, tarsal, or Müller's muscle) which is innervated by sympathetic neurons, have not been clarified.

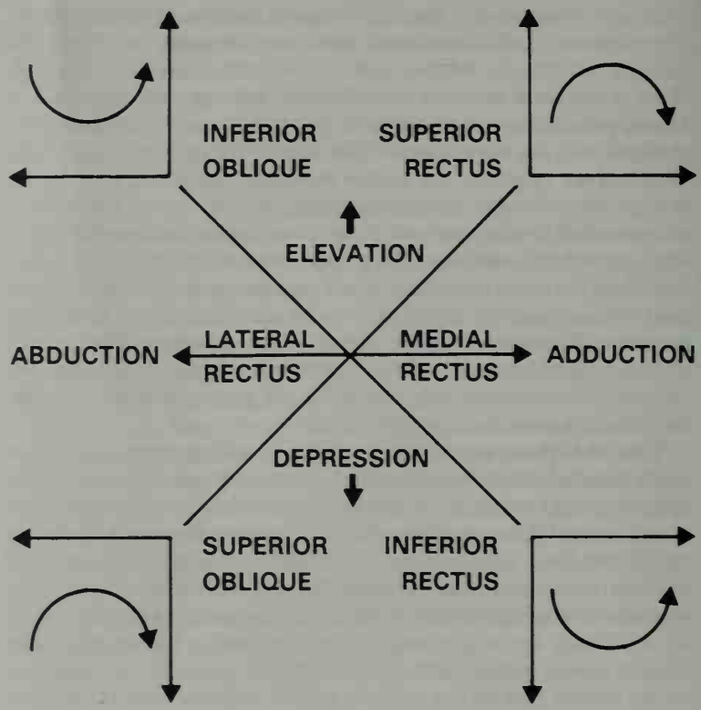


The six *extraocular muscles* all *rotate* the eyeball in directions dependent upon the geometrical relationship between their osseous and global attachments (7.270), which are, of course, influenced by the ocular movements themselves. Before considering these activities it is important to recognize that the *human* extraocular muscles are not accessible to inspection, and that consequently much opinionation regarding them depends on

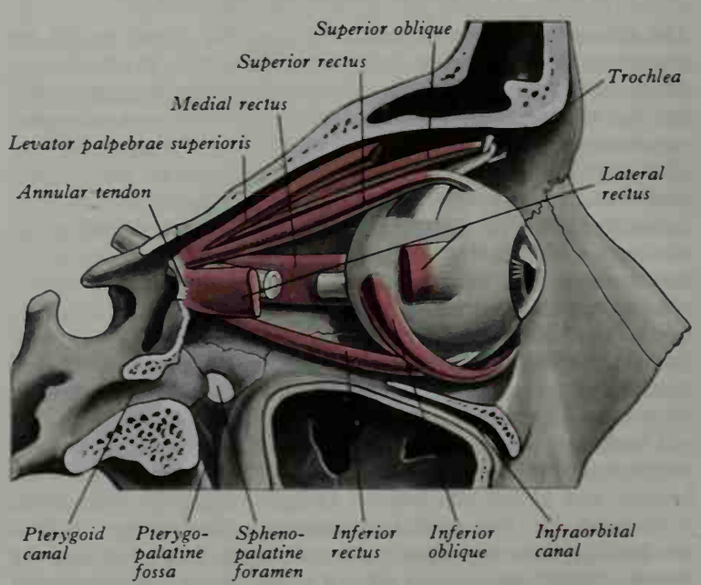
7.266 A diagram of the levator palpebrae superioris, showing its connexions. *A*. Superficial lamella of aponeurosis; *M*. Deep lamella, superior tarsal muscle (of Müller); *P*. Interval between superficial and deep lamellae of aponeurosis; *T*. Tarsus; *S*. Orbital septum.

deductions from disturbances due to lesions of their nerve supplies. A complete assessment of the exact nature of the nerve injury is rarely possible; but this is not to say that, in the vast clinical literature available on this topic, there are not at least some entirely valid observations. It is also essential to note that in any movement of an eyeball, changes in tension and/or length may occur in *all six* of the extraocular muscles, although the direct observation of these has rarely been carried out, even in experimental animals (Sherrington 1905; Szentágothai 1950). It is at least likely that all six muscles are continuously involved, and it is therefore merely a preliminary but necessary exercise to consider each muscle in isolation. Because they form more obvious groupings as antagonists or synergists, it is appropriate to consider the four recti and the two obliques as separate groups, remembering always that they act in concert.

Of the four *recti*, the *medial* and *lateral* muscles exert comparatively straightforward forces on the eyeball. Being approximately horizontal (at least, when the visual axis is in its primary position, directed to the horizon), they rotate the eyeball medially (adduction) or laterally (abduction) about an imaginary vertical axis (7.270). They are antagonists, and by reciprocal adjustment of their lengths the visual axis can be swept through a horizontal arc. When both eyes are involved, as is usual, the four medial and lateral recti can either adjust both visual axes in a *conjugate* movement from point to point at infinity, the axes remaining parallel, or they can *converge* or *diverge* the two axes to and from nearer or more distant objects of interest in the visual field. However, since they do not rotate the eyeball around its transverse axis, the medial and lateral recti cannot make the extremely commonplace action of elevating or depressing the visual axes as the gaze is transferred from nearer to more distant objects or the reverse. This is the contribution of the *superior* and *inferior recti* (aided, as will become apparent, by the two oblique muscles). However, the geometry of these muscles is a little more complex, and the key to the rotational effects which they impart to the eyeball is the obliquity of the orbit (7.270), whose axis does not correspond with the visual axis in its primary position, but is inclined to it by an angle of approximately 23°. The latter value varies somewhat in different individuals being dependent upon the angle between the two orbital axes (7.270A). Hence, the simple rotation caused by an isolated *superior rectus*, when analysed with reference to the three hypothetical axes of the eyeball, appears to be complex—being primarily *elevation* (transverse axis), and secondarily a less powerful *medial rotation* (vertical axis), and a slight *intorsion* (anteroposterior axis) in which the upper rim of the cornea (often referred to as 12 o'clock) is rotated medially towards the nose. These actions—which are in fact a simple, single rotation—are easily appreciated as long as it is realized that the direction of traction of the superior rectus runs *posteromedially* from its attachment *anterior* to the equator and *superior* to the cornea, to its osseous attachment near the apex of the orbit (7.270).

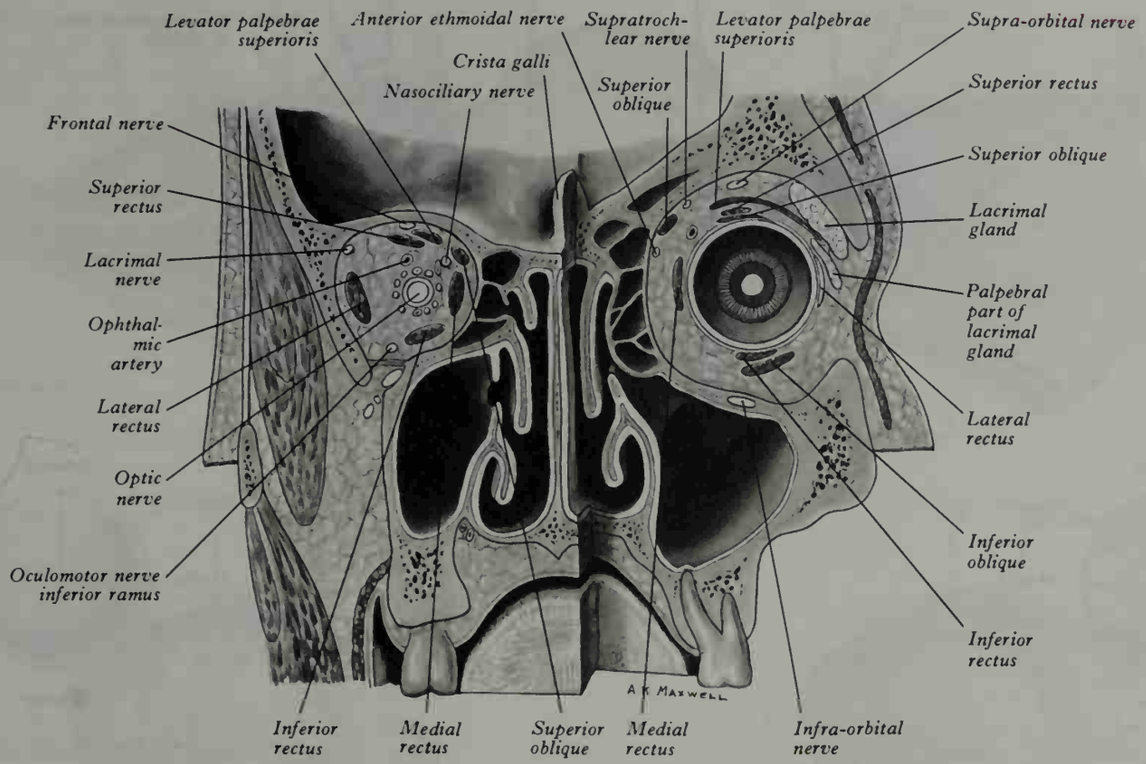


7.267A A sagittal section through the right orbital cavity.



The *inferior rectus* pulls in the same direction, but naturally rotates the visual axis downwards about the transverse axis. It is also clear, that if reference is made to the comparable geometry of the situation, that this muscle will also rotate the eye medially about the vertical axis, but that its action around the anteroposterior axis will *extort* the eye, i.e. rotate it so that the 12 o'clock point on the cornea turns laterally. The superior and inferior recti, therefore, both rotate the eyeball medially, and since their turning movements around the transverse and anteroposterior axes are opposed, their combined contraction could rotate the eye medially. In binocular movements they could thus assist the medial recti in converging the visual axes. By reciprocal adjustment the same two muscles can elevate or depress the visual axes. It may be added that, as the eyeball is rotated laterally, the line of traction of the superior and inferior recti more nearly approaches the plane of the anteroposterior axis (7.270), and hence their rotational effects about this and the vertical axis diminish. In abduction to about 20° or so, these two muscles become almost purely an elevator and a depressor of the visual axis.

The *superior oblique muscle* acts on the eyeball from the trochlea, and since the attachment of the *inferior oblique* is for practical purposes vertically inferior to this, both muscles approach the eyeball at the same angle, being attached in approximately similar positions in the *superior* and *inferior posterolateral* quadrants of the eyeball (7.270). From these attachments it is easy to understand that the superior oblique elevates the *posterior* aspect of the eyeball, the inferior muscle depressing it. Hence, the former rotates the visual axis *downwards*, the latter *upwards*, both movements being around the transverse axis. But the obliquity of both muscles is such that their traction, when the eye is in the primary position, is in a direction posterior to the vertical axis, and thus both rotate the eyeball *laterally* around this axis. In regard to the anteroposterior axis it is not difficult to conclude that in isolation the superior oblique would *intort* the eyeball, the inferior oblique *extorting* it. Like the superior and inferior recti, therefore, the two obliques have a turning movement in common around the vertical axis, but opposed forces in respect of the other two. Acting in concert they could therefore assist the lateral rectus in abduction of the visual axis, as in *divergence* movements of the eyes in transferring attention from near objects to those further away. Just as in the case of the superior and inferior recti, the actions of the oblique muscles also vary with the position of the eyeball; they are more nearly a pure elevator and a depressor as the eye is adducted.

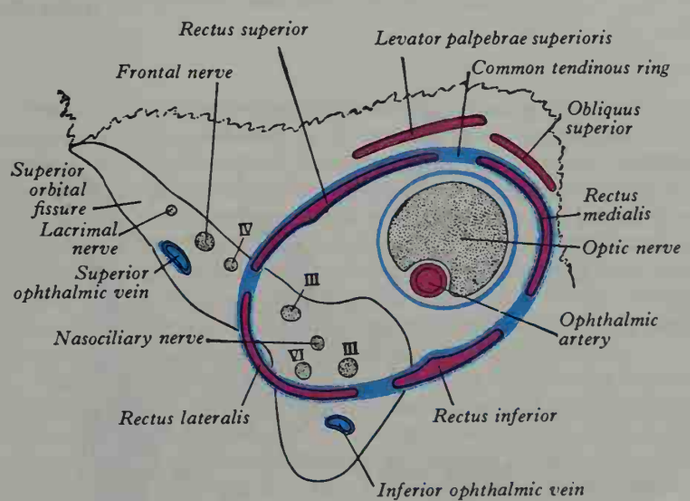


In a short analysis of this kind much must be omitted, and nothing can be said of the defects of ocular movement. For those desiring further information references Whitnall (1932); Cooper *et al.* (1955); Cogan (1956); Schlossman and Priestley (1966); Alpern (1969); Davson (1972), will prove useful; for those requiring the barest data, the actions of the extraocular muscles may be summarized as follows:

There is a misleading custom of linking extraocular muscles together, usually into pairs—such as the right superior oblique and left inferior rectus—which are supposed thus to deviate both visual axes downwards and to the right, as doubtless they do. Limited views of this kind may have a mnemonic value, but they ignore the inescapable fact that in any ocular rotation *all* six muscles must change in length. Since we do not know enough of the reciprocal innervation circuits of the extraocular muscles, it is impossible to dogmatize as to whether every muscle is contracted precisely in step with the progressive inhibition of an antagonist, although the few experiments previously quoted, in fact, support such a view. However that may be, it would be more useful to link the superior, inferior and medial recti together, as adductors, or *convergence* muscles, and the two obliques with the lateral rectus as abductors, or *divergence* muscles. This is a useful concept in view of the very frequent convergent and divergent movements of

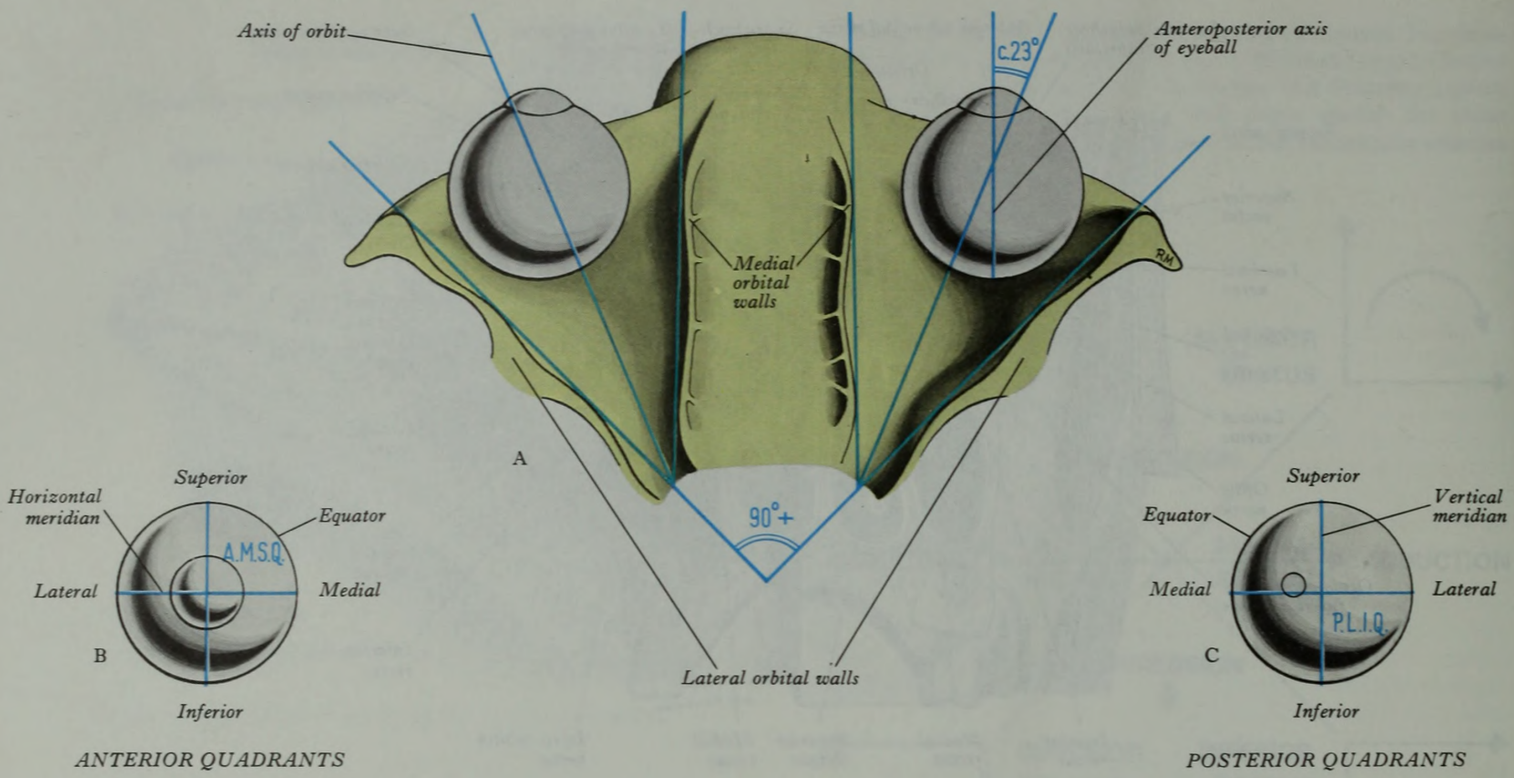
7.267B The muscles of the right orbit. Lateral aspect.

7.268 Coronal sections through the two orbits. Posterior aspect. On the left side the plane of the section is more posterior and passes behind the eyeball.

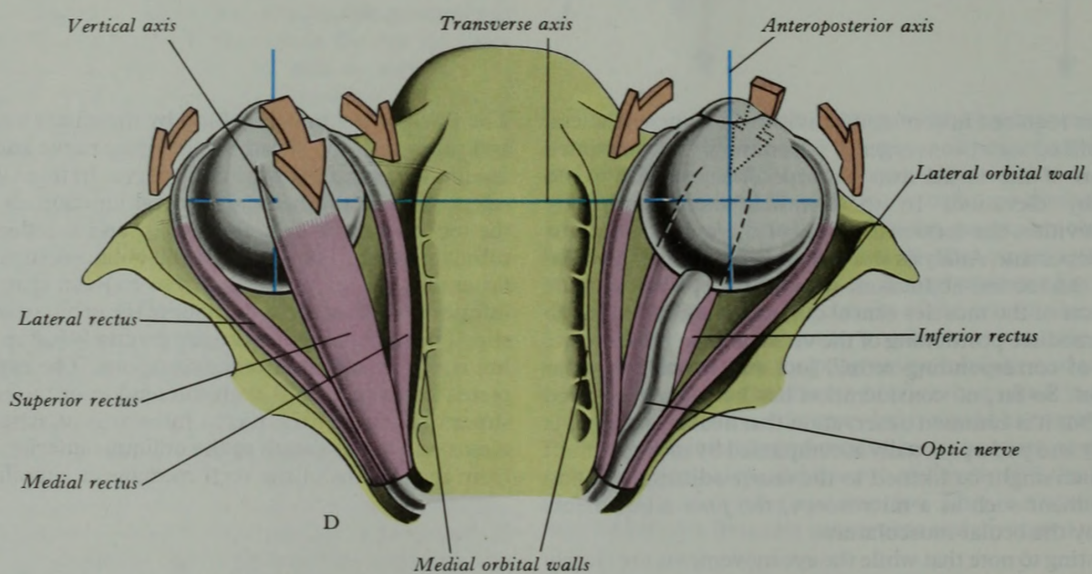


the visual axes required in common activities. It is, nevertheless, an over-simplified view; convergence is commonly accompanied by depression of the visual axes towards objects nearby, and divergence by elevation. In these much more complexly concerted activities, the torsional effects of the muscles become much more important. Analysis shows that in the simple, *cardinal* movements (adduction-abduction, elevation-depression), the torsional effects of the muscles cancel out, and they must also do so in all intermediate positioning of the visual axes to preserve the relationship of corresponding retinal loci and hence binocular (single) vision. So far, no consideration has been given to head movements, but it is common observation that ocular movements are frequently and perhaps usually accompanied by movements of the head, which might be likened to the *coarse* adjustment of an optical instrument such as a microscope, the *finer* adjustments being made by the ocular musculature.

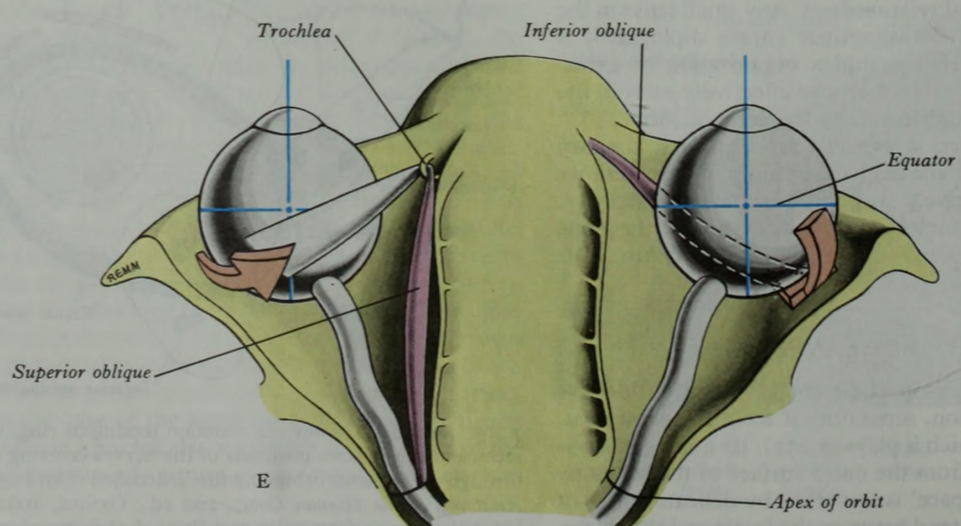
It is interesting to note that while the eye movements are clearly under voluntary control, *torsional* movements cannot be voluntarily incepted. But when the head is tilted relative to the body, reflex torsion movements become apparent, and are in fact necessary to preserve retinal relationships. Any small lapse in the concerted adjustment of the two retinae entails diplopia; it is indeed surprising that such a complex organization of extra-ocular, neck and other muscles is learnt so effectively early in life that diplopia is so rarely experienced by the great majority.



Since the four recti exert a *posterior* traction, and the two obliques pull the globe to some degree *anteriorly*, it is sometimes suggested that they collectively suspend it in the orbital cavity, and that they thus prevent anteroposterior movement of the globe of the eye, assisted perhaps by various 'check ligaments' (*vide infra*).



THE FASCIAL SHEATH OF THE EYEBALL



A thin fascial membrane envelops the eyeball from the optic nerve to the sclerocorneal junction, separating it from the orbital fat, and forming a socket in which it plays (7.271). Its inner surface is smooth, and is separated from the outer surface of the sclera by the *episcleral space*; this 'space' is traversed by delicate bands of connective tissue which extend between the fascia and the sclera. The fascia is perforated behind by the ciliary vessels and nerves, and fuses with the sheath of the optic nerve and with the sclera around the entrance of the optic nerve. In front it blends with the sclera just behind the sclerocorneal junction. It is perforated by the tendons of the orbital muscles, and is reflected on each as a tubular sheath. The sheath of the obliquus superior is carried as far as the fibrous trochlea of that muscle; that on the obliquus inferior reaches as far as the floor of the orbit, to which it gives off a slip. The sheaths on the recti are gradually lost in the perimysium, but they give off important expansions. The expansion from the rectus superior blends with the tendon of the levator palpebrae superioris; that of the rectus inferior is attached to the inferior tarsus and to the sheath of the obliquus inferior. The expansions from the sheaths of the recti medialis et lateralis are strong and

triangular in shape, and are attached to the lacrimal and zygomatic bones respectively; since they may check the actions of these two recti they have been named the *medial* and *lateral check ligaments*. A thickening of the lower part of the fascial sheath of the eyeball, is named the *suspensory ligament of the eye* (Lockwood 1886); it is slung like a hammock below the eyeball, being expanded in the centre and narrow at its extremities; it is formed by the union of the margins of the sheath of the rectus inferior with the medial and lateral check ligaments. Anomalies of the various parts of the above fascial arrangement may interfere with the normal movements of the eyes and cause various types of squint (Nutt 1955). It must be added that, apart from the suspensory ligament, there is little real evidence that any of the so-called check ligaments actually limit eye movements. The connective tissue link between the fasciae covering the superior rectus and levator palpebrae superioris is probably of little functional significance. It certainly does not impede independent movement of the lid and eyeball. It is, however, an almost unavoidable deduction that the orbital connective tissue must be so arranged as to locate the eyeball in its orbit, though in such a manner as to offer no obstruction to the activities of the extrinsic muscles. Moreover, its connexions must be such as to prevent gross displacement of orbital fat, which would interfere with the accurate relative positioning of the two eyes in binocular vision. An interesting re-appraisal of the disposition of the orbital adipose and connective tissues has been made by Koornneef (1977), who emphasizes a series of radial septa which he describes as extending from the fascial sheath of the eyeball to the periorbita. These would provide an excellent suspensory system. His dissections support the concept of separate muscular sheaths, as noted above.

The orbital fascia forms the periosteum of the orbit, but is loosely connected to the bones. Behind, it is united with the dura mater and with the sheath of the optic nerve. In front it is connected with the periosteum at the margin of the orbit, and sends off a stratum which assists in forming the orbital septum. From it two processes are given off: one holds the trochlea of the obliquus superior in position, the other, named the *lacrimal fascia*, forms the roof and lateral wall of the sulcus in which the lacrimal sac is lodged (p. 300). For details of the vascularization of the orbital periosteum and fascia consult Lang (1975).

VISUAL REFLEXES

The impulses concerned with *visual reflexes*, which bring about movements of the eyes, head and neck in response to visual stimuli, follow the pathway provided by the optic nerves and tracts to the superior colliculi. After traversing synapses there, the impulses travel along the tectospinal and tectobulbar tracts to the neurons of the motor columns associated with the spinal and cranial nerves (p. 941).

Pupil light reflex. On exposure of the eye to bright light the pupils contract reflexly. The impulses concerned travel by the optic nerves and tracts to the pretectal nucleus (p. 942) where secondary neuron fibres arise. These, which are very short and run close to the central grey matter, convey the impulses to the accessory oculomotor (Edinger-Westphal) nucleus (p. 1057), whose neurons send preganglionic fibres to the ciliary ganglion through the oculomotor nerve and its branch to the obliquus inferior. The postganglionic fibres from the ganglion traverse the short ciliary nerves to reach the sphincter pupillae. If light be shone into one eye only, both pupils contract (*consensual pupil light reflex*); this is due to the fact that fibres from one optic tract pass to both pretectal nuclei, the crossing fibres passing via the posterior commissure. The dilatator pupillae is supplied by fibres which arise in the superior cervical ganglion of the sympathetic trunk. The preganglionic fibres of this pathway arise from cells of the lateral grey column in the first and second thoracic segments of the spinal cord and pass by the upper thoracic nerves and their white rami communicantes to the sympathetic trunk, in which they ascend to the superior cervical ganglion (p. 1127). As the condition of the pupil at any time is the result of the *balanced action* of these two systems, the pupil becomes dilated when the stimulus of bright light is removed. The pupil will dilate, also, in response to painful stimulation of almost any part of the body. Presumably the fibres of the sensory pathways establish connexions with the efferent preganglionic neurons of the sympathetic described above. Some believe, however, that this reflex dilatation of the pupil is largely due to inhibition of the accessory oculomotor nucleus, though the pathways involved are uncertain. One manifestation of this reflex is the dilatation produced by pinching the skin of the neck; it is termed the *pupillary skin reflex*, and it provides a reminder that to the above, simplified account must be added many other afferent influences, such as connexions of the reticular system with the superior collicular nucleus (*see* p. 942, 947).

Accommodation reflexes. In the process of accommodation for the viewing of near objects the eyes converge and, at the same time, the ciliaris contracts to modify the shape of the lens, and the pupil is constricted to increase the depth of focus. The pathways for the accommodation reflex comprise the optic nerve, optic tract, lateral geniculate body, optic radiation and the visual area of the cerebral cortex. The latter is connected by the superior longitudinal fasciculus to the eye field of the frontal cortex, whence fibres descend through the internal capsule to the nuclei of the oculomotor nerves in the midbrain. From the accessory oculomotor nuclei fibres pass to the ciliaris and sphincter pupillae (relaying in the ciliary ganglion), and from the ventral part of the oculomotor nucleus (*see* p. 1057) fibres supply the medial recti for the action of convergence of the eyes (*see* p. 1180). These pathways have not been so definitely established as those for the pupil light reflex, and it has been suggested (Wilkinson 1927) that the contraction of the pupil in the accommodation reflex is secondary to the convergence of the eyes and that the afferent impulses arise in the proprioceptor nerve endings in the orbital muscles and travel in the oculomotor nerve direct to the accessory nuclei. In certain diseases of the central nervous system (e.g. tabes dorsalis due to syphilis) the pupil light reflex may be lost while the constriction of the pupil as part of the accommodation reflex is unaffected (Argyll Robertson pupil). The site of the lesion that could produce such an effect is probably located between the accessory oculomotor nucleus and the lateral geniculate body, where the pathways for the two reflexes diverge from each other.

Conjunctival and corneal reflexes. If the conjunctiva or cornea be touched lightly, blinking occurs. Afferent impulses travel via the ophthalmic part of the trigeminal nerve and efferent impulses in the branches of the facial nerve to the orbicularis oculi.

THE EYEBROWS AND EYELIDS

The eyebrows are two arched eminences of skin, which surmount the orbits and support numerous short, thick hairs directed obliquely on the surface. Fibres of the orbicularis oculi, corrugator and frontal belly of the occipitofrontalis are inserted into the skin of the eyebrows.

The eyelids or **palpebrae** are thin, movable folds, adapted to the front of the eye, and protecting it, by their closure, from injury. The upper eyelid is the larger and more movable, and is furnished with an elevator muscle, the levator palpebrae superioris (p. 1178); the two eyelids are united to each other at

their ends, and when the eye is open an elliptical space, termed the *palpebral fissure*, is left between their margins; the extremities of the fissure are called the angles of the eye.

The *lateral angle of the eye* (lateral canthus) is more acute than the medial, and lies in close contact with the eyeball. The *medial angle* (medial canthus) is prolonged for a short distance towards the nose, and is about 6 mm away from the eyeball; the two eyelids are here separated by a triangular space, named the *lacus lacrimalis*, in which a small reddish body, termed the *caruncula lacrimalis*, is situated (7.272). On the margin of each eyelid, at the basal angles of the lacus lacrimalis, there is a small conical elevation, termed the *lacrimal papilla*, the apex of which is pierced by the commencement of the lacrimal canaliculus. This minute orifice (7.272) is known as the *punctum lacrimale*.

The *eyelashes* are attached in the free edges of the eyelids from the lateral angle of the eye to the lacrimal papillae. They are short, thick, curved hairs, arranged in double or triple rows: those of the upper eyelid, more numerous and longer than those of the lower, curve upwards; those of the lower eyelid curve downwards so that the upper and lower eyelashes do not interlace when the lids are closed. A number of enlarged and modified sudoriferous glands, termed *ciliary glands*, are arranged in several rows close to the free margin of each lid and open near the attachments of the eyelashes. (*See* also p. 1223.)

Structure of the Eyelids

From without inwards, each eyelid consists of: skin, subcutaneous areolar tissue, fibres of the orbicularis oculi, tarsus and orbital septum, tarsal glands and conjunctiva. The upper eyelid contains, in addition, the aponeurosis of the levator palpebrae superioris (7.273).

The *skin* is extremely thin, and continuous at the margins of the eyelids with the conjunctiva.

The *subcutaneous areolar tissue* is very lax and delicate, and seldom contains any adipose tissue.

The *palpebral fibres of the orbicularis oculi* are thin, pale in colour and parallel with the palpebral fissure. Deep to the muscle there is a layer of loose areolar tissue, which, in the case of the upper eyelid, is continuous with the subaponeurotic layer of the scalp (p. 530), so that effusions of fluid (blood or pus) in this layer of the scalp can pass down into the upper eyelid. It is in this layer of the eyelids that the main nerves lie, so that local anaesthetics have to be injected deep to the orbicularis oculi.

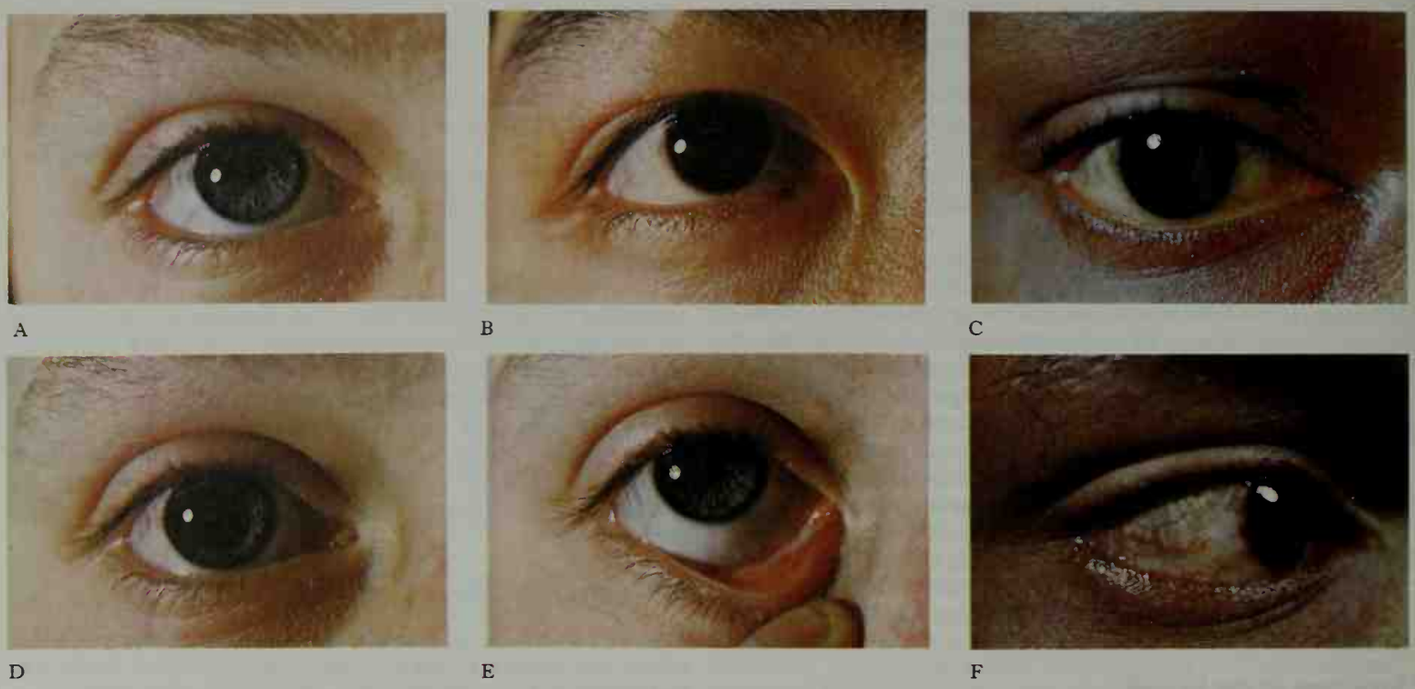
The *tarsi* (7.274) are two thin elongated plates of dense fibrous tissue, about 2·5 cm long; one is placed in each eyelid and contributes to its form and support. The *tarsus of the upper eyelid*, the larger, is of a semi-oval form, about 10 mm in height at the centre, and gradually narrowing towards its extremities. The lowest fibres of the superficial lamella of the aponeurosis of the levator palpebrae superioris are attached to its anterior surface, and the deep lamella of the same aponeurosis is inserted into its upper margin (7.266). The *tarsus of the lower eyelid*, the smaller, is a narrower plate, the vertical diameter of which is about 5 mm. The free or ciliary margins of the tarsi are thick and straight. The attached or orbital margins are connected to the circumference of the orbit by the orbital septum. The lateral ends of the tarsi are attached by a band, named the *lateral palpebral ligament*, to a tubercle on the zygomatic bone, just within the orbital margin; this ligament is separated from the more superficially placed *lateral palpebral raphe* (p. 531) by a few lobules of the lacrimal gland. The medial ends of the tarsi are attached by a strong tendinous band, named the *medial palpebral ligament*, to the upper part of the lacrimal crest, and to the adjoining part of the frontal process of the maxilla in front of this crest; the lower edge of this ligament is separated from the lacrimal sac by some fibres of the orbicularis oculi, since the latter is attached to the ligament.

The *orbital septum* is a weak membranous sheet, attached to the edge of the orbit, where it is continuous with the periosteum. In the upper eyelid it blends with the superficial lamella of the aponeurosis of the levator palpebrae superioris, and in the lower eyelid with the anterior surface of the tarsus. It is perforated by the vessels and nerves which pass from the orbital cavity to the face and scalp, by the aponeurosis of the levator palpebrae superioris, and by the palpebral part of the lacrimal gland.

The *tarsal glands* (7.275) are embedded in the thickness of the tarsi, and may be visible through the conjuctiva on everting the eyelids; they present an appearance like parallel strings of pearls. They are yellow in colour, arranged in a single row, and number about thirty in the upper eyelid, and somewhat fewer in the lower. They are embedded in grooves on the deep surfaces of the tarsi and correspond in length with the breadth of these plates; they are, consequently, longer in the upper than in the lower eyelid. Their ducts open on the free margins of the lids by minute foramina.

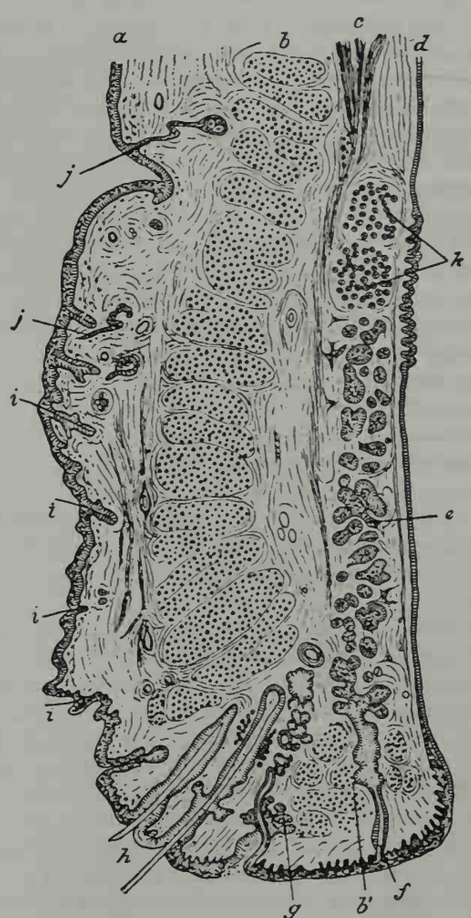
The tarsal glands are modified sebaceous glands, each consisting of a straight tube with numerous small lateral diverticula. The tubes are supported by a basement membrane and are lined at their mouths by stratified epithelium; the deeper parts of the tubes and the lateral offshoots are lined by a layer of polyhedral cells. The secretion of the glands spreads over the margin of the eyelid and tends to prevent the tears from overflowing on to the cheek. It has also been suggested that it spreads over the external surface of the tear film and reduces evaporation.

THE CONJUNCTIVA



The conjunctiva is the transparent mucous membrane which passes, in a modified form, over the inner surfaces of the eyelids, and is reflected over the front part of the sclera and the cornea.

The *palpebral conjunctiva* is highly vascular, and has numerous subepithelial connective tissue papillae, its deeper part containing a considerable amount of lymphoid tissue, especially near the fornices. It is intimately adherent to the tarsi. At the margins of the lids it is continuous with the skin, with the lining epithelium of the ducts of the tarsal glands, and, through the lacrimal canaliculi, with the lining membrane of the lacrimal sac and nasolacrimal duct and thence with that lining the nasal cavity. The line of reflexion of the conjunctiva from the eyelids on to the eyeball is named the *conjunctival fornix*, and its different parts are known as the superior and inferior fornices; the ducts of the lacrimal gland open into the lateral part of the superior fornix. Over the sclera the *ocular conjunctiva* is loosely connected to the eyeball; it is thin, transparent, destitute of papillae, and only slightly vascular. Upon reaching the cornea, the ocular conjunctiva continues as the corneal epithelium (p. 1153). The epithelium of the palpebral conjunctiva near the margins of the eyelids is stratified squamous; about 2 mm from the edge of each eyelid there is a groove in which foreign bodies frequently lodge and at which the epithelium comes to consist of two layers, a superficial one of columnar cells and a deeper one of flattened cells. This structure persists throughout most of the palpebral conjunctiva, but as the fornices are approached an intermediate layer of polygonal cells appears and this trilaminar arrangement comprises the structure of the conjunctival epithelium over the sclera. Near the sclerocorneal junction the epithelium changes to the stratified type characteristic of the corneal epithelium (p. 1153). Scattered throughout the conjunctival epithelium there are mucus-secreting goblet cells, but they are few in the palpebral and circumcorneal regions of the epithelium.



The *lacrimal caruncle* (7.272) is a small, reddish, conical body situated in the lacus lacrimalis at the medial angle of the eye; it consists of a small island of skin, and contains sebaceous and sudoriferous glands; a few slender hairs are attached to its surface. Lateral to, and partly obscured by the caruncle there is a semilunar fold of conjunctiva, the *plica semilunaris*, the concave free lateral edge of which is directed towards the cornea. Its epithelium resembles that of the conjunctiva on the sclera but it contains numerous goblet cells. Beneath the epithelium there is some fat and a little nonstriated muscle. The *nictitating membrane*—present as a conjunctival specialization in some amphibians, reptiles and mammals—may be represented by the semilunar fold; but the homologies of these structures are uncertain.

Vessels and nerves. The eyelids receive their blood supply from the medial palpebral branches of the ophthalmic artery and from the lateral palpebral branches of the lacrimal artery (p. 688).

The ocular conjunctiva is supplied by the ophthalmic division

7.272A–F In the top row of photographs the typical appearances of the living eye are compared in a Caucasian female (A), a Mongoloid male (B) and a Negroid male (C). All subjects are about 20 years of age. Note the pale sclera and grey-blue iris in A, the epicanthus overlapping the medial end of the lower eyelid in B, and the dark brown pigmentation of the iris in both B and C, rendering the pupil almost invisible. Compare the size of the pupil in the same eye, photographed under steady bright light in A and by sudden exposure to the same illumination after a period of dark adaptation in D. In E the lower eyelid had been everted somewhat to exhibit the lacrimal punctum and the rich subepithelial network of blood vessels. In F note the circumcorneal pigmentation and the conjunctival blood vessels, deep to which can be seen some details of the episcleral vessels. All photographs are of the right eye.

of the trigeminal nerve. The conjunctiva of the upper eyelid is supplied by the ophthalmic nerve, that of the lower eyelid by the maxillary nerve. Many of the nerves to the conjuctiva end in bulbous corpuscles (p. 855).

The lymph vessels of the eyelids and the conjunctiva are described on p. 786.

Movements of the eyelids. The position of the lids at any particular time depends on the reciprocal tone of the orbicularis oculi and levator palpebrae superioris and on the degree of protrusion of the eyeball. The usual position when the eyes are open is that the margin of the lower lid crosses the eyeball at the lower edge of the circumference of the iris whilst the upper lid covers about half the width of the uppermost portion of the iris. The eyes are closed by movement of *both* upper and lower lids produced by contraction of the orbicularis oculi and at the same time the levator palpebrae superioris relaxes. On looking upwards, the levator palpebrae superioris contracts and the upper lid follows the movement of the eyeball. At the same time the eyebrows are raised by the contraction of the frontal bellies of the occipitofrontalis so as to diminish the degree to which the eyebrows jut beyond the eye. The lower lid lags behind the movement of the eye so that much more of the sclera is exposed below the iris and the lid is bulged forwards to some extent by the pressure exerted against its deep surface by the lower part of the eyeball. When the eye is depressed both lids move, the upper retaining its normal relationship to the eyeball and still covering about half the width of the upper region of the iris. The lower lid is probably dragged downwards by the pull exerted on it by the conjunctiva reflected on to its deep surface from the sclera. In conditions of fear the palpebral fissure is widened by the contraction of the fibres of the nonstriated superior and inferior tarsal muscles, in response to the increased activity of the sympathetic nervous system. For further comments on eyelid movement see p. 1178.

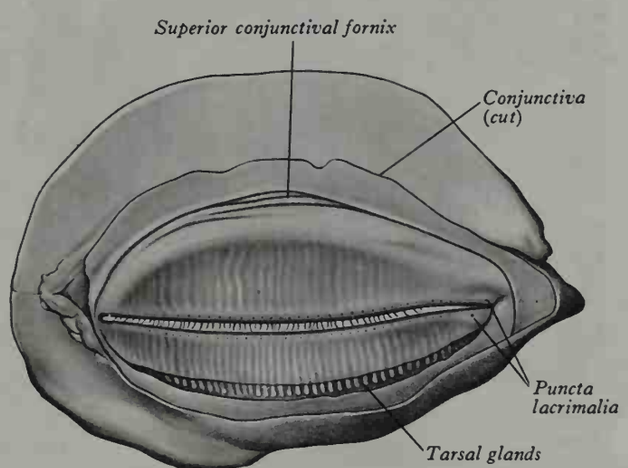
THE LACRIMAL APPARATUS

The lacrimal apparatus (7.276, 279) consists of the lacrimal gland, which secretes a complex fluid, known as the tears, and its excretory ducts which convey the fluid to the surface of the eye;

7.274 The tarsi and their ligaments. Anterior aspect.

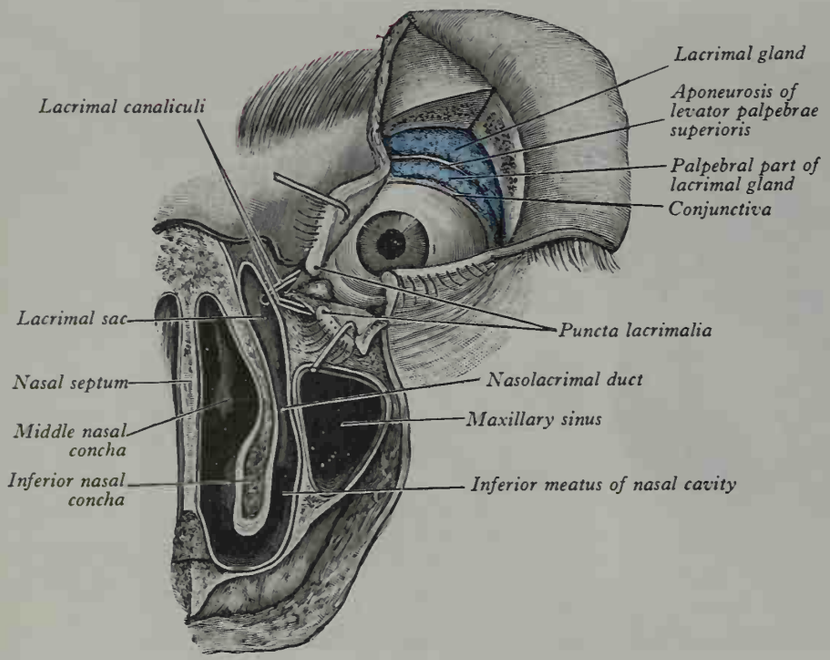
the lacrimal canaliculi, lacrimal sac, and nasolacrimal duct, by which the fluid is conveyed into the nasal cavity.

The lacrimal gland (7.276) is probably homologous with the *Harderian gland* of lower mammals, and is derived from a serous secreting element and a gland secreting an oily material. In primates the lacrimal (serous) element has migrated from its original position in the lower lid to the upper. The human lacrimal gland consists of a larger upper *orbital part* and a lower smaller *palpebral part*, the two parts being continuous with each other posterolaterally around the lateral concave edge of the aponeurosis of the levator palpebrae superioris. The orbital part is about the size and shape of an almond and is lodged in the lacrimal fossa on the medial side of the zygomatic process of the frontal bone, just within the margin of the orbit. It lies above the levator (and, further laterally, above the lateral rectus); its lower surface is connected to the sheath of the levator, its upper surface is connected to the orbital periosteum, its anterior border is in contact with the orbital septum and its posterior border is attached to the orbital fat. The palpebral part, which is about one-third of the size of the orbital part, is subdivided into two or three lobules and extends below the aponeurosis of the levator into the lateral part of the upper eyelid, where it is attached to the superior fornix of the conjunctiva, through which it can be seen when the eyelid is everted. The ducts of the gland, about twelve in number, open into the superior conjunctival fornix. Those from the orbital part (four or five in number) pass through the palpebral part and are joined by some of the ducts form this latter part, while other ducts of the palpebral part (six to eight in number) open independently. Thus all the ducts pass through the palpebral part, so that excision of this part of the gland is functionally equivalent to removal of the entire gland.



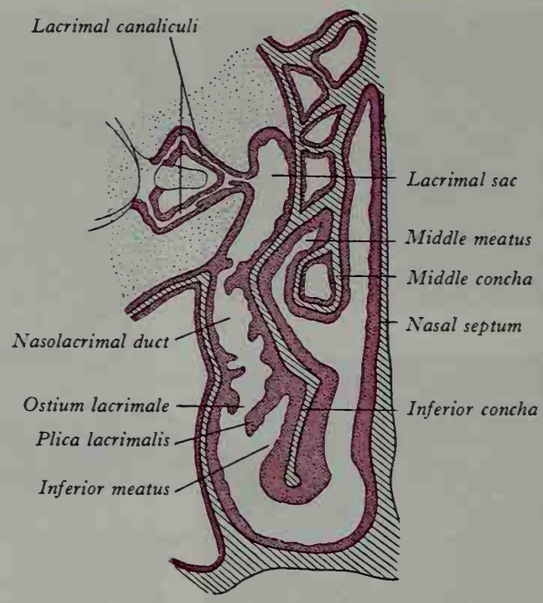
Many small accessory lacrimal glands are present in and near the conjunctival fornices; they are more numerous in the upper lid than in the lower. Their existence may explain why the conjunctiva does not dry up after extirpation of the lacrimal gland proper.

Structure of the lacrimal gland (7.277)



The lacrimal gland is a lobulated tubulo-acinar structure (p. 43), the secretory units or 'endpieces' of which consist of glandular cells resembling those of salivary glands (p. 1275). The secretion produced by the gland is a watery fluid (tears) with an electrolyte content similar to that of plasma, and containing an enzyme, lysozyme, which has bacteriocidal properties. The primary secretion is produced by the secretory units and is modified by the ducts into which they lead.

Although many of the earlier published accounts of the ultrastructure of the lacrimal gland were concerned with rodents and lagomorphs (Obayashi 1959; Scott and Pease 1959; Ichikawa and Nakajima 1962), that of the primate lacrimal gland has now received attention (Ruskell 1968, 1969; Egeberg and Jensen 1969; Orzalesi *et al.* 1971; Ruskell 1975; Hirsch-Hoffmann 1976, 1978).



The glandular cells of the secretory endpieces are divisible into two categories in the rhesus monkey (Ruskell 1968, 1969; Hirsch-Hoffmann 1976), and into either two (Ito and Shibaski 1964; Kühnel 1968), three (Ruskell 1975) or four (Hirsch-Hoffmann 1978) in man, depending on which ultrastructural and histochemical criteria are considered significant. In the rhesus monkey, glandular cells with uniformly electron-dense secretory granules have been described as *serous*, and those with paler heterogeneous granules as *mucous* (Ruskell 1968). In man, the histochemical and ultrastructural investigations of Ito and Shibasaki (1964) and of Kühnel (1968) led them to propose that there are two distinct types of glandular cell: one, designated the K cell, contains small, electron-lucent granules and has the staining characteristics of a mucous cell, while the other, termed the G cell, contains large, electron-dense granules and has the staining characteristics of a serous cell. In the opinion of Allen *et al.* (1972) and Ruskell (1975) the majority of the glandular cells are of the mucous type, a surprising finding in view of the patently serous nature of tears. Ruskell (1975) distinguishes three categories of glandular cell in man, arbitrarily grouping them into 'light', 'medium' and 'dark' classes according to the electron density of their secretory granules; acini contain either two or all three categories of glandular cell, together with lymphocytes and myoepitheliocytes. In contrast, Hirsch-Hoffmann (1978) groups the glandular cells of the human lacrimal gland into four categories, distinguishable by the number and electron density of their granules, together with the electron density of the surrounding cytoplasm; using this classification, the largest group

7.275 The posterior surfaces of the upper and lower eyelids of the left side. The orifices of the tarsal glands can be seen on the free margins of the lids.

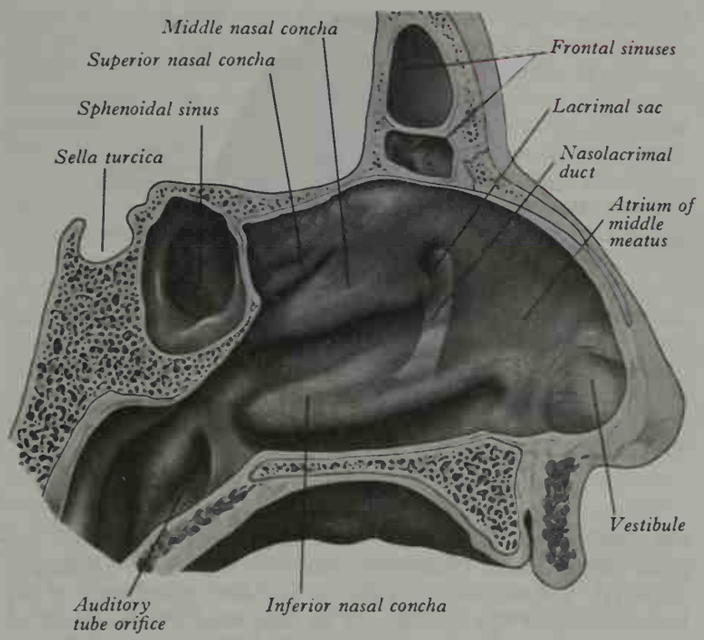
have pale cytoplasm and numerous granules of variable electron density, a second group have pale cytoplasm and fewer such granules, a third have darker cytoplasm and numerous electron-dense granules, while the remainder have dark cytoplasm and fewer uniformly electron-dense granules. Hirsch-Hoffmann has suggested that at least some of these categories may represent different stages in secretory activity of one or two distinct cell populations, an interpretation which has the support of other investigators (Egebert and Jensen 1969; Orzalesi *et al.* 1971).

The human lacrimal gland contains both interstitital (epilemmal, p. 1280) and parenchymal (hypolemmal, **8**.39B) nerve terminals (Ruskell 1975). The ultrastructure of most interstitial and all parenchymal nerve terminals is consistent with their being cholinergic (parasympathetic). A minority of the interstitial terminals contain small granular vesicles, suggesting that they are adrenergic (sympathetic). Of the glandular cells, only the 'dark' or 'serous' types have a parasympathetic, hypolemmal, innervation (Ruskell 1975), a situation similar to that found in the rhesus monkey (Ruskell 1969), where ultrastructural changes following parasympathectomy have led to the proposal that the serous cells are under direct parasympathetic control, mediated by the hypolemmal terminals, while the mucous cells may function autonomously. Parasympathetic hypolemmal terminals are also associated with the ducts and terminal tubules of the human lacrimal gland. Terminal tubules lie between the secretory endpieces and the ducts, and contain in their walls cells which are intermediate in form between glandular cells and duct cells (Ruskell 1975); these cells of the terminal tubules are smaller than the glandular cells and contain disproportionately fewer granules. Most of the nerve terminals of the ducts and terminal tubules lie adjacent to myoepitheliocytes, suggesting that in these regions their main function is to induce myoepitheliocyte contraction and thus assist in the flow of secretion. Curiously, the myoepitheliocytes associated with the secretory endpieces do not appear to have a direct, hypolemmal, innervation; Ruskell (1975) has suggested that they may be controlled by nearby interstitial parasympathetic terminals, which may only release transmitter in sufficient quantity to induce their contraction at times of hypersecretion. The role of the interstitial sympathetic terminals in the control of the human lacrimal gland remains to be determined, as do the ultrastructure and functions of its duct system.

7.277 A section through a part of the lacrimal gland, showing the acini lined by a layer of columnar cells; a few myoepithelial cells can be seen outside the basement membrane. Magnification about × 320.

The lacrimal canaliculi, one in each eyelid, are about 10 mm long; they commence at the *puncta lacrimalia* (7.272, 276, 278). The *superior canaliculus*, smaller and shorter than the inferior, at first ascends, and then bends at an acute angle, and passes medially and downwards to the lacrimal sac. The *inferior canaliculus* at first descends, and then runs almost horizontally to the lacrimal sac. At the angles they are dilated into *ampullae*. The mucous lining of the ducts is covered with stratified squamous epithelium, placed on a basement membrane; outside the latter there is a corium rich in elastic fibres (rendering the ducts easily dilatable during the passage of a probe) and a layer of striped muscular fibres which is continuous with the lacrimal part of the orbicularis oculi. At the base of each lacrimal papilla the muscular fibres are circularly arranged and form a kind of sphincter.

The lacrimal sac (7.274, 276, 278) is the upper blind end of the nasolacrimal duct, and is lodged in a fossa formed by the lacrimal bone, the frontal process of the maxilla and the lacrimal fascia. It measures about 12 mm in length, its upper, closed end is flattened from side to side, but its lower part is rounded and is continued into the nasolacrimal duct; the openings of the lacrimal canaliculi are situated in its lateral wall slightly below its upper end.



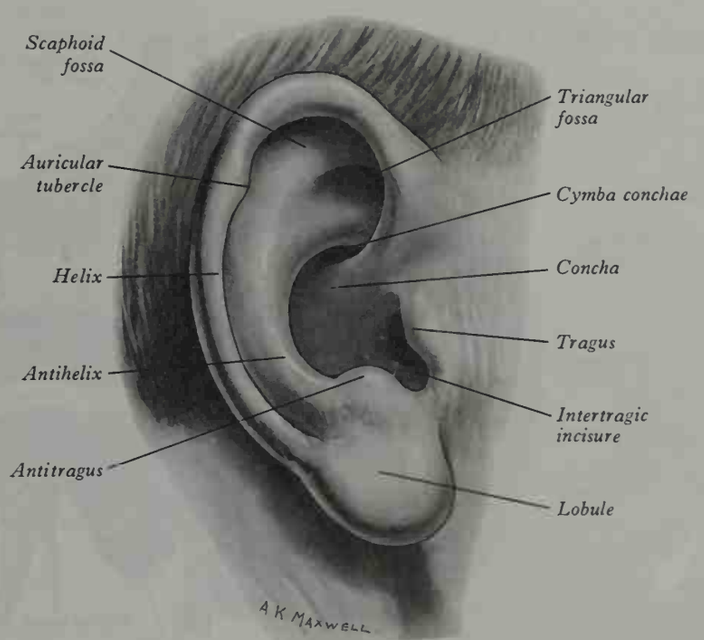
A layer of fascia, continuous with the periosteum of the orbit and named the *lacrimal fascia*, passes from the lacrimal crest of the

maxilla to the crest of the lacrimal bone, and forms the roof and lateral wall of the fossa in which the lacrimal sac is sited; between the fascia and the lacrimal sac there is a plexus of minute veins. The lacrimal fascia separates the sac from the medial palpebral ligament in front, and from the lacrimal part of the orbicularis oculi behind. The lower half of the fossa which lodges the lacrimal sac is related medially to the anterior part of the middle meatus of the nasal cavity; the upper half is related to the anterior ethmoidal sinuses. (In an examination of 100 skulls, Whitnall 1911, it was found that in 14 the anterior ethmoidal sinuses came into relation only in the posterior wall of the fossa; in 32 they reached as far as the suture between the lacrimal bone and the maxilla; while in 54 one large irregular sinus extended as far as the anterior lacrimal crest.)

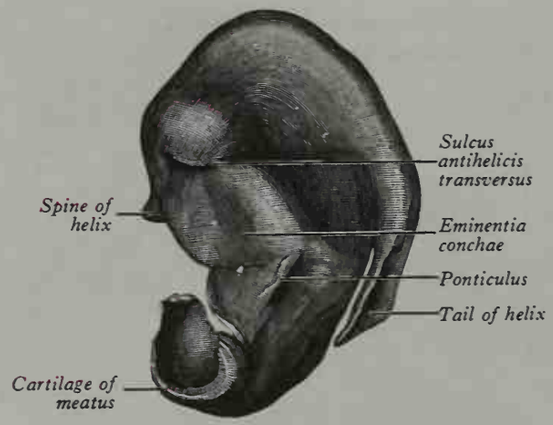
The lacrimal sac consists of a fibro-elastic coat, lined internally by mucous membrane; the latter is continuous through the lacrimal canaliculi, with the conjunctiva, and through the nasolacrimal duct with the mucous membrane of the nasal cavity.

The nasolacrimal duct (7.278, 279) is a membranous canal about 18 mm long, which extends from the lower part of the lacrimal sac to the anterior part of the inferior meatus of the nose, where it ends in a somewhat expanded orifice. A fold of the mucous membrane forms an imperfect valve just above the opening and is known as the *lacrimal fold*. The duct is contained in an osseous canal, formed by the maxilla, the lacrimal bone and the inferior nasal concha; it is narrower in the middle than at either end, and is directed downwards, backwards and a little laterally. The mucous lining of the lacrimal sac and nasolacrimal duct is covered with two layers of columnar epithelium which in places is ciliated. Around the duct there is a rich plexus of veins, forming an erectile tissue, engorgement of which may obstruct the duct.

Tear fluid secreted by the lacrimal gland enters the conjunctival sac at its superolateral angle and, under the influence of capillarity aided by blinking movements of the eyelids, is carried across the sac to the lacus lacrimalis mainly along the groove between the lower lid margin and the eyeball. From the lacus it passes into the lacrimal canaliculi. Contraction of the orbicularis oculi tends to press the puncta lacrimalia more firmly into the lacus, and capillary attraction serves to draw the lacrimal secretion into the lacrimal sac. The sudden dilatation of the lacrimal sac produced by the lacrimal part of the orbicularis oculi during blinking movements (p. 531) probably assists the process. Under normal conditions the secretion of the tarsal glands prevents the tears from overflowing the lid margins and also covers the capillary film of fluid on the front of the eyeball with a film of oil which delays evaporation (Mishima and Maurice 1961; Wolff 1976).



7.279 The left lateral wall of the nasal cavity viewed from the medial side. The lacrimal sac and the nasolacrimal duct of the left side have been projected on to the lateral wall of the nasal cavity to show their positions relative to the middle nasal concha, the middle meatus and the inferior concha.



THE AUDITORY AND VESTIBULAR APPARATUS

The peripheral auditory apparatus consists of the various parts of the ear, but including in particular, the *cochlear part* of its *membranous labyrinth*. Essentially, each ear is a *distance receptor* concerned with the collection, conduction, modification, amplification and parametric analysis of the complex sound waveforms which impinge on the head. The latter are converted into coded spatio-temporal patterns of nerve impulses in the afferent fibres of the cochlear part of the vestibulocochlear nerve, for onward transmission to the auditory pathways in the central nervous system (pp. 909, 911, 941, 976, 1021).

The molecular vibrations of the air which constitute the sound waves approaching the head vary according to: (1) the *direction* and *distance*, or *location* of the source of the waves; (2) the *intensity* or *energy content* of the waves; and (3) the relative purity of admixture of different *frequencies* which make up the wave train. The morphological and functional design of the ears is such that they are, within particular ranges of values, extremely sensitive to differences in frequency and intensity of the sound waves, and together, they are also very effective range and direction finders. Further, they are highly responsive to the *rate of change* of all of these sound wave parameters. The *frequency* of a sound wave is expressed as *cycles per second* or *Hertz* (c/s or Hz); it is subjectively appreciated as the *pitch* of the sound, and young adult ears are responsive to frequencies of about 20–20,000 Hz, although higher or lower values are not uncommon in very young ears. The *intensity* of a sound is expressed as the *quantity of energy* which is transmitted in *unit time* through a *unit area* which is perpendicular to the direction of wave propagation. The subjective appreciation of the intensity of a sound is related to the logarithm of its absolute intensity as defined above, but is also dependent upon the frequency of the sound. The human ear is most sensitive (i.e. has the lowest threshold) for sounds in the 1,500–3,000 Hz range, and above and below these levels the threshold rises sharply. For

7.280 The right auricle. Lateral aspect.

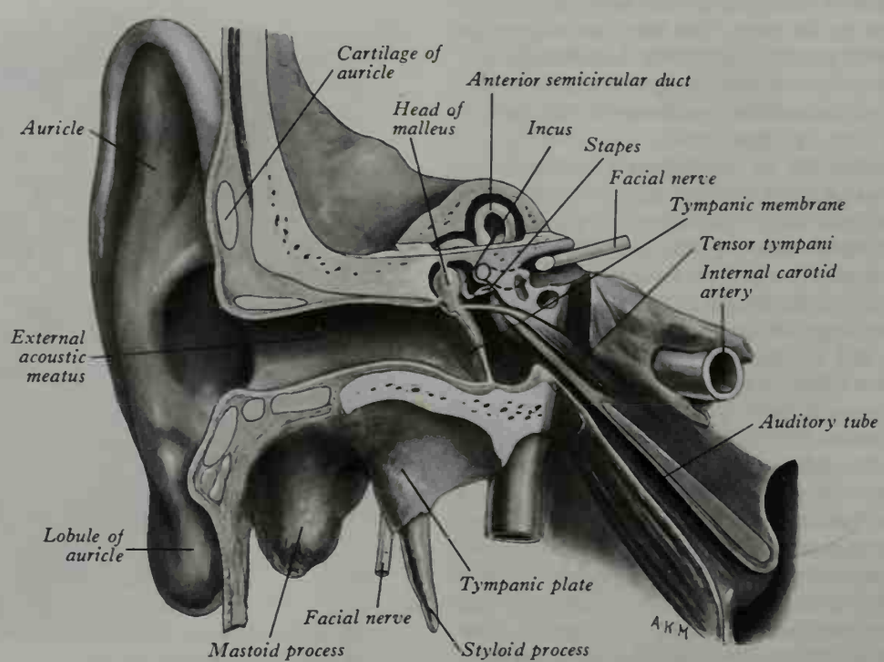
7.281 The medial surface of the right auricular cartilage.

example, about 10,000 times more energy is necessary for the equal perception of a sound of 15,000 Hz than is for a sound of 2,000 Hz. The sensitivity of the ear is indeed astounding; it has been calculated that sounds may be discerned which are due to pressure changes as small as 10^{-10} atmospheres—a change equivalent to ascending or descending 1/30,000 of an inch! Because of the great variation in the intensity level of sounds commonly encountered, the concept of the *decibel* has been introduced for convenience. A decibel is defined as 10 times the logarithm of the ratio of the intensity of the sound in question, to the intensity of an accepted reference level. A difference in intensity level of about one decibel is usually just perceptible by the human auditory system.

The *quality* of a sound depends upon the admixture of frequencies it contains. Musical sounds consist of one or more fundamental frequencies each with its mathematically related series of *overtones* or *harmonics*. Mixtures of unrelated or *irregular* frequencies are perceived simply as 'noise'. It is interesting to note that human speech has a considerable noise content. Moreover, some consonants involve somewhat higher frequencies than do vowels. It is due to these facts that speech is easily obscured by concomitant noise, and that, with increasing age and consequent reduction at the high frequency range of the human ear, the elderly find speech less easy to interpret.

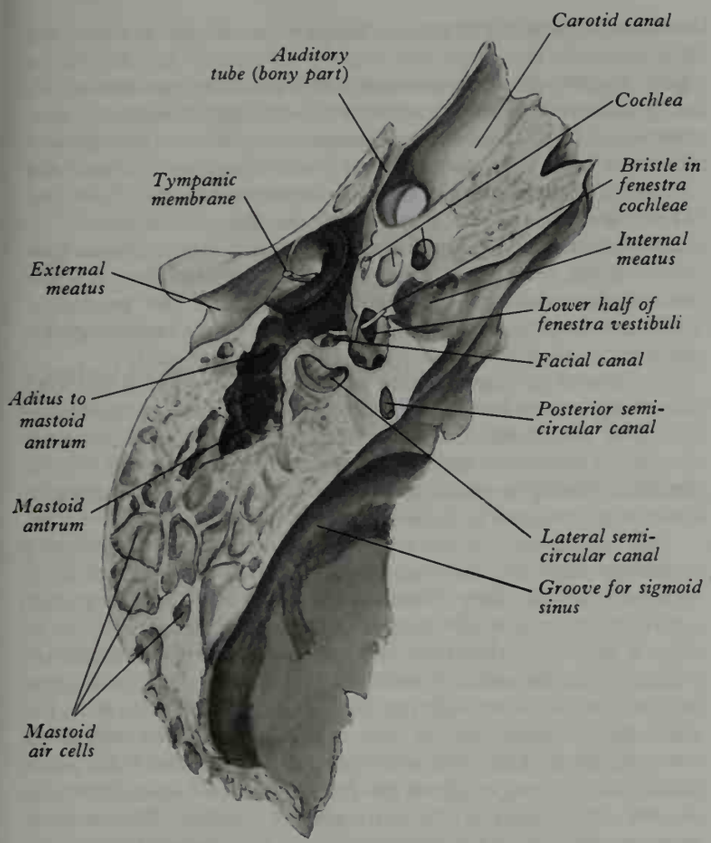
The elegant researches into the manner in which the ear operates as a peripheral analyser of frequency and intensity, and how intensity and phase differences impinging on the two ears are related to range and direction finding, can only receive the briefest mention in the present volume. For such details the reader should consult Rasmussen and Windle (1960); Whitfield (1967); De Reuck and Knight (1968); Wolstenholme and Knight (1970).

What follows is a structural account of the human ear, which on phylogenetic, developmental, structural and functional grounds, may be divided into *external*, *middle* and *internal* parts. Intimately associated structurally with the auditory cochlear part of the membranous labyrinth are the sensory receptors in specialized regions of the walls of the utricle and saccule, and in the ampullae of the semicircular ducts. The latter parts of the membranous labyrinth, their contained and surrounding fluids, the bony cavities in which they lie, and the vestibular part of the vestibulocochlear nerve, together constitute **the peripheral vestibular apparatus**. Its essential function is to provide the central nervous system with a constant flow of information concerning the static position of the head in space, or of its state of linear or angular acceleration or deceleration.



(The evolution of the auditory apparatus in land vertebrates has attracted an enormous literature, which cannot even be considered here. For a recent survey and a speculative reinterpretation of the evidence consult Lombard and Bolt 1977.)

The External Ear



The external ear consists of the *auricle*, or *pinna*, and the *external acoustic meatus*. The former projects from the side of the head and serves to collect the air vibrations which constitute the sound waves; the meatus leads inwards from the bottom of the auricle conducting the vibrations which are thereby transmitted to the tympanic membrane.

THE AURICLE

The lateral surface of the auricle (7.280) is irregularly concave, looks slightly anteriorly, and presents numerous eminences and depressions. The curved prominent rim of the auricle is called the *helix*; where it turns postero-inferiorly, a small *auricular tubercle* (of Darwin) is frequently seen; this tubercle is very evident about the sixth month of intrauterine life, when the whole auricle closely resembles that of some adult monkeys. Another curved prominence, parallel with and anterior to the posterior part of the helix, is the *antihelix*; this divides above into two crura, between which is a depressed *triangular fossa*. The narrow curved depression between the helix and the antihelix is the *scaphoid*

7.282 The external and middle regions of the right ear. Anterior aspect.

7.283 An oblique section through the left temporal bone viewed from above. (From a section prepared by Mr. P. F. Milling.) Compare with 7.285 and 7.288.

fossa; the antihelix partly encircles a deep, capacious cavity, the *concha of the auricle*, which is incompletely divided into two by the *crus* or anterior end of the helix. The part of the concha above the crus of the helix is the *cymba conchae*; it overlies, and through it can be felt, the supermeatal triangle of the temporal bone (pp. 302, 326), deep to which lies the mastoid antrum. Below the crus of the helix and in front of the concha, a small, curved flap, the *tragus*, projects posteriorly, partly overlapping the orifice of the meatus. Opposite the tragus, separated from it by the *intertragic incisure*, is a small tubercle, the *antitragus*. The *lobule* lies below the antitragus, and being composed of fibrous and adipose tissues it is soft, unlike the rest of the auricle which is firm and elastic.

The cranial surface of the auricle presents elevations which correspond to the depressions on its lateral surface, and after which they are named, e.g. eminentia conchae, eminentia fossae triangularis, etc.

In addition to acting as a collecting 'trumpet' for sound waves and channelling them into the relatively narrow meatus, the asymmetry of the pinnae and their variations in thickness, probably introduce *variable delay paths* in sound transmission which may be important in the efficient binaural (and also the cruder monaural) localization of sound sources.

In its **structure** the auricle is composed of a thin plate of elastic fibrocartilage, covered with skin, and connected with the surrounding parts by ligaments and muscles; it is continuous with the cartilaginous portion of the external acoustic meatus, and the latter is joined to the margins of the bony meatus by fibrous tissue.

The *skin of the auricle* is thin, closely adherent to the cartilage, and covered with fine hairs which are furnished with sebaceous glands; these glands are most numerous in the concha and scaphoid fossa. On the tragus and antitragus, and intertragic incisure the hairs are strong and numerous, especially in the male in old age. The skin of the auricle is continuous with that lining the external acoustic meatus.

The cartilage of the auricle (7.281) consists of a single piece of elastic fibrocartilage; upon its surface the eminences and depressions described above are found. It is absent from the lobule; it is deficient, also, between the tragus and beginning of the helix, the gap being filled up by dense fibrous tissue. Anteriorly, where the helix bends upwards, there is a small cartilaginous projection, the *spine of the helix*, while at its other extremity the cartilage is prolongated inferiorly as the *tail of the helix*; the latter is separated from the antihelix by the *fissura antitragohelicina*. The cranial surface of the cartilage shows the *eminentia conchae* and the *eminentia triangularis* which correspond to the depressions on the lateral surface. A transverse furrow, the *sulcus antihelicis transversus*, corresponding with the inferior crus of the antihelix on the lateral surface, separates the eminentia conchae from the eminentia triangularis. The eminentia conchae is crossed by an oblique ridge, the *ponticulus*, which gives attachment to the auricularis posterior. There are two fissures in the auricular cartilage, one behind the crus helicis and another in the tragus.

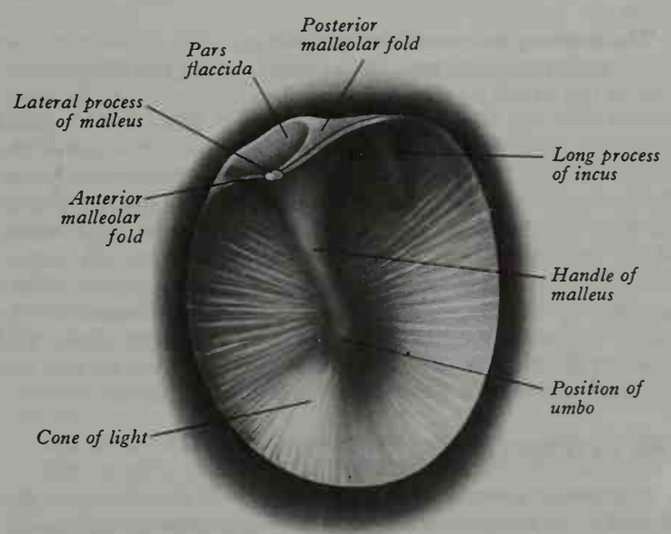
The ligaments of the auricle consist of two sets: (1) extrinsic, connecting it to the temporal bone; (2) intrinsic, connecting various parts of its cartilage together.

The *extrinsic ligaments* are two in number, anterior and posterior. The *anterior ligament* extends from the tragus and spine of the helix to the root of the zygomatic process of the temporal bone; the *posterior ligament* passes from the posterior surface of the concha to the lateral surface of the mastoid process.

The chief *intrinsic ligaments* are: (*a*) a strong fibrous band, stretching from the tragus to the helix, completing the meatus in front, and forming part of the boundary of the concha; and (*b*) a band between the antihelix and the tail of the helix. Other less prominent bands are found on the cranial surface of the auricle.

THE AURICULAR MUSCLES

These consist of two sets: *extrinsic*, which connect it with the skull and scalp and move the auricle as a whole; and *intrinsic*, which extend from one part of the auricle to another.



The extrinsic muscles are the auriculares anterior, superior et posterior.

The *auricularis anterior*, the smallest of the three, is thin, fan-shaped, and its fibres are pale and indistinct. It arises from the lateral edge of the epicranial aponeurosis, and its fibres converge to be inserted into the spine of the helix.

The *auricularis superior*, the largest of the three, is thin and fan-shaped. Its fibres arise from the epicranial aponeurosis, and converge to be inserted by a thin, flattened tendon into the upper part of the cranial surface of the auricle.

The *auricularis posterior* consists of two or three fleshy fasciculi, which arise by short aponeurotic fibres from the mastoid portion of the temporal bone, and are inserted into the ponticulus on the eminentia conchae.

Nerve supply. The auriculares anterior et superior are

7.284 The left tympanic membrane, external aspect as seen through a speculum.

supplied by the temporal branches, and the auricularis posterior by the posterior auricular branch of the facial nerve.

Actions. In man, these muscles have very little obvious action; the auricularis anterior draws the auricle forwards and upwards; the auricularis superior raises it slightly; and the auricularis posterior draws it backwards. Nevertheless, despite the absence of marked auricular movement, auditory stimuli evoke patterned responses from these small muscles; electromyographic recording of the latter form the basis of the 'crossed acoustic response' of investigative clinical neurology.

The intrinsic muscles are helicis major and minor, tragicus, antitragicus, transversus auriculae and the obliquus auriculae. Their effect in modifying the shape of the pinna is minimal or absent in most human ears. Occasional individuals can, however, modify the shape and position of their external ears to a much greater extent.

The *helicis major* is a narrow vertical band situated upon the anterior margin of the helix. It arises from the spine of the helix, and is inserted into the anterior border of the helix, where the latter is about to curve backwards.

The *helicis minor* is an oblique fasciculus, covering the crus helicis.

The *tragicus* is a short, flattened vertical band on the lateral surface of the tragus.

The *antitragicus* arises from the outer part of the antitragus, and is inserted into the tail of the helix and antihelix.

The *transversus auriculae* is placed on the cranial surface of the auricle. It consists of scattered fibres, partly tendinous and partly muscular, extending from the eminentia conchae to the eminentia scaphae.

The *obliquus auriculae*, also on the cranial surface, consists of a few fibres extending from the upper and posterior parts of the eminentia conchae to the eminentia triangularis.

The nerve supply to the intrinsic muscles on the lateral surface is provided by the temporal branches of the facial nerve, to the intrinsic muscles on the cranial surface by the posterior auricular branch of the same nerve.

The arteries of the auricle are: (*a*) the posterior auricular branch of the external carotid artery, which supplies three or four branches to its cranial surface; twigs from these reach the lateral surface, some by passing through the fissures of the auricular cartilage, and others by turning round the margin of the helix; (*b*) the anterior auricular branches of the superficial temporal artery, which are distributed to the lateral surface; (*c*) a branch from the occipital artery.

The veins of the auricle accompany their corresponding arteries. Arteriovenous anastomoses are numerous in the skin of the auricle.

The lymphatics of the auricle drain into (*a*) the parotid lymph nodes, especially the node in front of the tragus; (*b*) the upper deep cervical lymph nodes; and (*c*) the mastoid lymph nodes.

The sensory nerves of the auricle are: (*a*) the great auricular nerve, which supplies most of the cranial surface and the posterior part of the lateral surface (helix, antihelix, lobule); (*b*) the lesser occipital nerve, which supplies the upper part of the cranial surface; (*c*) the auricular branch of the vagus, which supplies the concavity of the concha and the posterior part of the eminentia; (*d*) the auriculotemporal nerve, which supplies the tragus, the crus of the helix and the adjacent part of the helix; (*e*) the facial nerve, which in company with the auricular branch of the vagus, probably supplies small areas of skin on both aspects of the auricle—in the conchal depression and over its eminence. The details of this cutaneous innervation by the facial nerve, and whether facial fibres also reach the external acoustic meatus and tympanic membrane, however, remain undetermined.

THE EXTERNAL ACOUSTIC MEATUS

The external acoustic meatus (7.282, 283) extends from the concha to the tympanic membrane. Its length, measured from the bottom of the concha, is approximately 2·5 cm (measured from the tragus it is about 4 cm long). It consists of two structurally different parts: the lateral third is *cartilaginous*, and the medial two-thirds *osseous*. It forms an S-shaped curve, and is directed at first medially, anteriorly and slightly superiorly (*pars externa*); it then passes medially, posteriorly and superiorly (*pars media*), and lastly is carried medially, anteriorly, and slightly inferiorly (*pars interna*). The canal is oval in transverse section, with its greatest diameter obliquely placed with a postero-inferior inclination at the external orifice, but it is nearly horizontal at the medial end. There are two constrictions, one near the medial end of the cartilaginous part, and another, the *isthmus*, in the osseous part, about 2 cm from the bottom of the concha. The tympanic membrane, which closes the medial end of the meatus, is obliquely directed; in consequence the floor and anterior wall of the meatus are longer than its roof and posterior wall.

The lateral *cartilaginous part* of the meatus is about 8 mm long; it is continuous with the auricular cartilage and is fixed by fibrous tissue to the circumference of the medial osseous part of the meatus. The meatal cartilage is deficient posterosuperiorly, the deficiency being occupied by a sheet of collagen; two or three deep fissures are present in the anterior part of the cartilage.

The *osseous part* of the meatus is about 16 mm long, and is narrower than the cartilaginous part. It is directed medially, anteriorly and slightly inferiorly, forming in its course a slight curve the convexity of which is posterosuperior in position. Its medial end is smaller than the lateral end, and it is obliquely placed, with the anterior wall projecting medially about 4 mm beyond the posterior wall; this end is marked, except at its upper part, by a narrow groove, the *tympanic sulcus*, to which the circumference of the tympanic membrane is attached. Its lateral end is dilated, and rough in the greater part of its circumference for the attachment of the cartilaginous meatus. The anterior, inferior and most of the posterior parts of the osseous meatus are formed by the tympanic element of the temporal bone, which, in the fetus, exists only as a *tympanic ring* (p. 330). The postero-superior region of the osseous part is formed by the squama of the temporal bone.

The skin which envelops the auricle is continued into the external acoustic meatus and covers the outer surface of the tympanic membrane. It is thin, shows no dermal papillae on section, and is closely adherent to the cartilaginous and osseous parts of the tube; hence inflammatory conditions are extremely painful owing to the increased tension in these tissues. In the thick subcutaneous tissue of the cartilagionous part of the meatus there are numerous *ceruminous glands*, which secrete the ear wax or *cerumen*; their coiled tubular structure resembles that of the sweat glands (p. 1225). When active the cells of the secretory part are columnar, but when quiescent they are cuboidal; they are clothed externally by myoepithelial cells. The ducts of the ceruminous glands open either on to the general epithelial surface or into a neighbouring sebaceous gland of a hair follicle. The cerumen prevents maceration of the meatal lining by trapped water, and may discourage epithelial attacks by insects. Over production, or prolonged retention of ear wax may, however, completely block the meatus, or, when in contact with the tympanic membrane, embarrass its vibratory responses. The ceruminous glands, as well as hair follicles, are largely limited to the cartilaginous part of the meatus, but a few small glands and fine hairs are found in the roof of the lateral part of the osseous meatus.

In addition to the protective value of the cerumen, and the opposition to the entry of insects and foreign bodies afforded by the meatal hairs, the warm humid environment provided by the relatively enclosed meatal air is essential for the effective mechanical responses of the tympanic membrane.

Relations of the Meatus

The condyloid process of the mandible is anterior to the meatus, partially separated from its cartilaginous part by a small part of the parotid gland. A blow on the chin may cause the condyle to break into the meatus. The movements of the mandible influence to some extent the lumen of the cartilaginous part. Superior to the osseous part is the middle cranial fossa; behind it are the mastoid air cells, separated from the meatus by a thin layer of bone. The deepest part of the meatus is related superiorly to the epitympanic recess of the tympanic cavity, and posterosuperiorly to the mastoid antrum, the bone separating the antrum being only 1–2

mm thick, so that it can be opened surgically by this 'transmeatal approach'.

The meatal *arteries* are the posterior auricular branch of the external carotid, the deep auricular branch of the maxillary, and auricular branches of the superficial temporal. The *veins* drain into the external jugular and maxillary veins and the pterygoid plexus. The *lymphatics* drain with those of the auricle (p. 786).

The *nerves* supplying the meatus are derived from the auriculotemporal branch of the mandibular nerve, which supplies the anterior and upper walls of the meatus, and the auricular branch of the vagus nerve which supplies the posterior and inferior walls (*see* also below).

Clinical Examination of the Meatus

The external acoustic meatus can be examined most satisfactorily by light reflected down a funnel-shaped speculum, when the greater part of the canal and tympanic membrane can be viewed. In using this instrument, the auricle should be drawn upwards, backwards and a little laterally, to render the meatus as straight as possible.

At the point of junction of the osseous and cartilaginous parts of the meatus an obtuse angle projects into the tube antero-inferiorly; this produces a constriction which is important when attempting to remove foreign bodies lodged in the meatus. The shortness of the meatus in children should be remembered when an aural speculum is used, because of the risk of injuring the tympanic membrane; indeed, even in the adult, the speculum should not be introduced beyond the constriction which marks the junction of the osseous and cartilaginous parts. Immediately anterolateral to the membrane there is a marked depression, on the floor of the meatus, bounded laterally by a prominent ridge; here foreign bodies may become impacted. By means of the speculum, combined with traction of the auricle upwards and backwards, the greater part of the tympanic membrane is rendered visible (7.284). It is a pearly-grey, slightly glistening membrane, which in the adult is placed obliquely, forming an acute angle of about 55° with the floor of the meatus, while with the roof it forms an obtuse angle. At birth it is more horizontal, situated in almost the same plane as the base of the skull.

A reddish-yellow streak can be seen about midway between the anterior and posterior margins of the membrane which extends from the centre obliquely upwards and forwards; this is due to the handle of the malleus, attached internally to the membrane. At the upper part of this streak, close to the roof of the meatus, a little white, round prominence is clearly seen; this is the lateral or short process of the malleus, projecting against the membrane. The tympanic membrane does not present a plane surface; on the contrary, its centre is drawn inwards, reflecting its connexion with the handle of the malleus, the centre of the concavity corresponding to the *umbo* (p. 1194) on the deep surface of the membrane. A bright reflected 'cone of light', is seen in the antero-inferior quadrant of the membrane. Anterior and posterior to the short process of the malleus, the variably prominent *anterior* and *posterior malleolar folds* are seen, with the flaccid part of the tympanic membrane (p. 1194) between them. Posterior and parallel to the upper part of the handle of the malleus, the long process of the incus is often seen as a whitish streak; sometimes it can be seen to end below near a round spot which is the head of the stapes.

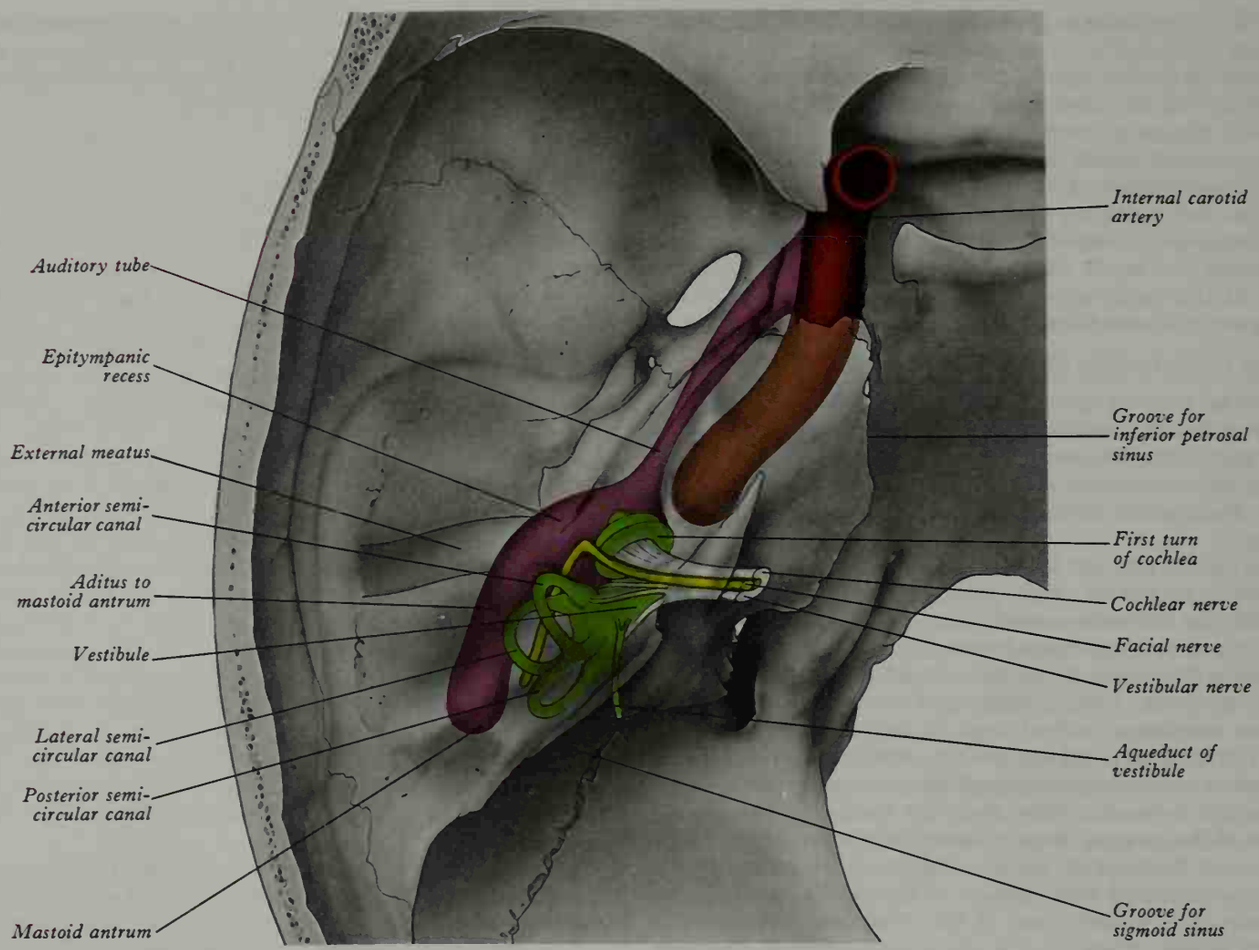
Applied Anatomy. Malformations such as imperfect development of the external parts, supernumerary auricle, preauricular cysts, fistulae and sinuses, or absence of the meatus, are occasionally met with. In the child up to the age of four or five years there is a gap in the antero-inferior wall of the osseous part of the meatus, the *foramen of Huschke* (pp. 331, 348), which is filled by membrane; it may persist in the adult.

The connexions of the nerves of the meatus explain the occurrence of reflex coughing and sneezing, from implication of the vagus, when there exists any source of irritation in the meatus, and the vomiting which may follow syringing the ears of children, and the occasional heart failure similarly induced in elderly people. Probably the association of earache with toothache or with cancer of the tongue is due to involvement of the mandibular branch of the trigeminal nerve, which supplies the teeth and the tongue also. The upper half of the tympanic membrane is much more vascular than the lower half: for this reason, and also to avoid the chorda tympani nerve and ossicles, incisions through the membrane should be postero-inferior.

The Tympanic Cavity

The middle ear or tympanic cavity (7.283, 285, 287, 288) is an irregular, laterally compressed space within the temporal bone. It is lined with mucoperiosteum (p. 1199) and filled with air, which is conveyed to it from the nasal part of the pharynx through the auditory tube. It contains a chain of movable bones, which connect its lateral to its medial wall and transmit the vibrations of the tympanic membrane across the cavity to the internal ear.

The essential functional significance of the tympanic cavity with its tympanic membrane and associated chain of ossicles, is the efficient transfer of energy from the relatively weak vibrations in the elastic, compressible medium *air* in the external acoustic meatus, to overcome the inertia in the virtually incompressible aqueous *fluids* which surround the delicate membrane-supported receptors of the internal ear. Thus the mechanical coupling between the two systems must be such that their resistances to deformation or 'flow', that is, their *impedances*, are matched as closely as possible. To this end the high-amplitude, low-force per unit area, vibrations of the air are communicated to the *tympanic membrane*, which, in surface area exceeds that of the *footplate of the stapes* (in contact with the perilymph) by 15 to 20 times. In this manner, the *force per unit area* generated by the footplate is increased by a similar amount, whilst its *amplitude* of vibration is little changed.



Protective mechanisms are also incorporated in the design of the tympanic cavity. These include the connexion via the auditory (pharyngotympanic) tube, whereby pressure is equalized on the two sides of the delicate tympanic membrane, and the protection afforded by the shape of the articulations between the ossicles, and the reflex contractions of the stapedius and tensor tympani muscles, which prevent damage due to sudden and potentially excessive excursions of the ossicles.

The tympanic cavity consists of two parts: the *tympanic cavity proper*, opposite the tympanic membrane, and the *epitympanic recess*, above the level of the membrane; the latter contains the upper half of the malleus and the greater part of the incus. Including the epitympanic recess, the vertical and antero-posterior diameters of the cavity are each about 15 mm. The transverse diameter measures about 6 mm above and 4 mm below; opposite the centre of the tympanic membrane it is only about 2 mm. The tympanic cavity is bounded *laterally* by the tympanic membrane; *medially*, by the lateral wall of the internal ear; it communicates, posteriorly, with the mastoid antrum and through it with the mastoid air cells, and anteriorly with the auditory tube (7.285).

THE BOUNDARIES OF THE TYMPANIC CAVITY

The roof of the tympanic cavity (7.286) is a thin plate of compact bone, the *tegmen tympani*, which separates the cranial and tympanic cavities, and forms the greater part of the anterior surface of the petrous part of the temporal bone; it is prolonged posteriorly as the roof of the mastoid antrum, and anteriorly to cover the canal for the tensor tympani. In the young, the unossified petrosquamosal suture (p. 329) may allow direct spread of infection from the tympanic cavity to the cerebral meninges. In the adult, veins from the tympanic cavity pass through this suture to the superior petrosal sinus, or the petrosquamous sinus if present (p. 746), and may transmit infection to the intracranial sinuses.

The floor of the tympanic cavity is narrow, and consists of a thin, convex plate of bone which separates the cavity from the superior bulb of the internal jugular vein (7.288); in places the bone may be deficient, and then the cavity is separated from the vein by mucous membrane and fibrous tissue only. In the floor of the tympanic cavity, near the medial wall, there is a small aperture for the passage of the tympanic branch of the glossopharyngeal

7.285 Scheme showing the parts of the left auditory apparatus as if viewed through a semi-transparent temporal bone. Compare with 7.283 and 7.288.

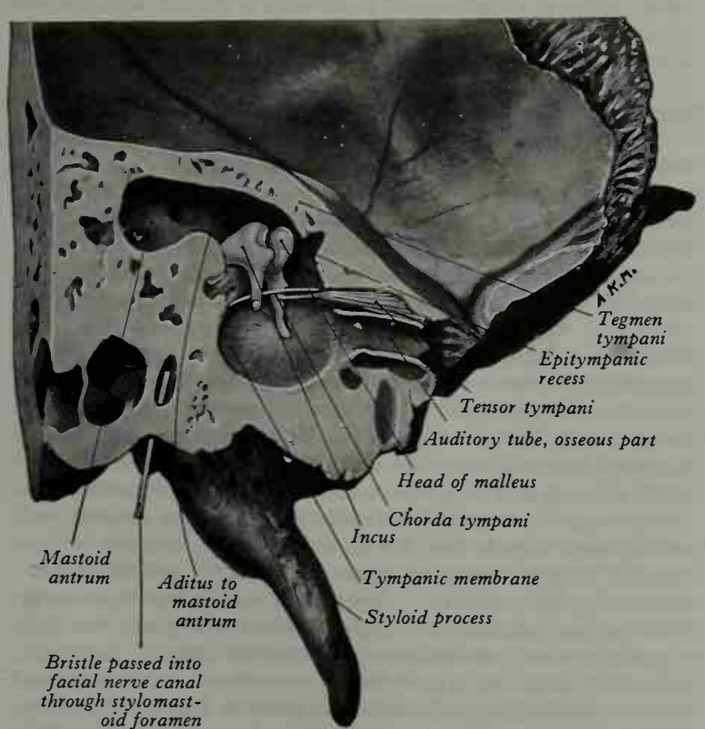
nerve. The floor is sometimes thick and may contain some accessory mastoid air cells.

The lateral wall of the tympanic cavity (7.286, 287) is formed mainly by the tympanic membrane, but partly also by the ring of bone to which this membrane is attached. There is a deficiency or notch in the upper part of the ring, close to which are three small apertures—the anterior and posterior canaliculi for the chorda tympani nerve, and the petrotympanic fissure.

The *posterior canaliculus for the chorda tympani nerve* is situated in the angle of junction between the posterior and lateral walls of the tympanic cavity immediately behind the tympanic membrane and on a level with the upper end of the handle of the malleus; it leads into a minute canal, which descends in front of the canal for the facial nerve, and ends in that canal about 6 mm above the stylomastoid foramen. Through it the chorda tympani nerve and a branch of the stylomastoid artery enter the tympanic cavity.

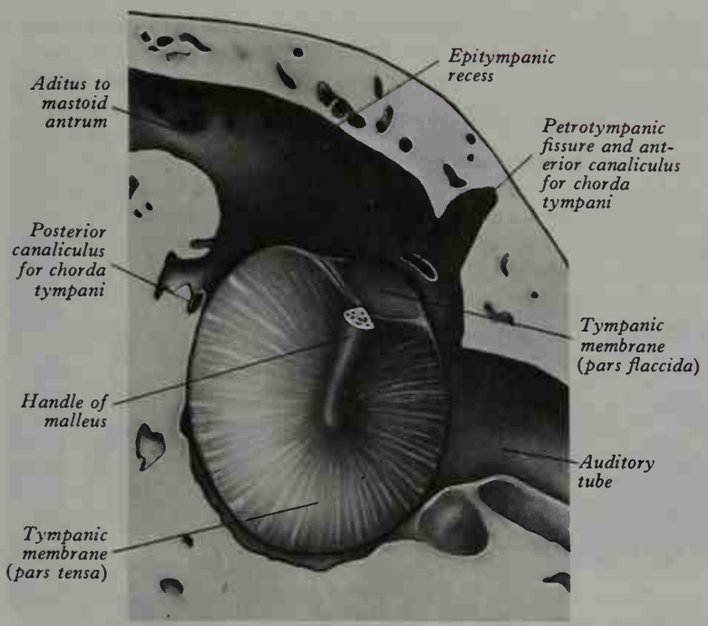
The *petrotympanic fissure* opens just above and in front of the ring of bone into which the tympanic membrane is inserted; in this situation it is a mere slit about 2 mm in length. It lodges the anterior process and anterior ligament of the malleus, and transmits to the tympanic cavity the anterior tympanic branch of the maxillary artery.

The *anterior canaliculus for the chorda tympani nerve* is placed at the medial end of the petrotympanic fissure; through it the chorda tympani nerve leaves the tympanic cavity.



The tympanic membrane (7.286, 287) separates the tympanic cavity from the external acoustic meatus. It is thin and semi-transparent, nearly oval in form, somewhat broader above than below, and very obliquely placed, forming an angle of about 55° with the floor of the meatus. Its longest diameter is downwards and forwards, and measures from 9 to 10 mm; its shortest diameter from 8 to 9 mm. The greater part of its circumference is thickened, and forms a *fibrocartilaginous ring* which is attached to the *tympanic sulcus* at the medial end of the meatus. This sulcus is deficient superiorly, and from the ends of the notch two bands, the *anterior* and *posterior malleolar folds*, are prolonged to the lateral process of the malleus. The small, somewhat triangular part of the membrane situated above these folds is lax and thin, and is named the *pars flaccida*; a small perforation is sometimes present. The remainder of the membrane is taut and is the *pars tensa*. The handle of the malleus is firmly attached to the inner surface of the tympanic membrane as far as its centre, which projects towards the tympanic cavity; the inner surface of the membrane is thus convex, and the point of greatest convexity is named the *umbo*. Although the membrane as a whole is convex on its inner surface, its radiating fibres (*vide infra*) are curved with their concavities directed inwards.

Structurally, the tympanic membrane is composed of three strata: an outer (cuticular), an intermediate (fibrous), and an inner (mucous). The *cuticular layer* is derived from the thin skin which lines the external acoustic meatus, and consists of stratified epithelium. It is hairless, and the subepithelial connective tissue, which carries a number of small blood vessels, does not develop dermal papillae except for a few rudimentary ones around the periphery of the membrane. The *fibrous stratum* consists of two layers: a superficial layer of radiate fibres which diverge from the handle of the malleus, and a deep layer of circular fibres, which are plentiful around the circumference, but sparse and scattered near the centre of the membrane. Near the centre and around the margins of the membrane fine meshes of elastic fibres are said to be interspersed between the collagen fibres (but see below). The *mucous layer* is a part of the mucous membrane of the tympanic cavity; it is thickest towards the upper part of the membrane, and may be covered, it has been claimed, by a layer of ciliated columnar epithelial cells. However, the ciliated epithelium may be present only in patches, or entirely absent, when it is replaced by a low cuboidal or simple squamous epithelium.



The foregoing traditional account of tympanic membrane

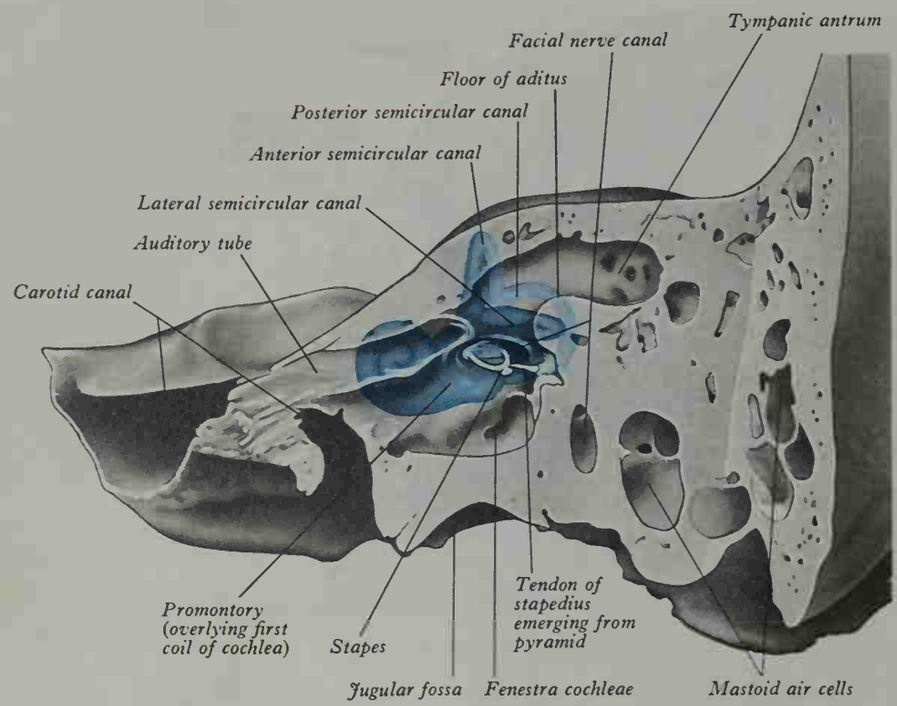
structure, based on light microscopy, may well have needed a substantial revision, if the detailed ultrastructural and chemical studies carried out on the membrane of the guinea-pig (Johnson *et al.* 1968) also applied to the human membrane. In this mammal the external epithelium is approximately ten cells thick and consists of two zones, the superficial one consisting of non-nucleated squames, the deep zone resembling, in many respects, the stratum spinosum of the skin with numerous desmosomes and tight junctions between adjacent cells; the deepest cells lie on a continuous basal lamina, but lack epithelial pegs and hemidesmosomes. The internal (mucous) epithelium consists of a single layer of extremely flattened cells, with overlapping or interdigitating boundaries, which carry desmosomes and tight junctions between adjacent cells. Their cytoplasm contains only a sparse population of the usual organelles, micropinocytotic vesicles are few, and the free surfaces of these apparently metabolically inert cells bear occasional irregular microvilli and are coated with an amorphous electron-dense material. Ciliated columnar cells are not present. Most interestingly, the intermediate (fibrous) layer consists of filaments about 10μm in diameter, with what are apparently cross-bridges between adjacent filaments at 25 nm intervals. The filaments are disposed in outer radial, and inner non-radial zones, the former more profuse, and in neither situation do their ultrastructural appearance resemble collagen or elastin. In their amino acid composition, also, the filaments are quite distinctive, and it is proposed that they consist of a protein specialized for the unique function of the tympanic membrane. Recent studies (McMinn and Taylor 1978), however, on the development of the fibrillar component of the tympanic membrane in both guinea-pig and human embryos and fetuses have shed further light on this matter. The findings on the guinea-pig mentioned above were confirmed. In human fetuses, in contrast, small groups of true collagen fibrils were apparent by eleven weeks *in utero*, together with small bundles of elastic microfibrils. Later specimens showed increasing numbers of typically cross-banded collagen fibrils and the development of an amorphous elastin component in association with the microfibrils.

Large fibroblasts lie between the outer radial fibres and the basal lamina of the external epithelium, whilst blood capillaries and their basement membranes lie immediately deep to the basal lamina of the internal epithelium. In the flaccid part of the tympanic membrane the fibrous stratum is replaced by loose connective tissue.

7.286 An oblique vertical section through the left temporal bone, to show the lateral wall of the middle ear and the mastoid antrum.

7.287 The lateral wall of the left tympanic cavity.

The *arteries* of the tympanic membrane are derived from the deep auricular branch of the maxillary artery, beneath the cuticular stratum, and from the stylomastoid branch of the occipital or posterior auricular artery, and tympanic branch of the maxillary artery, which are distributed in the mucous surface. The *superficial veins* open into the external jugular vein; those in the *deep surface* drain partly into the transverse sinus and veins of the dura mater and partly into the plexus of veins of the auditory tube. The *nerve supply* of the tympanic membrane is from the auriculotemporal branch of the mandibular nerve, the auricular branch of the vagus nerve, from the tympanic branch of the glossopharyngeal nerve, and possibly from the facial nerve.



The medial wall of the tympanic cavity (7.288, 289) is also the lateral wall of the internal ear. Its structural features are the promontory, the fenestra vestibuli, the fenestra cochleae and the prominence caused by the underlying facial nerve canal.

The *promontory* is a rounded elevation furrowed by small grooves which contain the nerves of the tympanic plexus. It overlies the lateral projection of the basal turn of the cochlea. A minute spicule of bone frequently connects the promontory to the pyramidal eminence on the posterior wall. In front of the promontory the apex of the cochlea is closely related to the medial wall of the tympanum (7.282, 288). A depression behind the promontory, the *sinus tympani*, indicates the position of the ampulla of the posterior semicircular canal.

The *fenestra vestibuli* (*f. ovalis*) is a reniform opening, posterosuperior to the promontory, which connects the tympanic cavity to the vestibule of the internal ear; its long diameter is horizontal, and its convex border is directed superiorly. In life it is occupied by the base of the stapes, the circumference of which is fixed to the margin of the fenestra by an annular ligament.

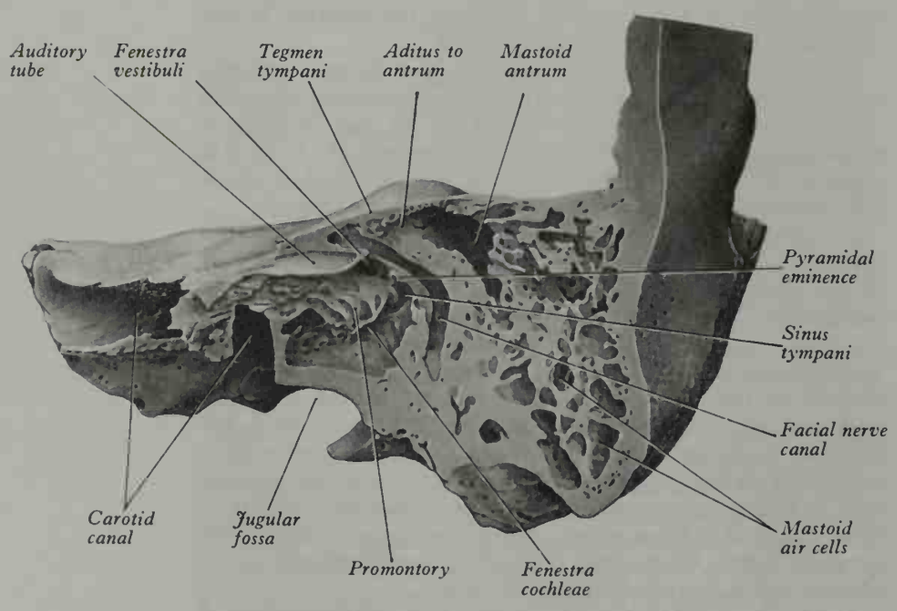
The *fenestra cochleae* (*f. rotunda*) is below and a little behind the fenestra vestibuli, from which it is separated by the posterior part of the promontory. It lies completely under cover of the overhanging edge of the promontory in a deep hollow or niche. It is placed very obliquely, and, in the macerated bone, opens upwards and forwards from the tympanic cavity into the scala tympani of the cochlea. In life it is closed by the *secondary tympanic membrane*, which is somewhat concave towards the tympanic cavity and convex towards the cochlea, the membrane being bent so that its posterosuperior one-third forms an angle with its antero-inferior two-thirds. This membrane consists of three layers: an external, derived from the mucous lining of the tympanic cavity; an internal, from the lining membrane of the cochlea; and an intermediate, fibrous, layer.

The *prominence of the facial nerve canal* indicates the position of the upper part of the bony canal in which the facial nerve is

7.288 An oblique section through the left temporal bone, to show the medial wall of the middle ear. The cochlea and the semicircular canals are in blue. Note the relationship of the first coil of the cochlea to the promontory, and the closeness of the facial nerve canal and the lateral semicircular canal to the medial wall of the aditus.

contained; this canal, the lateral wall of which may be partly deficient, traverses the medial wall of the tympanic cavity from before backwards, immediately above the fenestra vestibuli, and then curves downwards in the posterior wall of the cavity.

The posterior wall of the tympanic cavity (7.288) is wider above than below, and its main structural features are the entrance to the mastoid antrum, the pyramid, and the fossa incudis.



The *aditus to the mastoid antrum* is a large irregular aperture, which leads backwards from the epitympanic recess into the upper part of an air sinus, the *mastoid antrum*. On the medial wall of the aditus to the antrum there is a rounded eminence, situated above and behind the prominence of the facial nerve canal; it corresponds with the position of the underlying lateral semicircular canal.

The *pyramidal eminence* is situated immediately behind the fenestra vestibuli, and in front of the vertical portion of the facial nerve canal; it is hollow, and contains the stapedius; its summit projects forwards towards the fenestra vestibuli, and is pierced by a small aperture which transmits the tendon of the muscle. The cavity in the pyramidal eminence is prolonged downwards and backwards in front of the facial nerve canal, and communicates with the latter by an aperture which transmits a twig from the facial nerve to the stapedius. (See also p. 1072.)

The *fossa incudis* is a small depression in the lower and posterior part of the epitympanic recess; it contains the short process of the incus, which is fixed to the fossa by ligamentous fibres.

The mastoid antrum (7.283, 285, 286, 287, 288, 289) is an air sinus in the petrous part of the temporal bone, and its topographical relations are of considerable surgical importance. In the upper part of its *anterior wall* is an opening, the aditus to the mastoid antrum, which leads forwards into the epitympanic recess; medially, the aditus is related to the lateral semicircular canal. The *medial wall* of the antrum itself is related to the posterior semicircular canal (7.285). *Posteriorly* the antrum is closely related to the sigmoid sinus; some of the mastoid air cells may intervene between them. The *roof* of the antrum, formed by the tegmen tympani, is related to the middle cranial fossa and the temporal lobe of the brain. The floor has a number of apertures through which the antrum communicates with the mastoid air cells. *Antero-inferiorly*, the antrum is related to the descending part of the canal for the facial nerve. The *lateral wall* of the antrum, the usual surgical approach to the cavity, is formed by the postmeatal process of the squamous part of the temporal bone. This wall is only 2 mm thick at birth, but increases in thickness at the rate of approximately 1 mm a year, attaining a final thickness of 12–15 mm. The lateral wall of the antrum in the adult corresponds to the *suprameatal triangle* on the outer surface of the skull (pp. 302, 326); it lies beneath and can be felt through the cymba conchae (p. 1191). The superior side of the triangle, formed by the supramastoid crest, is on a level with the floor of the middle cranial fossa; the antero-inferior side, formed by the posterosuperior margin of the orifice of the external acoustic meatus, lies approximately along the course of the descending part of the canal for the facial nerve; and the posterior side, formed by a vertical tangent to the posterior margin of the meatal orifice, lies just in front of the course of the sigmoid sinus. In the adult, the mastoid antrum has a capacity of about 1 ml, each of its diameters being about 10 mm. At birth, unlike the other cranial air sinuses, it is well developed and almost the same size as in the adult; it lies at a higher level in relation to the external acoustic meatus than in the adult. In the very young child, owing to the thinness of the lateral wall of the antrum and the absence or feeble development of the mastoid process, the stylomastoid foramen and the emerging facial nerve are very superficially situated.

The mastoid air cells (7.283, 288, 289) vary considerably in number, form and size in different individuals. In general, they are a series of intercommunicating cavities, lined by mucous membrane, with a flattened squamous non-ciliated epithelium, continuous with that of the mastoid antrum and tympanic cavity. In some cases they extend throughout the mastoid process, even to its tip, and some of the cells may be separated from the sigmoid sinus and the posterior cranial fossa by extremely thin bone, which occasionally shows deficiencies. Some of the cells may lie superficial to, and even behind the sigmoid sinus, and others may lie in the posterior wall of the descending part of the canal for the facial nerve. Those contained in the squamous part of the temporal bone may sometimes be separated from the deeper cells in the petrous part by a plate of bone lying in the situation of the squamomastoid suture of early life. In other cases, the cells only extend very slightly into the mastoid process, and the process consists largely either of dense bone or of cancellous bone containing bone marrow. Varieties of mastoid process occur, with varying mixtures of the above structures (3.95), but three types of mastoid are commonly described, namely, *pneumatic*, containing many air cells, *sclerotic*, with few or no air cells, and *mixed*, containing air cells and bone marrow. Pannier (1970) has proposed a somewhat more elaborate categorization dependent upon the degree of pneumatization and the relation of air cells to the lateral sinus. In his series (100 mastoid processes) the cells

7.289 An oblique section through the left temporal bone, showing the medial wall of the middle ear. Compare with 7.288.

most distant from the antrum were the largest. The cells may extend beyond the confines of the mastoid process. They may extend for some distance into the squamous part of the temporal bone above the supramastoid crest, and also into the posterior root of the zygoma. Others may extend forwards into the roof of the osseous part of the external acoustic meatus, lying immediately below the middle cranial fossa. Some may extend into the floor of the tympanic cavity, lying in very close relation to the superior jugular bulb. Rarely, a few cells may excavate the jugular process of the occipital bone. An important group of cells may extend medially into the petrous part of the temporal bone, even reaching as far as its tip, and they are related to the auditory tube, the carotid canal, the labyrinth and the abducent nerve. Some investigators maintain that these petrous cells are not directly continuous with the mastoid cells proper, but are independent outgrowths from the tympanic cavity. The extensions of the mastoid air cells described above are of considerable importance to the clinician. Infection of the cells may spread to the structures mentioned above as related to them. Whereas the mastoid antrum is well developed at birth, the mastoid air cells, at this time, are only just beginning to develop as tiny diverticula from the antrum. As the mastoid process begins to develop in the second year, the cells gradually extend into it, and by the fourth year they are well formed, though their greatest growth occurs at about the age of puberty. In about 20 per cent of skulls the mastoid process is not excavated by air cells.

The anterior wall of the tympanic cavity is constricted owing to the approximation of the medial and lateral walls of the cavity. Its inferior and larger part consists of a thin lamina of bone which forms the posterior wall of the carotid canal, and is perforated by the superior and inferior caroticotympanic nerves, and the tympanic branch or branches of the internal carotid artery. At the superior part of the anterior wall there are two parallel canals, placed one above the other; superiorly placed is the *canal for the tensor tympani*, inferiorly, the *osseous part of the auditory tube*. These canals incline anteriorly, inferiorly and medially to open in the angle between the squamous and petrous parts of the temporal bone; they are separated by a thin, bony septum. The canal for the tensor tympani and the septum run posterolaterally on the medial wall of the tympanic cavity, and end immediately above the fenestra vestibuli, where the posterior end of the septum is curved laterally to form a pulley, the *processus trochleariformis* (*cochleariformis*), over which the tendon of the tensor tympani bends in a lateral direction to reach its attachment to the upper part of the handle of the malleus.

THE AUDITORY TUBE

The *auditory* or *pharyngotympanic* tube (7.282, 285, 286) is the channel through which the tympanic cavity communicates with the nasal part of the pharynx. Through it air passes between pharynx and tympanic cavity thus equalizing the air pressure on the medial and lateral surfaces of the tympanic membrane. Its length is about 36 mm, and its direction is downwards, forwards and medially, forming an angle of some 45° with the sagittal plane and one of about 30° with the horizontal plane. It is formed partly of bone, partly of cartilage and fibrous tissue.

The *bony part of the tube* is about 12 mm long. It begins in the anterior wall of the tympanic cavity, and, gradually narrowing, ends at the angle of junction of the squamous and petrous portions of the temporal bone, its extremity presenting a jagged margin which serves for the attachment of the cartilaginous part; the carotid canal lies on its medial side. It is oblong in transverse section with its greater dimension lying horizontally.

The *cartilaginous part of the tube*, about 24 mm long, is formed of a triangular plate of cartilage, the greater part of which is situated in the posteromedial wall of the tube. The apex of the fibrocartilage is attached by fibrous tissue to the circumference of the medial end of the bony part of the tube, while its base lies directly under the mucous membrane of the lateral wall of the nasal part of the pharynx, where it forms the *tubal elevation*, behind the pharyngeal orifice of the tube. The superior part of the cartilage is bent laterally and downwards, and the cartilage therefore consists of a broad *medial lamina*, and a narrow *lateral lamina*. On transverse section the cartilage has the appearance of a hook; the groove or furrow produced by the bend in the cartilage is open below and laterally, and this part of the wall of the canal is completed by fibrous membrane. The cartilage is fixed to the base of the skull in the groove between the petrous part of the temporal bone and the greater wing of the sphenoid bone; this groove ends near the root of the medial pterygoid plate. The cartilaginous and bony parts of the tube are not in the same plane, the former inclining downwards a little more than the latter. The diameter of the tube is greatest at the pharyngeal orifice, least at the junction of the bony and cartilaginous parts, and again increased towards the tympanic cavity; the narrowest part of the tube is termed the *isthmus*.

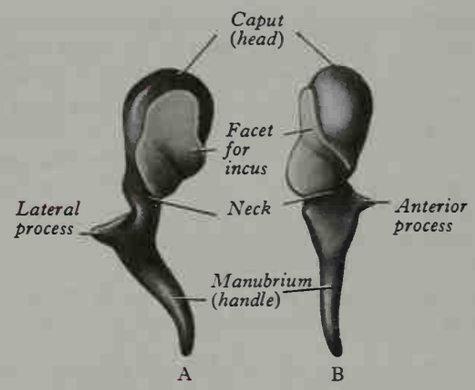
The mucous membrane of the tube is continuous medially with that of the pharynx, and laterally with that of the tympanic cavity; it is covered with ciliated columnar epithelium and is thin in the bony part, while in the cartilaginous part it contains many mucous glands, and near its pharyngeal orifice a variable, sometimes considerable aggregation of lymphoid tissue, the *tubal tonsil*.

Relations of the auditory tube. Anterolaterally the tensor veli palatini separates the tube from the otic ganglion, the mandibular nerve and its branches, the chorda tympani nerve and the middle meningeal artery. This muscle receives some fibres from the lateral lamina of the cartilage and from the membranous part of the tube; these fibres constitute the *dilatator tubae*. The salpingopharyngeus (p. 1308) is attached to the inferior part of the cartilage of the tube near its pharyngeal opening. *Posteromedially* the tube is related to the petrous part of the temporal bone and to the levator veli palatini, which arises partly from its medial lamina. The position and relations of the pharyngeal orifice are described with the nasal part of the pharynx (p. 1308).

The tube is opened during deglutition, but the mechanism is uncertain. Some claim that the dilatator tubae, possibly aided by the salpingopharyngeus, is responsible, though others deny the existence of the dilatator tubae. It is also claimed that the levator veli palatini, by elevating the cartilaginous part of the tube, allows the tube to open passively by releasing tension on the cartilage.

In the newborn child the auditory tube is about half as long as that of the adult. Its direction is more horizontal and its bony part is relatively shorter, but much wider than in the adult. Its pharyngeal orifice is a narrow slit, which is on a level with the palate and is devoid of a tubal elevation.

Vessels and nerves. The *arteries* of the auditory tube are derived from the ascending pharyngeal branch of the external carotid artery and from two branches of the maxillary artery, namely, the middle meningeal artery and the artery of the pterygoid canal. The *veins* open into the pterygoid venous plexus. The *nerves* of the tube spring from the tympanic plexus (p. 1200) and from the pharyngeal branch of the pterygopalatine ganglion. The precise contribution from the nerves which form the plexus i.e. the glossopharyngeal, the cervical sympathetic and possibly the facial, remains uncertain in man.



THE AUDITORY OSSICLES

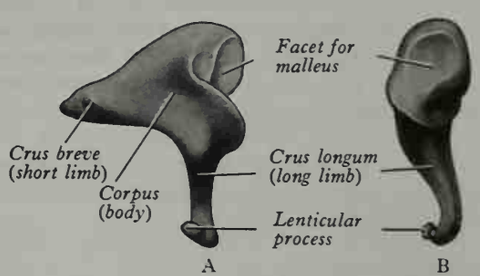
The tympanic cavity contains a chain of three movable ossicles: the *malleus*, *incus* and *stapes*. The malleus is attached to the tympanic membrane and the base of the stapes to the circumference of the fenestra vestibuli, while the incus is placed between, and articulates with both malleus and stapes.

The malleus (7.290), so named from its fancied resemblance to a mallet, is from 8 to 9 mm long, and is the largest of the auditory ossicles. It consists of a head, neck and three processes—the manubrium or handle, and the anterior and lateral processes.

The *head*, which is the large upper end of the bone, is situated within the epitympanic recess; it is ovoid in shape, and articulates posteriorly with the incus, being clothed with mucous membrane over the rest of its surface. The cartilage-covered facet for articulation with the incus is constricted near the middle, and consists of an upper larger and a lower smaller part, situated nearly at right angles to each other. Opposite the constriction the lower margin of the facet projects in the form of a process which is named the *cogtooth* or *spur* of the malleus.

The *neck* is the narrow part just beneath the head; inferior to the

7.290 The left malleus. A Posterior aspect. B Medial aspect.



neck there is an enlargement to which the various processes are attached.

The *manubrium mallei* is connected by its lateral margin with the tympanic membrane. It is directed downwards, medially and backwards; it decreases in size towards its free end, which is curved slightly forwards and flattened transversely. Near the upper end of its medial surface there is a slight projection, into which the tendon of the tensor tympani is inserted.

The *anterior process* is a delicate bony spicule, directed forwards from the enlargement below the neck; it is connected to the petrotympanic fissure by ligamentous fibres (*vide infra*). In the fetus this is the longest process of the malleus, and it is continuous in front with the cartilage of Meckel (p. 150).

The *lateral process* is a conical projection which projects from the root of the handle of the malleus; it is directed laterally, and is attached to the upper part of the tympanic membrane and, by means of the anterior and posterior malleolar folds, to the extremities of the notch at the upper part of the tympanic sulcus.

Ossification. The cartilaginous precursor of the malleus is derived from near the dorsal end of the embryonic Meckel's cartilage. With the exception of its anterior process, it is ossified from a single endochondral centre, which appears near the future neck of the bone in the fourth month of fetal life. The anterior process is ossified separately, in dense connective tissue, and joins the main part of the bone about the sixth month of fetal life.

7.291 The left incus. A Medial aspect. B Anterior aspect.

The incus (7.291) received its name from its supposed resemblance to an anvil, but its shape is more like that of a premolar tooth, with two widely diverging roots. It consists of a body and two processes.

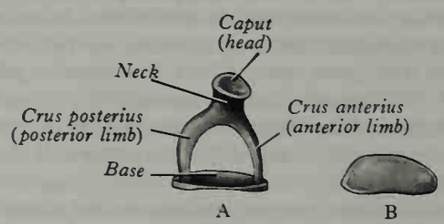
The *body* is somewhat cubical, but compressed laterally. On its anterior surface there is a cartilage-covered saddle-shaped facet, for articulation with the head of the malleus.

The *long process*, rather more than half the length of the handle of the malleus, descends nearly vertically, behind and parallel to that process; its lower end bends medially, and terminates in a rounded projection, the *lenticular process*, the medial surface of which is covered with cartilage, and articulates with the head of the stapes.

The *short process*, somewhat conical in shape, projects posteriorly, and is attached by ligamentous fibres to the fossa incudis, in the postero-inferior part of the epitympanic recess.

Ossification. The incus has a cartilaginous precursor which is continuous with the dorsal extremity of the embryonic Meckel's cartilage (*see* p. 145). Its ossification often spreads from a single endochondral centre, which appears in the upper part of its long process in the fourth month of fetal life; the lenticular process, however, may have a separate centre of ossification.

The stapes (7.292), so called from its resemblance to a stirrup, consists of a head, neck, two limbs and a base.



The *head* (*caput*) is directed laterally, and has a small cartilage-covered depression for articulation with the lenticular process of the incus.

The *neck* is the constricted part adjoining the head; the tendon of the stapedius is inserted into its posterior surface.

The *limbs* (*crura*) diverge from the neck and merge at their ends with a roughly oval or reniform plate, the *base*, which forms the footplate of the stirrup, and is fixed to the margin of the fenestra vestibuli by a ring of ligamentous fibres (the annular ligament). The anterior limb is shorter and less curved than the posterior.

Ossification. The stapes is preformed in the perforated dorsal moiety of the hyoid arch cartilage of the embryo. Its ossification starts from a single endochondral centre, which appears in the base of the bone in the fourth month of fetal life, and then gradually spreads through the stapedial limbs to coalesce in its body.

At birth the auditory ossicles have reached an advanced state of maturity.

7.292 The left stapes. A Superior aspect. B Basal aspect.

The Articulations of the Auditory Ossicles

These are typical synovial joints. The incudomalleolar joint is a saddle-shaped articulation. The incudostapedial joint is a 'ball and socket' articulation. Their articular surfaces are covered with articular cartilage, and each is enveloped by an articular capsule containing a considerable amount of elastic tissue, and lined by synovial membrane.

The Ligaments of the Auditory Ossicles

The ossicles are connected to the walls of the tympanic cavity by ligaments: three for the malleus, and one each for the incus and stapes. Some of these 'ligaments' are mere folds of mucous membrane which carry blood vessels and nerves to and from the ossicles and their articulations. Others contain a central, strong band of collagen fibres.

The *anterior ligament of the malleus* is attached by one end to the neck of the malleus, just above the anterior process, and by the other to the anterior wall of the tympanic cavity, close to the petrotympanic fissure, some of its collagen fibres being prolonged through the fissure to reach the spine of the sphenoid bone; some fibres are continued into the sphenomandibular ligament. Both the latter ligament and the anterior ligament of the malleus are derived from the fibrous perichondrial sheath of the cartilage of Meckel (p. 150). The ligament may contain muscle fibres (the *laxator tympani* or *musculus externus mallei*).

The *lateral ligament of the malleus* is a triangular band passing from the posterior part of the border of the tympanic incisure to the head of the malleus.

The *superior ligament of the malleus* connects the head of the malleus to the roof of the epitympanic recess.

The *posterior ligament of the incus* connects the end of the short process of the incus to the fossa incudis.

The *superior ligament of the incus* is little more than a fold of mucous membrane, passing from the body of the incus to the roof of the epitympanic recess.

The vestibular surface and the circumference of the base of the stapes are covered with hyaline cartilage; that encircling the base is attached to the margin of the fenestra vestibuli by a ring of elastic fibres, termed the *annular ligament of the base of the stapes*. Certain parts are much narrower, and act as a kind of hinge on which the base of the stapes moves when the stapedius contracts and during acoustic oscillation (*see* below).

THE MUSCLES OF THE TYMPANIC CAVITY

The muscles of the tympanic cavity are the tensor tympani and stapedius.

The tensor tympani (7.282, 286), a long slender muscle, is contained in the bony canal superior to the bony part of the auditory tube, from which it is separated by a thin bony septum. It arises from the cartilaginous part of the auditory tube and the adjoining part of the greater wing of the sphenoid, as well as from the bony canal in which it is contained. Passing backwards through the canal, it ends in a slim tendon which bends laterally round the pulley-like processus trochleariformis, and is attached to the handle of the malleus, near its root.

Nerve supply. The tensor tympani is supplied by a branch of the nerve to the medial pterygoid, which in its turn is a branch of the mandibular nerve and traverses the otic ganglion without interruption (p. 1076). Through this it receives both a motor and a proprioceptive innervation (Candiollo 1965).

The stapedius arises from the wall of a conical cavity in the pyramidal eminence and from the continuation of this cavity which passes down in front of the descending part of the facial canal (p. 1072); its minute tendon emerges from the orifice at the apex of the pyramid, and, passing forwards, is inserted into the posterior surface of the neck of the stapes (7.288). This small muscle is of an asymmetric bipennate form, and consists of numerous small motor units, each containing only six to nine muscle fibres. A few neuromuscular spindles are present near the myotendinous junction.

Nerve supply. The stapedius is supplied by a branch of the facial nerve. (For details of the stapedius muscle and its innervation *see* Blevins 1967.)

Actions. Under normal conditions, the tensor tympani and the stapedius contract simultaneously and reflexly in response to sounds of fairly high intensity, exerting 'a protective damping effect upon sound vibrations reaching the internal ear' (Hallpike 1935). The tensor on contraction pulls inwards the tympanic membrane and renders it more tense; its action also results in the base of the stapes being pushed more tightly into the fenestra vestibuli. The stapedius opposes the latter action of the tensor. Paralysis of the stapedius muscle results in hyperacusis.

MOVEMENTS OF THE AUDITORY OSSICLES

The manubrium faithfully follows all movements of the tympanic membrane, while the malleus and incus rotate together around an axis which runs through the short process and posterior ligament of the incus and the anterior ligament of the malleus. When the tympanic membrane and the manubrium are displaced medially, the long process of the incus also moves in the same direction and pushes the base of the stapes towards the labyrinth. This motion is communicated to the perilymph (p. 1200), the movement of which causes an outward bulging of the secondary tympanic membrane which occupies the fenestra cochleae. The conditions are reversed when the tympanic membrane moves in an outward direction, but if this movement of the membrane is exaggerated the incus does not follow the full outward excursion of the malleus but merely glides on this bone at the incudomalleolar joint, thus avoiding the danger of pulling the base of the stapes out of the fenestra vestibuli. When the manubrium is carried in a medial direction, the tooth or *cog* at the lower margin of the head of the malleus locks the incudomalleolar joint, and this necessitates a medial movement of the long process of the incus; the joint is unlocked when the handle of the malleus is carried outwards. The three bones collectively act as a bent lever, so that the base of the stapes does not move in and out of the fenestra vestibuli like a piston, but rocks on a fulcrum which is situated on the anteroinferior border of the fenestra, and at this site the annular ligament is thickened. More complex movements of the stapes have also been described (Békésy 1960). The rocking movement around a vertical axis, which has been likened to a door opening and closing, occurs only at moderate sound intensities. With loud, low-pitched sounds, the axis becomes horizontal, the upper and lower margins of the stapedial base oscillating in opposite directions around this central axis, thus immediately and automatically preventing excessive displacement of the perilymph.

THE TYMPANIC MUCOSA

The mucous membrane of the tympanic cavity is continuous with that of the pharynx, through the auditory tube. It invests the auditory ossicles and the muscles and nerves contained in the tympanic cavity, forms the inner layer of the tympanic membrane and the outer layer of the secondary tympanic membrane, and lines the mastoid antrum and mastoid air cells. It forms several vascular folds which extend from the walls of the tympanic cavity to the ossicles; of these, one descends from the roof of the cavity to the head of the malleus and upper margin of the body of the incus, and a second invests the stapedius; other folds invest the chorda tympani nerve and the tensor tympani. These folds separate off saccular recesses, and give the interior of the tympanic cavity a somewhat honeycombed appearance. One of these pouches, termed the *superior recess of the tympanic membrane*, lies between the neck of the malleus and the pars flaccida. Two other recesses, termed the *anterior* and *posterior recesses of the tympanic membrane*, may be mentioned: they are formed by the mucous membrane which envelops the chorda tympani nerve, and are situated, one in front of, and the other behind, the handle of the malleus. In the tympanic cavity the mucous membrane is pale, thin and slightly vascular. It is covered with ciliated columnar epithelium except over the posterior part of the medial wall, the posterior wall, often parts of the tympanic membrane, and the auditory ossicles where the cells are flatter and non-ciliated. Near the orifice of the auditory tube numerous goblet cells are present, but apart from this there are no mucous glands. The mastoid antrum and the mastoid air cells are lined by a flattened non-ciliated epithelium. Undoubtedly, there are considerable variations in the regions of the tympanic cavity and associated structures, which are lined by squamous, cuboidal, columnar, or ciliated columnar epithelium. As yet there has been no systematic exhaustive ultrastructural study of this problem. (For an account of the ultrastructure of restricted regions consult Kawabata and Paparella 1969.)

It is to be noted that the tympanic cavity and mastoid antrum, the auditory ossicles and the structures comprising the internal ear are more or less fully developed by birth and undergo little subsequent alteration. In the fetus the tympanic cavity contains a jelly-like tissue, which has practically disappeared by birth, at which time the cavity is filled with a fluid that is absorbed after birth when air enters the cavity through the auditory tube.

THE VASCULATURE OF THE TYMPANIC CAVITY

The *arteries* supplying the walls and contents of the tympanic cavity are six in number. Two of them are larger than the others—the *anterior tympanic* branch of the *maxillary artery*, which supplies the tympanic membrane, and the *stylomastoid* branch of the *occipital* or *posterior auricular arteries* supplying the posterior tympanic cavity and mastoid air cells. The smaller arteries are—the *petrosal* branch of the *middle meningeal artery*, which enters through the hiatus for the greater petrosal nerve; the *superior tympanic* branch of the *middle meningeal artery*, which traverses the canal for the tensor tympani; a branch from the *ascending pharyngeal artery*, and another from the *artery of the pterygoid canal*, which accompany the auditory tube, and the *tympanic branch*, or branches from the *internal carotid artery*, given off in the carotid canal and perforating the thin anterior wall of the tympanic cavity. In early fetal life the *stapedial artery* passes through the ring of the stapes (p. 189). The *veins* terminate in the pterygoid venous plexus and in the superior petrosal sinus. From

the mucous membrane of the mastoid antrum a small group of veins runs medially through the arch formed by the anterior semicircular canal. They emerge on the posterior surface of the petrous part of the temporal bone through the subarcuate fossa, and open into the superior petrosal sinus. These small veins are the remains of the large *subarcuate veins* of the child, and constitute a pathway of infection from the mastoid antrum to the meninges of the brain. The *lymph vessels* are described on p. 786.

THE NERVES OF THE TYMPANIC CAVITY

The *nerves* constitute the *tympanic plexus*, which ramifies upon the surface of the promontory. The plexus is formed by (1) the tympanic branch of the glossopharyngeal nerve, and (2) the caroticotympanic nerves. (For details consult Arslan 1960.) The *tympanic branch of the glossopharyngeal* enters the tympanic cavity by the *canaliculus for the tympanic nerve*, and divides into branches which ramify on the promontory and enter into the formation of the tympanic plexus. The *superior and inferior caroticotympanic nerves*, from the carotid plexus of the sympathetic, pass through the wall of the carotid canal, and join the plexus. The tympanic plexus supplies: (*a*) branches to the mucous lining of the tympanic cavity, auditory tube and mastoid air cells; (*b*) a branch which goes through an opening in front of the fenestra vestibuli and joins the greater petrosal nerve; (*c*) the *lesser petrosal nerve*, which may be looked upon as the continuation of the tympanic branch of the glossopharyngeal nerve through the tympanic plexus. The lesser petrosal nerve traverses a small canal below the canal for the tensor tympani, runs past, and receives a connecting branch from the genicular ganglion of the facial nerve; it emerges from the anterior surface of the temporal bone through a small opening on the lateral side of the hiatus for the greater petrosal nerve. It then passes through the foramen ovale, or through the small canaliculus innominatus (p. 323), and joins the otic ganglion. Postganglionic fibres pass from the otic ganglion, via the auriculotemporal nerve, to provide the secretomotor supply for the parotid gland.

The *chorda tympani* is a nerve derived from the facial nerve, about 6 mm above the stylomastoid foramen. It runs anterosuperiorly in a canal, and enters the tympanic cavity through the *posterior canaliculus*. It then curves anteriorly in the substance of the tympanic membrane lying between its mucous and fibrous layers (p. 1194). After crossing the medial aspect of the upper part of the handle of the malleus it reaches the anterior wall, and enters the *anterior canaliculus*. (For its further course see p. 1072.) The other nerves which are closely related, topographically, to the tympanic cavity include the facial nerve with its genicular ganglion and stapedial and greater petrosal branches; the auricular branch of the vagus; the afferent and efferent terminals of the vestibulocochlear nerve; and the internal carotid sympathetic plexus. These are all described in greater detail elsewhere in the present section.

The *meningeal branch* (p. 1066), of the mandibular nerve, supplies branches to the mastoid air cells.

Applied Anatomy. Fractures of the middle fossa of the base of the skull almost invariably involve the tympanic roof, and are accompanied by a rupture of the tympanic membrane or fracture through the roof of the bony part of the external acoustic meatus. Such injuries are associated with prolonged bleeding from the ear, and, if the dura mater has also been torn, with discharge of cerebrospinal fluid.

The tympanic cavity is frequently the seat of disease, both suppurative and non-suppurative, and in practically every case the inflammation spreads upwards from the nasal cavity and nasal part of the pharynx along the auditory tube. Acute inflammation spreading up to the tympanic cavity is usually associated with much swelling of the mucous membrane of the tube, thus occluding it, and the products of inflammation, confined in the tympanic cavity, may spread directly to the mastoid antrum. In such circumstances the only means of escape for the products is by rupture of the tympanic membrane, which may occur spontaneously or be induced surgically and is followed by a free discharge of pus. Should the swelling of the walls of the auditory tube then subside, the normal drainage of the cavity will be established and the perforation in the drum will heal, but if not—as is often the case because the opening of the tube may be occluded by enlarged lymphatic aggregates in the nasal part of the pharynx or other cause—the pus may continue to accumulate in the middle ear and overflow through the perforation as a chronic otorrhoea. Several intracranial complications may result from purulent material being retained; thus an abscess may form between the bone and dura mater, (*a*) above the roof of the tympanic cavity, and immediately beneath the dura covering the temporal lobe of the brain, or (*b*) between the deep aspect of the mastoid process and the sigmoid sinus, possibly extending widely and surrounding the sinus. In this latter case thrombosis of the sinus may occur, and the infected clot tends to disintegrate and be carried into the general circulation, particles becoming lodged in the capillaries of the lungs and causing abscesses. In addition, bone disease of the tympanic cavity or mastoid antrum may be associated with severe and fatal septic meningitis, or with the formation of abscess in the brain, the most common sites being the temporal lobe of the cerebrum and the hemisphere of the cerebellum.

In some cases of chronic bone disease in the tympanic cavity, the facial nerve becomes exposed as it lies in its canal and an inflammatory process is set up in the nerve, leading to facial paralysis of the infranuclear or peripheral type (p. 1073).

THE INTERNAL EAR

The internal ear consists of two parts—the *osseous labyrinth*, a series of cavities within the petrous part of the temporal bone, and the *membranous labyrinth*, a series of communicating membranous sacs and ducts, contained within the bony cavities.

The Osseous Labyrinth

The osseous labyrinth (7.285, 293) consists of three parts—the *vestibule*, the *semicircular canals* and the *cochlea*. These are cavities hollowed out of the substance of the bone, and lined by periosteum; they contain a clear fluid, known as the *perilymph*, in which the membranous labyrinth is placed. The osseous labyrinth consists of harder, denser bone than the surrounding parts of the petrous portion of the temporal bone, so that it is possible, particularly in the very young skull, to separate the labyrinth from the petrous temporal by artificial dissection.

THE VESTIBULE

The vestibule is the central part of the bony labyrinth, and is situated medial to the tympanic cavity, posterior to the cochlea and anterior to the semicircular canals. It is somewhat ovoid in shape, but flattened transversely; it measures about 5 mm from before backwards, the same from above downwards, and about 3 mm across. In its *lateral wall* there is the opening of the fenestra vestibuli, closed in life by the base of the stapes and its annular ligament. On the anterior part of the *medial wall* there is a small *spherical recess*, containing the saccule and perforated by several minute holes, the *macula cribrosa media*. The recess corresponds to the inferior vestibular area in the bottom of the internal acoustic meatus (7.302), and the foramina transmit filaments of the vestibulocochlear nerve to the saccule. Behind this recess there is an oblique ridge, the *vestibular crest*, the anterior end of which is the *pyramid of the vestibule*; this ridge divides below to

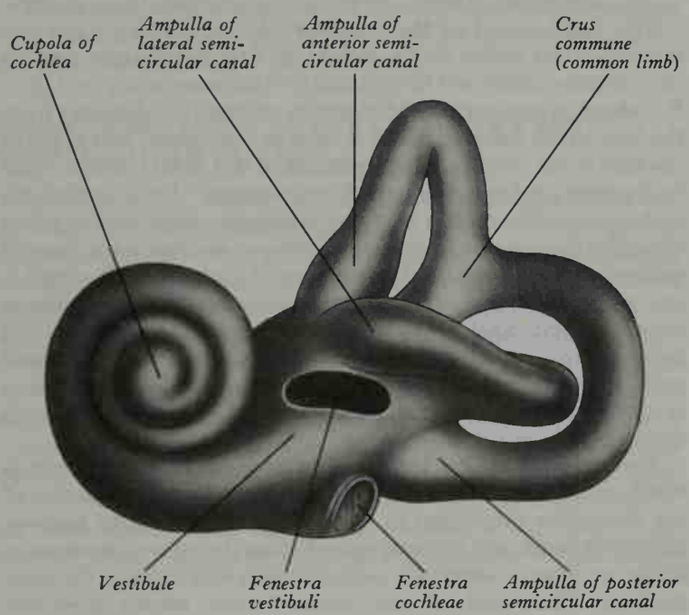
enclose a small depression, the *cochlear recess*, which is perforated by a number of holes for the passage of fibre bundles of the vestibulocochlear nerve to the vestibular end of the duct of the cochlea. Posterosuperior to the vestibular crest, and situated in the roof and medial wall of the vestibule there is an *elliptical recess* which contains the utricle. The pyramid and adjoining part of the elliptical recess are perforated by a number of holes, the *macula cribrosa superior*; the holes in the pyramid transmit the nerves to the utricle, and those in the elliptical recess, the nerves to the ampullae of the superior and lateral semicircular ducts. The pyramid and the adjoining part of the elliptical recess correspond to the superior vestibular area at the bottom of the internal acoustic meatus (7.302). The orifice of the *aqueduct of the vestibule* lies below the elliptical recess. This aqueduct extends to the posterior surface of the petrous part of the temporal bone; it transmits one or more small veins, and contains a tubular prolongation of the membranous labyrinth which is termed the *endolymphatic duct*. In the posterior part of the vestibule there are the *five orifices of the semicircular canals*, in the anterior wall, an elliptical opening leading into the *scala vestibuli* of the cochlea.

THE SEMICIRCULAR CANALS

The semicircular canals are three in number, anterior (superior), posterior and lateral, and are situated posterosuperior to the vestibule. They are compressed from side to side, and each occupies about two-thirds of a circle. They are unequal in length, but are all about 0·8 mm in diameter; each presents a dilatation at one end, called the *ampulla*, the diameter of which is nearly twice that of the canal. They open into the vestibule by five orifices, one of which is common to two of the canals.

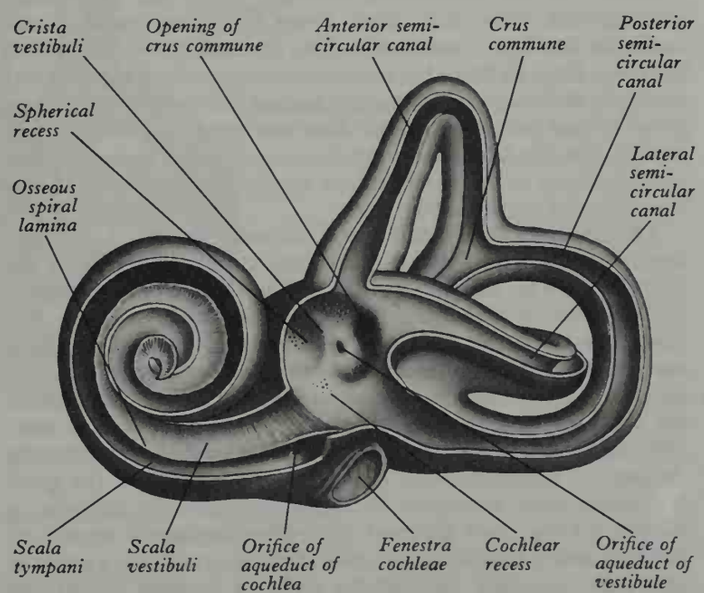
The *anterior (superior) semicircular canal*, 15 to 20 mm in length, is vertical in direction, and is placed transversely to the long axis of the petrous part of the temporal bone, on the anterior surface of which its arch underlies the arcuate eminence (p. 329). Some maintain, however, that the arcuate eminence does not accurately coincide with the anterior semicircular canal but is adapted to the occipitotemporal sulcus on the inferior surface of the temporal lobe of the cerebral hemisphere. The anterolateral end of the anterior semicircular canal is ampullated, and opens into the upper and lateral part of the vestibule; the opposite end unites with the upper end of the posterior canal to form the *crus commune*, which is about 4 mm long, and opens into the medial part of the vestibule.

The *posterior semicircular canal*, also vertical, is directed backwards, nearly parallel with the posterior surface of the petrous bone; it is from 18 mm to 22 mm long; its ampullated end opens into the lower part of the vestibule, where there are several small holes, the *macula cribrosa inferior*, for the transmission of the nerves to this ampulla, their position corresponding to the *foramen singulare* in the bottom of the internal acoustic meatus (7.302). Its upper end opens into the crus commune.



The *lateral* or *horizontal canal* is from 12 mm to 15 mm long, and its arch is directed horizontally backwards and laterally. Its anterior or ampullated end opens into the upper and lateral angle of the vestibule, just above the fenestra vestibuli and immediately below the ampullated end of the superior canal; its posterior end opens below the orifice of the crus commune.

The lateral semicircular canal of one ear is in the same plane as that of the other ear; while the anterior canal of one ear is in a plane nearly parallel with that of the posterior canal of the other.



Blanks *et al.* (1975) have measured the angular relations of the planes of the semicircular osseous canals in 10 human skulls. Although the planes of the three ipsilateral canals were approximately perpendicular to each other, some variation was apparent, the measured angles being as follows: horizontal/anterior—$111{\cdot}76 \pm 7{\cdot}55^{\circ}$, anterior/posterior—$86{\cdot}16 \pm 4{\cdot}72^{\circ}$, and posterior/horizontal—$95{\cdot}75 \pm 4{\cdot}66^{\circ}$. The planes of similarly orientated canals of the two sides showed marked departure from parallelism: left anterior/right posterior—$24{\cdot}50 \pm 7{\cdot}19^{\circ}$, left posterior/right anterior—$23{\cdot}73 \pm 6{\cdot}71^{\circ}$, and left horizontal/right horizontal—$19{\cdot}82 \pm 14{\cdot}93^{\circ}$. The same observers (Curthoys *et al.* 1977) have also measured the dimensions and radii of curvature of the canals; means for the radii of the osseous canals were as follows: horizontal—3·25 mm, anterior—3·74 mm, and posterior—3·79 mm. The functional implications of these data are still a matter of speculation. In diameter the osseous canals measure about 1 mm (minor axis) and 1·4 mm (major axis). The membranous ducts are much smaller, also ellipsoid in transverse section, with major and minor axes of 0·23 and 0·46 mm. Representative means for ampullary dimensions are are follows: length—1·94 mm, height—1·55 mm. Curthoys and his collaborators have recorded many other dimensions of the labyrinth both from their own observations and those of others. They attempt to equate these metrical data with theories of labyrinthine mechanics.

THE COCHLEA

The cochlea (7.285, 293, 294, 298) resembles the shell of the common snail; it forms the anterior part of the labyrinth, is conical in form, and placed anterior to the vestibule; it measures about 5 mm from base to apex, and its breadth across the base is about 9 mm. Its apex, or *cupula*, is directed laterally towards the upper and front part of the medial wall of the tympanic cavity (7.285); its base is directed towards the bottom of the internal acoustic meatus, and is perforated by numerous apertures for the

7.293A The left osseous labyrinth. Lateral aspect.

7.293B The interior of the left osseous labyrinth.

passage of the cochlear nerve. The cochlea consists of a cone-shaped central axis, the *modiolus*; of a canal, wound spirally around the central axis for roughly two turns and three-quarters; and of a delicate *osseous spiral lamina*, which projects from the modiolus into the canal, and partially divides it. In the recent state the division of the canal is completed by the *basilar membrane*, which stretches from the free border of the osseous spiral lamina to the outer wall of the bony cochlea; the two passages into which the cochlear canal is thus divided communicate with each other at the apex of the modiolus by a small opening, the *helicotrema*.

The modiolus is the conical, osseous, central pillar of the cochlea. Its base is broad, and appears at the lateral end of the internal acoustic meatus, where it corresponds with the *tractus spiralis foraminosus*, which is perforated by numerous orifices for the transmission of the branches of the cochlear nerve; the nerves for the first turn and a half of the cochlea pass through the foramina of the tractus spiralis; those for the apical turn, through the *foramen centrale*, in the centre of this tract. The canals of the tractus spiralis foraminosus pass through the modiolus and successively bend outwards to reach the attached margin of the osseous spiral lamina. Here they become enlarged, and by their apposition form the *spiral canal of the modiolus*, which follows the course of the attached margin of the osseous spiral lamina and lodges the *spiral ganglion*. The foramen centrale is continued into a canal which runs through the middle of the modiolus to its apex.

The bony canal of the cochlea takes about two turns and three-quarters round the modiolus; the first turn bulges towards the tympanic cavity and there underlies the promontory (p. 1195). It is about 35 mm long, and diminishes gradually in diameter from the base to the summit, where it ends in the *cupula*, which forms the apex of the cochlea. The beginning of this canal is about 3 mm in diameter, and in it there are three openings. One—the *fenestra cochleae*—communicates with the tympanic cavity and in life is closed by the *secondary tympanic membrane*; another is the *fenestra vestibuli* (p. 1195) occupied by the base of the stapes. The third is the aperture of the *cochlear canaliculus*, leading to a minute funnel-shaped canal which opens on the inferior surface of the petrous part of the temporal bone (p. 329). It transmits a small vein to join the inferior petrosal sinus, and establishes a communication between the subarachnoid space and the scala tympani (*vide infra*).

The osseous spiral lamina is a bony shelf or ledge which winds round and projects from the modiolus into the interior of the canal, like the thread of a screw. It reaches about halfway across the canal, and incompletely divides it into two passages or scalae: an upper, named the *scala vestibuli*, and a lower, the *scala tympani*. The width of the osseous spiral lamina gradually decreases from the basal to the apical coil of the cochlea, and near the summit of the cochlea the lamina ends in a hook-shaped process, the *hamulus of the spiral lamina*; this assists in forming the boundary of the *helicotrema*, through which the two scalae communicate with each other. From the spiral canal of the modiolus numerous canaliculi radiate through the osseous spiral lamina as far as its free edge and transmit branches of the cochlear nerve. In the lower part of the first turn of the cochlea a *secondary spiral lamina* projects inwards from the *outer* wall of the bony tube; it does not, however, reach the osseous spiral lamina, so that if the laminae be viewed from the vestibule a narrow *vestibular fissure* is seen between them.

The osseous labyrinth was classically described as being lined by a thin fibroserous membrane closely adherent to the periosteum of the neighbouring bone. The flattened epithelium of the membrane bounds the extensive *perilymphatic space*, the latter being filled with the fluid *perilymph* which bathes the external surface of the membranous labyrinth. However, ultrastructural studies have emphasized that the perilymphatic fluid-filled spaces are bounded by fibrocyte-like *perilymphatic cells*, with accompanying strands of extracellular fibres, the morphology of the cells varying in different parts of the labyrinth. Where the perilymphatic space is narrow, the cells are essentially *reticular* or *stellate* in form, their flattened sheet-like cytoplasmic extensions crossing and subdividing the perilymphatic space into a series of intercommunicating intercellular clefts of variable shapes and dimensions. Such tissue, and its accompanying spaces, occupies the cochlear canaliculus. Elsewhere, in regions where the perilymphatic space is much wider, as in the scala vestibuli and scala tympani, and throughout much of the vestibule, the perilymphatic cells which line the periosteum and cover the external surface of the membranous labyrinth are extremely flattened, with rather featureless cytoplasm. Despite occasional cytoplasmic projections into the neighbouring perilymph, in such situations the cellular arrangement approaches that of a true squamous epithelium. Over parts of the perilymphatic surface of the basilar membrane, the cells assume a cuboidal form. Closely related to the periosteal or membranous labyrinth aspect of the perilymphatic cells are bundles of collagen fibres which may, in part, be synthesized by these cells. However, in some species, fibres with a helical substructure, which differ from collagen in their ultrastructure, have been described in these situations. Their status in man remains to be determined.

The perilymph which occupies the perilymphatic spaces resembles cerebrospinal fluid fairly closely in its composition, although minor differences have been described (Ormerod 1960). Many regard it simply as an ultrafiltrate of plasma, with perhaps some addition from the cerebrospinal fluid. Its precise source, rate of production, circulation and absorption, cannot yet be regarded as settled. The status of the connexions which exist between the perilymphatic spaces and the general subarachnoid space through the *cochlear canaliculus* has been the subject of some debate. Originally, the canaliculus was often described as containing a simple patent, epithelium-lined duct, which connected the two. Later, this suggestion was rejected by a number of workers (Waltner 1948; Mygind 1948; Young 1952, 1953) who proposed that connective tissue barriers blocked the canaliculus and separated the two fluid compartments. It seems likely, however, that extracellular crevices persist between the perilymphatic cells which occupy the canal; certainly, large-moleculed electron-dense tracers such as thorotrast, when introduced into the craniovertebral subarachnoid space have a ready access to the perilymphatic spaces (Duvall and Quick 1969). Other investigators (Silverstein *et al.* 1969) point out that in cats, even particulates such as india ink or avian erthrocytes, will pass into the perilymphatic spaces via the cochlear canaliculus within twenty-four hours after their introduction into the subarachnoid space of the posterial cranial fossa. The latter authors regard perilymph as probably originating from three sources: (1) a transudate from the blood vessels surrounding the space; (2) from the fluid spaces surrounding the sheaths of the vestibulocochlear nerve fibres; and (3) from a slow continuous flow of cerebrospinal fluid along the cochlear canaliculus. The site of removal of perilymph is uncertain.

The part of the petrous bone which immediately surrounds the labyrinth is developed from the cartilaginous otic capsule; it is denser than the rest of the petrous bone, and exhibits interglobular spaces, which contain cartilage cells (7.295). The modiolus of the cochlea, on the other hand, is formed of trabecular membrane bone (Fraser and Dickie 1914).

The perilymphatic space of the vestibule communicates behind with that of the semicircular canals, and opens anteriorly into the scala vestibuli of the cochlea, which in turn opens into the scala tympani through the helicotrema, at the apex of the cochlea. The scala tympani is separated from the tympanic cavity by the secondary tympanic membrane, but is continuous with the subarachnoid space through the cochlear canaliculus (*vide supra*).

The Membranous Labyrinth

The membranous labyrinth (7.294), while contained within, is much smaller than the bony labyrinth; it is filled with fluid unique in composition named *endolymph*, and in its walls the branches of the vestibulocochlear nerve are distributed. It includes: (*a*) the *utricle* and *saccule*, two small sacs, occupying the vestibule; (*b*) three *semicircular ducts*, enclosed within the semicircular canals; (*c*) the *duct of the cochlea*, contained within the osseous cochlea. The various parts of the membranous labyrinth form a closed system of channels which, however, communicate freely with one another; the semicircular ducts open into the utricle and this into

the saccule through the ductus utriculosaccularis which also joins the ductus endolymphaticus, and the saccule opens into the duct of the cochlea through the ductus reuniens.

The membranous labyrinth is fixed at certain points to the wall of the bony labyrinth, but is separated from the greater part of the bony labyrinth by a perilymphatic space (*vide supra*). For details of the fine structure of the membranous labyrinth consult Wersäll (1956); Engström and Wersäll (1958); Iurato (1967); Kimura (1969); Babel *et al.* (1970).

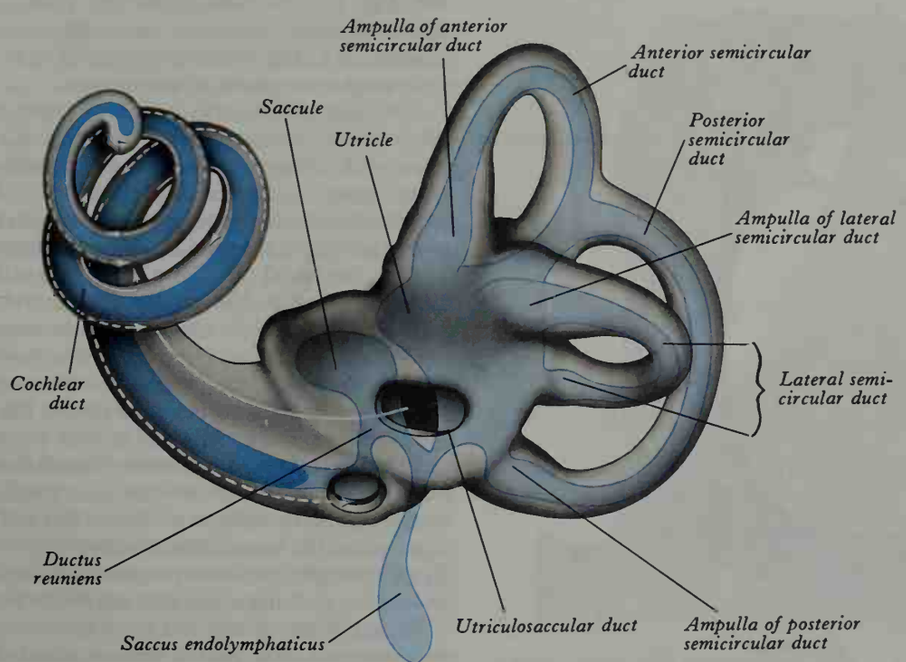
THE UTRICLE

The utricle, the larger of the two vestibular sacs, is irregularly oblong in shape, and occupies the posterosuperior region of the vestibule, lying in contact with the elliptical recess and also the area inferior to it. The part of the utricle in the elliptical recess forms a pouch or cul-de-sac; the lateral half of the floor and the adjoining lower part of the lateral wall of this pouch is thickened over an area measuring about 3 mm by 2 mm to form the *macula of the utricle* (p. 1204), which receives the utricular fibres of the vestibular nerve. The ampullae of the anterior and lateral semicircular ducts open into the lateral part of the utricle, while the ampulla of the posterior duct, the crus commune and the posterior end of the lateral duct open into the medial part of the utricle. The posterior end of the lateral duct widens into a flattened cone which joins the medial end of the utricle at a right angle. From the anteromedial part of the utricle a fine canal, named the *ductus utriculosaccularis*, is given off and opens into the ductus endolymphaticus.

THE SACCULE

The saccule lies in the spherical recess near the opening of the scala vestibuli of the cochlea. When seen from the anterior aspect it presents a nearly globular form, but it is prolonged posteroinferiorly in the form of a cone, part of the upper surface of which is in contact with the under surface of the utricle, and the utricle and saccule have here a common wall. In its anterior wall there is an oval thickening, termed the *macula of the saccule* (pp. 1204, 1205), which lies in a plane at right angles to the macula of the utricle, and to which the saccular fibres of the vestibulocochlear nerve are distributed. Its cavity communicates indirectly through a Y-shaped tube with that of the utricle. From its posterior part the *ductus endolymphaticus* is given off and it is joined by the ductus utriculosaccularis; the ductus endolymphaticus passes medially and then inferiorly along the aqueduct of the vestibule to end in a blind pouch, the *saccus endolymphaticus*, under the dura mater on the posterior surface of the petrous portion of the temporal bone. From the lower part of the saccule a short tube, the *ductus reuniens*, passes inferiorly and gradually widens into the vestibular or basal end of the duct of the cochlea (7.294).

THE SEMICIRCULAR DUCTS



The semicircular ducts (7.294, 295) are about one-fourth of the diameter of the semicircular canals, but are similar to them in shape and general form. Each has an ampulla at one end, which, of course, lies within the ampulla of the corresponding bony canal. The semicircular ducts open by five orifices into the utricle, one opening being common to the medial end of the anterior, and the upper end of the posterior duct.

In each of the ampullae the wall is thickened, and projects into the cavity as a transverse elevation shaped somewhat like the figure 8, and named the *septum transversum*; the most prominent part of this septum being the *ampullary crest*, which projects from the wall of each ampulla that is most distant from the centre of the circle of which the semicircular duct forms an arc, a situation in which 'any movement of the endolymph would be caught by the crista to the greatest advantage' (Dickie 1920).

The utricle, saccule and semicircular ducts are held in position by fibrocellular bands which stretch across the perilymphatic space to the bony walls.

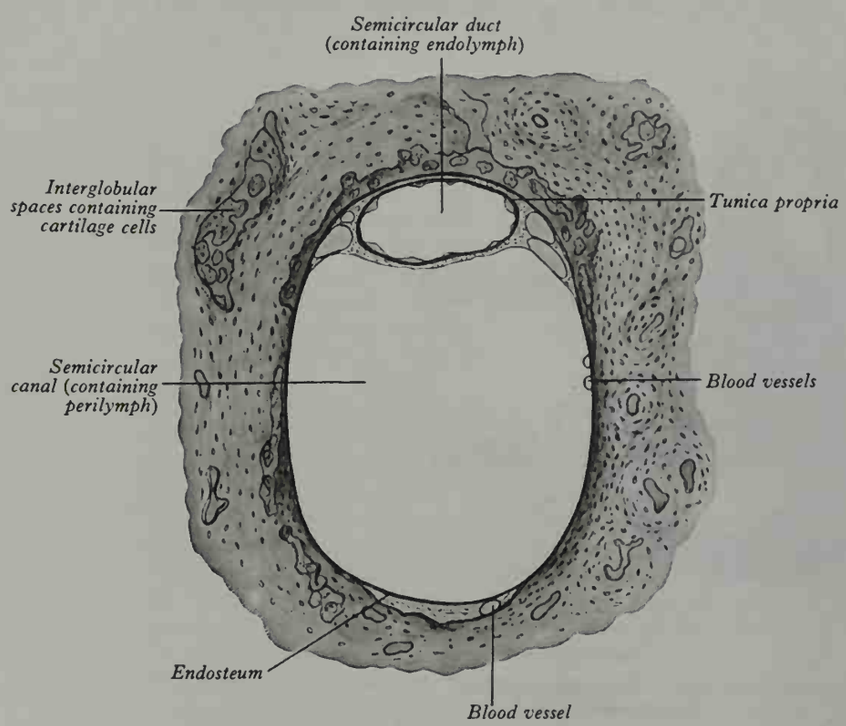
STRUCTURE OF THE UTRICLE, SACCULE AND SEMICIRCULAR DUCTS

The walls of the utricle, saccule and semicircular ducts are generally described as consisting of three layers. The *outer* layer is composed largely of fibrous tissue containing some blood vessels. Its superficial fibres are, in many places, clothed by flattened perilymphatic cells, and at some points this outer surface blends with the endosteum of the bony labyrinth. The *middle* layer, a more delicate vascular connective tissue, presents on its internal surface, especially in the semicircular ducts, a number of papilliform projections. The *inner* layer consists in general of a single layer of epithelial cells, which vary from squamous to cubical or polygonal in shape, resting on a basement membrane; they exhibit a *specialized* arrangement in the ampullary crests of the semicircular ducts and in the maculae of the utricle and saccule (7.294, 296). In these special sites, also, the middle coat is

7.294 Scheme of the membranous labyrinth (blue) projected on to the osseous labyrinth. The arrows indicate the direction of sound waves in the cochlea.

thickened. Flanking each crest, between this and the side wall of the ampulla is an area of tall epithelium which in cross-section appears crescentic and is termed the *planum semilunatum*.

Although the so-called 'non-specialized' parts of the membranous labyrinth so far described in fact have epithelia varying from squamous to tall columnar in different regions, ultrastructural studies (Kimura 1969) have also shown that they consist of either *light* or *dark* epithelial cells which are structurally quite dissimilar. In many regions the epithelium differs little from non-secretory simple epithelia elsewhere. The *light cells* comprising these regions contain elliptical or crenated heterochromatic nuclei, their luminal surfaces carry a few microvilli, and relatively few mitochondria, occasional ribosomes and some micropinocytotic vesicles occur in the cytoplasm. Adjacent cells show junctional complexes near their luminal borders, with also some interdigitation of neighbouring cell surfaces. Infolding of the basal plasmalemma is minimal. In contrast, some patches or strips of epithelium in the utricle and in the general and ampullated walls of the semicircular ducts consist of *dark cells*. These resemble light cells in a few respects only, their luminal surfaces carrying occasional microvilli and pinocytotic invaginations, whilst junctional complexes and interdigitations occur between adjacent cells. Their irregular nuclei are either centrally placed or situated rather near the luminal surface. The dense supranuclear cytoplasm contains numerous small coated vesicles, a profusion of larger smooth-walled vesicles, and many mitochondria, both free and membrane-attached polysomes, lipid droplets, lysosomes, lipofuscin granules, microfilaments and microtubules, and a prominent Golgi apparatus. The infranuclear part of the cell consists of numerous long cytoplasmic processes projecting towards the underlying basal lamina. Each process shows an elongate, fusiform dilatation of its contour, completely occupied by a long narrow mitochondrion. The plasmalemma of the processes is clothed externally by electron-opaque extensions from the basal lamina. Clearly, such cells are highly active, and on general morphological grounds, and their structural similarity to cells in other ion-transporting epithelia such as those in parts of the renal tubules (p. 1391), the ciliary body, the parotid duct, and the salt-secreting glands of various sub-mammalian forms, it has been suggested that the dark cells may be involved in controlling the ionic composition of the endolymph (see also below).



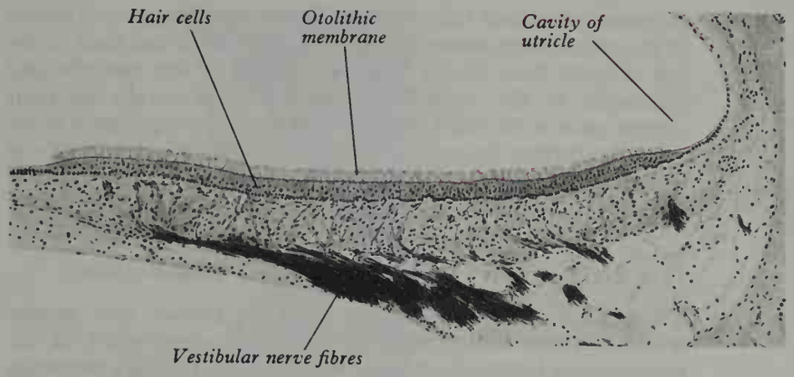
In the *ampullary crests* the epithelium consists of *hair cells* and *supporting cells*. **The hair cells** are the sensory cells and are of two types. *Type I* is piriform with a rounded base and a short neck. Except for its free end it is surrounded by a large goblet-shaped nerve terminal or *calix*; the apposed plasma membranes are separated by an interval of about 20–30 nm in width, but at a number of points the membranes approach each other more closely and the interval is reduced to about 5 nm. The nucleus of the hair cell is basally placed, and is surrounded by numerous mitochondria, and there is also a concentration of these organelles near the free surface of the cell. Scattered in the cytoplasm are occasional cisternae of granular endoplasmic reticulum, free polysomes, microfilaments and microtubules, numerous smooth vesicles about 20 nm in diameter, and a supranuclear Golgi apparatus is present.

The *type II* hair cell is cylindrical with its nucleus placed at varying levels, but usually more centrally placed than in the type I cell. Its cytoplasm contains similar organelles, but its population of smooth-walled vesicles is more abundant, and its supranuclear Golgi apparatus is more prominent. The basal part of the type II hair cell is not surrounded by a nerve terminal calix, but instead is in contact with a number of bud-like synaptic *boutons*. The latter are of two varieties; both contain mitochondria and numerous small membranous vesicles, but in the *non-granulated terminals* the vesicles are clear, whereas in the *granulated terminals* many of the vesicles contain electron-dense cores. It is now generally accepted that the non-granulated terminals are those of *afferent* nerve fibres conducting sensory information towards the central nervous system. The granulated terminals are regarded as derived from *efferent* fibres which innervate the type II hair cells, activity in which probably modifies the effective threshold of the hair cell to sensory stimuli. Thus, the granulated and non-granulated terminals are both considered to be sites of neurochemical transmission, but of course, polarized in opposite directions; however, the details of this transmission remain uncertain. The calix of the type I hair cell is also regarded as the terminal of an afferent vestibular fibre, but whether it operates mainly by neurochemical transmission, or whether low-resistance paths of the 'electrical synapse' type (p. 829) are extensively involved, is still to be determined. A number of granulated boutons are often present applied at points to the external aspect of the calix, and probably these are *efferent* terminals which modify the transmission characteristics of the calix.

In general, the type I hair cells may be regarded as the more 'discriminative' variety. The calices are derived from the larger-diameter, faster-conducting vestibular nerve fibres, and each fibre innervates a small localized group of type I cells. In contrast, the type II cells contact boutons from a number of relatively small-diameter vestibular nerve fibres, and each of the latter innervates a large number of type II cells which are distributed over a substantial area of membrane.

The apical, free surface of both types of hair cell are similar. They carry 40–100 'hairs' or stereocilia which are modified microvilli, of varying length and arranged in a regular hexagonal array when viewed from the surface. The array is, however, polarized with respect to a single long *kinocilium* which is attached to one border of the cell. The kinocilium possesses a typical basal body in the apical cytoplasm of the hair cell, and its shaft carries a ring of nine double microtubules, but the central pair of microtubules, which additionally characterize most other cilia, are sometimes less well developed and have even been claimed to be absent on occasion. Despite its name, any motile activity of this modified cilium remains uncertain. The stereocilia are non-motile microvilli, constricted at their point of attachment to the hair cell, and each contains a complement of longitudinal microfilaments which continue into a well-defined terminal web in the apical cytoplasm of the cell. On the border of the cell opposite to the kinocilium, the stereocilia are short, being about 1 μm in length, but those progressively nearer the cilium increase in length, reaching about 100 μm in the vicinity of the cilium.

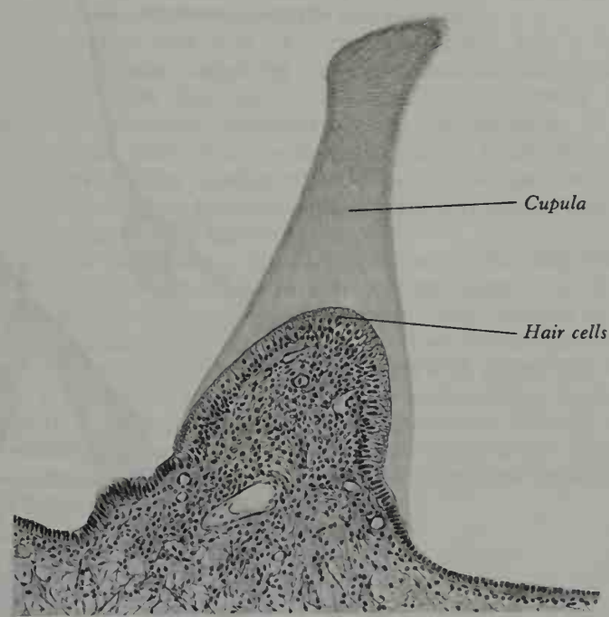
In each of the specialized vestibular receptor sites, the hair cells are arranged in *a precise pattern* which is of great functional significance (*vide infra*). In the ampullae of the lateral semicircular ducts, the sides of the hair cells which bear a kinocilium are all directed towards the neighbouring utricular



7.295 A transverse section through the left posterior semicircular canal and duct of an adult man. Magnification about × 50. (After Dr. J. K. Milne Dickie.)

cavity, whilst in the ampullae of the anterior and posterior ducts they are directed away from that cavity. In the maculae of the utricle and saccule, there is, in each, a sinuous '*parting line*' which crosses the central region of the macula. The polarization of the hair cells is reversed on the opposite sides of this line. In the utricle the hair cells are arranged in curved contours with their kinocilia nearer the parting line, whilst in the saccule they are directed away from this line. For details of the complex relationship of these arrays of hair cells, to the three planes of space, consult Iurato (1967); Babel *et al.* (1970); Ades and Engström (1974). **The supporting cells** are elongated and of variable diameter along their length. They rest on a basal lamina, and the nucleus is usually basal in position. The free surfaces are provided with microvilli, and the cytoplasm contains large osmiophilic granules which may be secretory in nature, in addition to a well-developed Golgi apparatus, numerous vertically running microtubules and microfilaments which enter a prominent subapical terminal web; mitochondria are plentiful. Whether the supporting cells are mainly involved in nutritive support of the hair cells, or in modifying the composition of the endolymph remains uncertain. Junctional complexes are established around the subapical parts of the hair cells and their neighbouring supporting cells. The processes of the hair cells and supporting cells project into a thick, dome-shaped gelatinous protein-polysaccharide containing mass called the cupula. The precise chemical composition of the cupula is, however, undetermined. It possesses a free apical border which almost reaches the opposite ampullary wall. The whole cupula can swing from side to side in response to currents in the endolymph. After displacement in one direction, when the endolymph current ceases, an elastic recoil causes the return of the cupula towards the intermediate vertical position, but some overshoot and oscillation occurs, before it comes to rest.

The epithelial cells of the *planum semilunatum* (Iurato 1967) lie adjacent to the crista on the one hand and gradually change to cuboidal epithelium of the side walls of the ampulla on the other. Their free surfaces are provided with a few microvilli. Basally they contain an abundance of parallel smooth-walled double membranes, arranged perpendicular to the basement membrane. They are infoldings of the basal plasma membrane; they end in vesicular enlargements in the cytoplasm. Between the membrane pairs are vesicles and mitochondria arranged in a linear manner. The nucleus is placed towards the apical part of the cell where there are abundant mitochondria, endoplasmic reticulum, a well-developed Golgi apparatus, polyribosomes and vesicles, some of which contain granules. It will be recalled that this description of the planum cells resembles that of the *dark cells* (*vide supra*) described by other investigators elsewhere in the labyrinth. The planum semilunatum is possibly concerned with the secretion of the endolymph. The *supporting* and *hair cells* of the *maculae* of the *utricle* and *saccule* are generally similar to those of the ampullary crests, but the gelatinous mass into which the cilia project is flatter and is termed an *otolithic membrane* (*membrana statoconiorum*), because it contains numerous minute crystalline bodies called *otoliths*, *otoconia*, or *statoconia* which consist of calcite (Carlström *et al.* 1953) and associated protein, and give the maculae, when fresh, an opaque white appearance.



The ampullary crests and the maculae of the utricle and saccule are the special end organs concerned with equilibratory vestibular reflexes influencing the position of the eyes in relation to movements of the head through the connexions of the vestibular nerves and their nuclei, via the medial longitudinal fasciculus (p. 839), with the nuclei of the third, fourth and sixth cranial nerves and influencing the general body musculature through the vestibulospinal tracts (p. 875). (The central connexions of the vestibular division of the vestibulocochlear nerve and its intimate relationship with the vestibulocerebellum are considered on pp. 908, 916, 918, 928.) Muscle activity is also influenced by the *position* of the head, and in this case the maculae of the utricle and saccule are the end organs concerned in that the otoliths, under the influence of gravity, exert traction on the cilia of the hair cells in varying positions of the head. The maculae are therefore often referred to as organs of *static balance* (*statotonic reflexes*), whereas the ampullary crests are called organs of *kinetic balance* in that

7.296A Section of the macula of the utricle of the cat. Stain—Weigert-Pal and iron haematoxylin. Magnification about × 112. (For source see 7.296B.)

they are stimulated by movement of, or pressure changes in, the endolymph caused by *angular acceleration* of the head (*statokinetic reflexes*) producing deviation of the cupulae. The maculae, however, may also be involved in signalling *linear acceleration* of the head. The terms static and kinetic as used above, therefore, are an oversimplification. The macula of the saccule, although it has the same histological structure as the macula of the utricle, is believed by some not to be concerned in vestibular reflexes but to be associated with the cochlea and concerned with the reception of slow vibrational (auditory) stimuli.

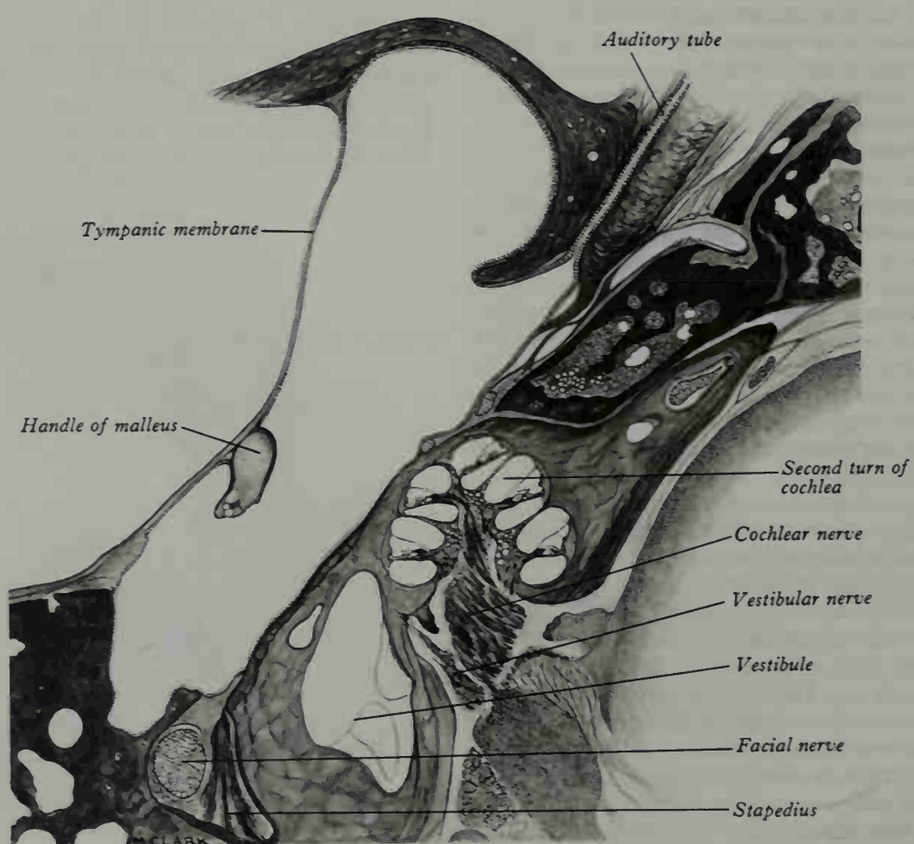
The manner in which deformation of the stereocilia, consequent upon movement of the cupulae or otolithic membrane, results in alteration of the ionic conductances of the hair cell membrane is not understood. However, it has been proposed, on the basis of electrophysiological recordings, that the majority of the vestibular nerve fibres have a steady, continuous basal discharge of afferent nerve impulses when the hair cells are receiving no mechanical stimulation. Bending of the stereocilia towards the kinocilium raises the frequency of nerve impulses, whilst bending in the opposite direction lowers the frequency. Thus, the position of the head, or its state of linear or angular acceleration, is reflected by the state of balance or relative imbalance in the impulse discharge patterns from mutually cooperative pairs of receptor sites in the right and left membranous labyrinths. For example, a horizontal swing of the head to the right results in an increased discharge of impulses from the ampulla of the right lateral semicircular duct, and a

7.296B Section of an ampullary crest of a six month old human fetus. Stained with haematoxylin and eosin. Magnification about × 75. (From a section kindly lent by E. W. Walls, Professor Emeritus, Middlesex Hospital Medical School, University of London.)

decreased discharge from the left. This occurs because the inertia of the endolymph causes a relative movement of this fluid to the left in both these canals. The positioning of the kinocilia and stereocilia in the ampullae is such that it results in their compression in the right ampulla, and their decompression in the left. (For further discussion of post-rotational effects, the effects of more complex movements in other planes, and methods of testing vestibular functional efficiency, *see* Fischer 1956.)

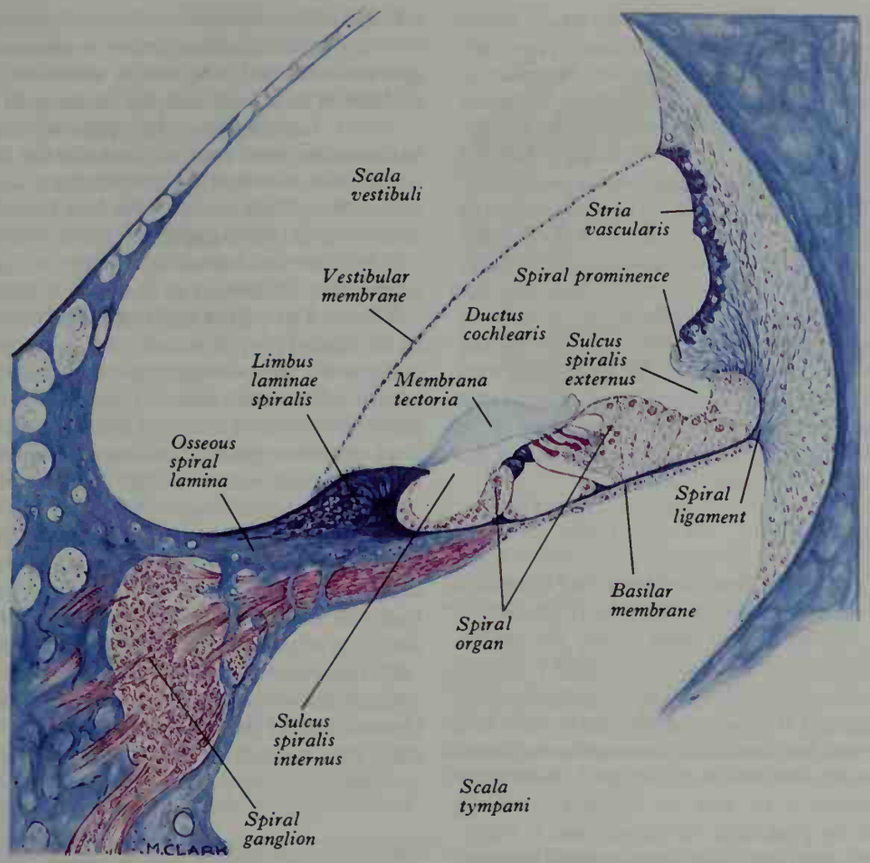
THE ENDOLYMPHATIC DUCT AND SAC

Throughout the endolymphatic duct, its surface cells closely resemble those lining the other non-specialized parts of the membranous labyrinth. As mentioned earlier, the duct continues into a blind-ended saccus endolymphaticus which expands under the dura mater on the posterior surface of the petrous temporal bone. Here the saccus is surrounded by a well-vascularized connective tissue, and its epithelium changes to tall columnar cells of two main types. The one variety has fairly dense cytoplasm, but is otherwise unspecialized. The other type is less dense, its luminal surface bears a profusion of long microvilli, and its cytoplasm carries numerous mitochondria, pinocytotic invaginations and vesicles, and larger smooth-walled vacuoles.



The endolymph which fills the different parts of the membranous labyrinth contrasts sharply in its composition with the perilymph which surrounds it externally. Whilst the latter is roughly comparable with extracellular tissue fluid or cerebrospinal fluid, the endolymph resembles intracellular fluid in its ionic composition, being rich in potassium ions, but poor in sodium ions. It is widely accepted that endolymph is a form of secretion, but its precise source is still an open question. The various structures considered to be involved in its production include the *dark cells* of the utricle and semicircular ducts, the columnar cells of the *planum semilunatum*, and the specialized epithelial cells and related blood vessels of the *stria vascularis* of the cochlear duct (*vide infra*). Whatever the relative contributions from these different sources, it is thought that the endolymph circulates and then enters the ductus endolymphaticus to be removed by the specialized epithelial cells of the saccus into the surrounding vascular plexus. Pinocytotic removal of fluid in other parts of the labyrinth is, however, not excluded.

A unique positive electrical potential exists in the endolymphatic spaces. This varies from +77 millivolts in the cochlear duct near the stria vascularis, to about +4 millivolts in the utricle, whilst it is absent or even negative in the ampullae of the semicircular ducts. Thus, a very large difference of potential of some 150 millivolts exists across the cell membrane of the cochlear hair cells, between the cochlear endolymph and the cell interior. This may account in part for the extreme sensitivity to mechanical deformation shown by these *auditory* hair cells (*vide infra*).



THE COCHLEAR DUCT

The duct of the cochlea (**7**.297, 298) consists of a spirally arranged tube within the bony canal of the cochlea and lying along its outer wall.

As already stated (p. 1202), the osseous spiral lamina extends only part of the distance between the modiolus and the outer wall of the cochlea, while the *basilar membrane* stretches from the free edge of the lamina to the outer wall of the cochlea, and completes the roof of the scala tympani. The endosteum of the outer wall of the cochlea is thickened to form the *spiral ligament of the cochlea*; it projects inwards and to it is attached the outer edge of the basilar membrane. A second and more delicate *vestibular membrane*, extends from the thickened endosteum covering the osseous spiral lamina to the outer wall of the cochlea, where it is attached at some distance above the outer edge of the basilar membrane. A canal is thus shut off between the scala tympani below and the scala vestibuli above; this is the *duct of the cochlea* (**7**.298). It is triangular on transverse section, its roof being formed by the vestibular membrane, its outer wall by the endosteum lining the bony canal, and its floor by the basilar membrane and the outer part of the osseous spiral lamina. The upper extremity of the duct of the cochlea is closed, and is named the *lagaena*; it is attached to the cupola (p. 1202). The lower end turns medially, and narrows

7.297 A horizontal section through the left temporal bone. (Drawn from a section prepared at the Ferens Institute and kindly lent by the late Professor J. Kirk.)

7.298A A section through the second turn of the cochlea indicated in the previous figure. The modiolus is to the left. (Mallory's stain.)

into the *ductus reuniens*, through which it communicates with the saccule (7.294). The spiral organ is situated on the basilar membrane. The vestibular membrane is thin and is covered on its two surfaces by a layer of flattened epithelium. The endosteum forming the outer wall of the duct of the cochlea is greatly thickened and forms the spiral ligament. It projects inwards, inferiorly, as a triangular prominence, termed the *crista basilaris*, to which the outer edge of the basilar membrane is fixed; immediately above this there is a concavity (the *sulcus spiralis externus*), above which the periosteum is thickened, highly vascular and forms a surface projection, the *spiral prominence*, which above this again continues into a specialized periosteal zone, the *stria vascularis*.

Ultrastructural studies have added many details concerning these different regions, including many features of the spiral organ. These can only be touched on briefly here, and the interested reader should consult Babel *et al.* (1970), who include an extensive bibliography.

THE VESTIBULAR MEMBRANE

The vestibular membrane (of Reissner) consists of two layers of flattened epithelial cells with an intervening basal lamina. The aspect facing the scala vestibuli is clothed with perilymphatic cells which are fairly thick in their central perinuclear zone, but elsewhere the cytoplasm is extremely attenuated; adjacent cells establish zonulae occludentes between them. The endolymphatic surface is covered with typical squamous epithelial cells, again joined by zonulae occludentes. Their cytoplasm contains a number of mitochondria and numerous vesicles; the basal surface is sometimes smooth but often complexly invaginated into the cell; the free surface carries numerous, short, irregular microvilli. These cells may be involved in fluid transport.

THE STRIA VASCULARIS

The stria vascularis, as noted above, lies on the outer wall of the cochlear duct immediately above the spiral eminence. It is unique in possessing a specialized stratified epithelium which carries a rich plexus of *intra-epithelial capillaries*. The epithelium consists of three cell types: (1) superficially placed *marginal*, *dark* or *chromophil cells*; (2) *intermediate*, *light*, or *chromophobe cells*; and (3) *basal cells*.

The endolymphatic surface is formed exclusively by the dark cells. The intermediate and basal cells are cytologically similar, differing merely in position. Their pale cytoplasm contains scattered mitochondria, numerous pinocytotic vesicles and a number of melanin granules. These cells send cytoplasmic processes towards the surface, where they are insinuated between and around the deeper parts of the marginal cells.

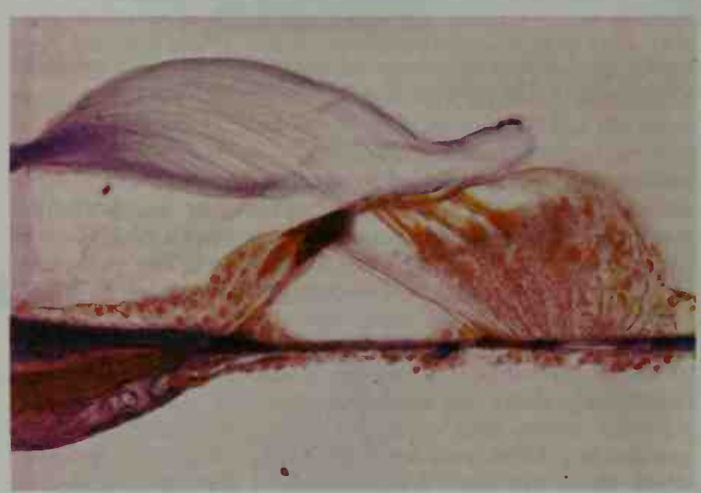
The marginal dark cells are highly specialized, with a dense granular cytoplasm containing many mitochondria and pinocytotic vesicles. The deep part of the cell consists of many long cytoplasmic processes separated by deep invaginations of the plasmalemma; each process contains a series of mitochondria. The intra-epithelial capillaries are closely enveloped both by descending processes from the dark cells and ascending processes from the intermediate and basal cells.

The stria vascularis is considered to be an ion-transporting mechanism which maintains the unique ionic composition of the endolymph. As indicated above, however, other regions of the membranous labyrinth may also be involved in this activity. It has been established by exploration of the stria with microelectrodes that it is the source of the large positive endocochlear electrical potential. The maintenance of this potential is directly and immediately dependent upon an adequate oxygenation level of the epithelial cells, provided by the blood circulation through its intra-epithelial capillaries.

THE OSSEOUS SPIRAL LAMINA

The osseous spiral lamina consists of two plates of bone, and between these are the canals for the transmission of the filaments of the cochlear nerve. On the upper plate of that part of the lamina which is contained within the duct of the cochlea the periosteum is thickened to form the *limbus laminae spiralis* (7.298, 299); this

ends externally in a concavity, the *sulcus spiralis internus*, which presents, on section, the form of the letter C; the upper part formed by the overhanging edge of the limbus is the *vestibular lip* (*labium*); the lower part, prolonged and tapering, is the *tympanic lip* (*labium*), and is perforated by numerous foramina for the passage of the branches of the cochlear nerve. The upper surface of the vestibular lip is intersected at right angles by a number of furrows, separated by numerous elevations; these present the appearance of teeth on the free surface and margin of the lip, the *auditory teeth* (*dentes acoustici*) (7.299). The limbus is covered by a layer appearing superficially as a squamous epithelium, but only the cells covering the teeth are flattened, those in the furrows (7.300) being columnar, and occupying the intervals between the elevations. This epithelium is continuous on the one hand with that lining the sulcus spiralis internus, and on the other with that covering the under surface of the vestibular membrane. It is considered by some observers that the interdental cells secrete the material forming the tectorial membrane (*vide infra*).



THE BASILAR MEMBRANE

The basilar membrane (7.298, 299) stretches from the tympanic lip of the osseous spiral lamina to the crista basilaris. It consists of two zones, a thin *zona arcuata*, stretching from its medial attachment, the limbus spiralis, to the bases of the outer rods and supporting the organ of Corti, and an outer thicker part, the *zona pectinata*, commencing beneath the bases of the outer rods and attached laterally to the crista basilaris. The zona arcuata is seen by electron microscopy to be composed of compact bundles of small collagen-like filaments 8–10 nm in diameter, mainly disposed radially. In the zona pectinata the membrane is three-layered with an upper layer composed of a homogenous network of transverse fibres, a lower layer of compact bundles of longitudinal fibres and an intermediate structureless layer containing a few cells. At its attachment to the crista basilaris, the upper and lower layers fuse and the membrane consists of one layer. The length of the basilar membrane is about 35 mm; its width gradually increases from 0·21 mm in the basal turn to 0·36 mm in the apical turn of the cochlea, and this increase is accompanied by a corresponding narrowing of the osseous spiral lamina, and a decrease in the thickness of the crista basilaris. The under surface of the membrane is covered by a layer of vascular connective tissue and elongate perilymphatic cells; one of the vessels in the connective tissue is larger than the rest, and is named the *vas spirale*; it lies below Corti's tunnel (*cuniculum internum*).

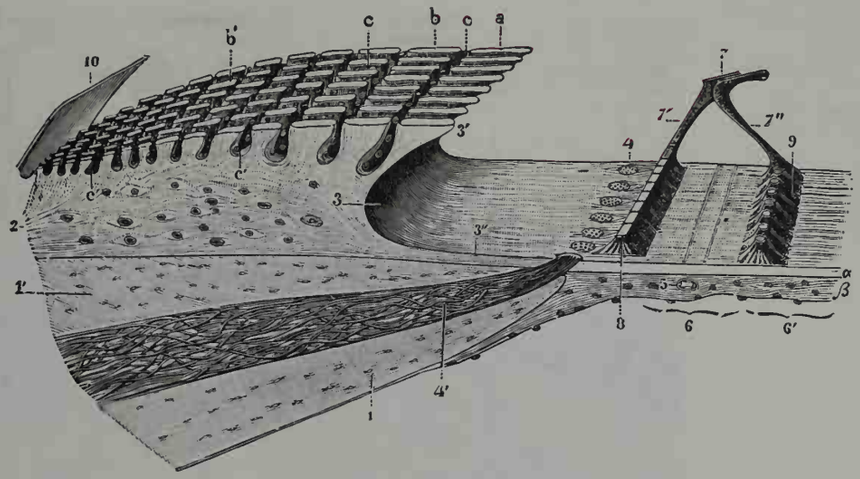
THE SPIRAL ORGAN OF CORTI

The spiral organ (Smith and Dempsey 1957; Engström and Wersäll 1958; Babel *et al.* 1970; Ades and Engström 1974) is composed of a series of epithelial structures placed upon the zona arcuata of the basilar membrane (7.298–301). The more central of these structures are two rows of rod-like bodies, the *internal and external rod cells of Corti* or *pillar cells*. The bases or *foot plates* (*crura*) of the rod cells are expanded, and rest on the basilar membrane, touching each other, but apically the neighbouring rods are widely separated; the two rows incline towards each other and, coming into contact above, enclose between them and the basilar membrane the *tunnel of Corti* (*cuniculum internum*) (7.300A), which is triangular in cross-section. On the medial side of the inner rods there is a single row in *internal* (*inner*) *hair cells*, and on the lateral side of the outer rods, three or four rows of *external* (*outer*) *hair cells*, together with certain supporting cells, the *phalangeal cells of Deiters*, and the *cells of Hensen* (*cellulae limitans externae*). The free ends of the outer hair cells and the apical processes of the cells of Deiters form a highly regular mosaic of cell apices termed collectively the *reticular lamina or membrane* (Engström *et al.* 1966). The entire organ is covered by the tectorial membrane, a narrow gap separating this structure from the reticular lamina except where the apical stereocilia of the outer hair cells project to make contact with the tectorial membrane. In addition to the tunnel of Corti, sometimes termed the *inner tunnel* (*cuniculum internum*), described above, other spaces exist in relation to the outer hair cells which connect through intercellular crevices with each other and with the inner tunnel. These include the *outer tunnel* (*cuniculum externum*) situated between the outermost hair cells and the inner cells of Hensen, beneath the reticular lamina, and the *space of Nuel* (*cuniculum medium*) between the outer rods of Corti and the outer hair cells. The latter is continuous with the extracellular spaces which surrounded the upper two-thirds of the outer hair cells. This complex system of intercommunicating spaces is filled with a fluid termed *cortilymph* which is not continuous with either perilymph or endolymph, and is probably distinct in its chemical constitution (Engström 1960).

The rod or pillar cells of Corti each consist of a base or *crus*, an elongated part or *scapus*, and an upper end or *caput*; each foot plate and head is closely applied to it neighbour but the bodies are separate from each other. The nucleus lies in the triangular foot plate. The body of each rod is finely striated, but in the head there is an oval nonstriated portion which stains deeply with carmine. Electron microscopy shows many microtubules 13–15 nm in diameter, often arranged in parallel bundles, running lengthwise in the body of the rods and then diverging above to terminate in a superficial layer of dense granular cytoplasm, the *cuticle*, in the head. Below, the microtubules arise over a wide area of the limiting membrane of the basal crus from the cytoplasmic densities of an array of hemidesmosomes. Within the body of the rod, transverse sections show that the microtubules are often arranged in a regular square lattice. Detailed analysis of the upper termination of the microtubules shows that many of them curve into the reticular lamina (*vide infra*) to end in junctional complexes (p. 6; 1.4) established with either similar expansions

7.298B A transverse section of the spiral organ of Corti (cat), stained with the Mallory trichome method to show the inner and outer hair cells (orange), the basilar membrane (dark blue) and tectorial membrane (light blue), and various supporting cells, including those surrounding the tunnel of Corti. Magnification × 400.

from the supporting cells of Deiters or with the subapical lateral surfaces of the hair cells. The nucleated cytoplasmic zones which partly envelop the rods and extend on to the floor of Corti's tunnel, occupy the angles between the rods and the basilar membrane; these may be looked upon as the less differentiated parts of the cells from which the rods have been formed.



The *inner rods* number nearly 6,000, and their bases rest on the basilar membrane close to the tympanic lip of the sulcus spiralis internus. The body of each is sinuously curved and forms an angle of about 60° with the basilar membrane. The head resembles the proximal end of the ulna, and presents a deep concavity which accommodates a convexity on the head of the outer rod. The head plate, or portion overhanging the concavity, overlaps the head plate of the outer rod.

The *outer rods*, almost 4,000 in number, are longer and more obliquely set than the inner, forming with the basilar membrane an angle of about 40°. Their heads are convex internally; they fit into the concavities on the heads of the inner rods, and are continued outwards as thin flattened plates, the *phalangeal*

processes, which unite with the phalangeal processes of Deiters' cells to form the *reticular lamina or membrane* (*vide infra*).

The distances between the bases of the inner and outer rods increase from the base to the apex of the cochlea, while the angles between the rods and the basilar membrane diminish.

The hair cells are short columnar or piriform cells depending upon their site in the spiral organ; their free ends are on a level with the heads of the rods of Corti, and each is surmounted by about 50–100 hair-like stereocilia. The deep ends of the cells reach about halfway along the rods of Corti, and each contains a large open-faced euchromatic nucleus. The plasma membrane at the basal pole of the cell forms synaptic contacts with cochlear nerve fibres. The cytology and supporting structures vary with the position of the hair cells, which are arranged as inner and outer groups set at an angle to each other. The *inner* hair cells, about 3,500 in number, are arranged in a single row on the inner side of the inner rods of Corti, and since their diameters are greater than those of the rods, each is related to more than one rod. The free ends of the inner hair cells are encircled by a cuticular membrane which is fixed to the heads of the inner rods (*vide infra*). Adjoining the inner hair cells there are one or two rows of columnar supporting cells, which, in turn, are continuous with the cubical cells lining the sulcus spiralis internus. The columnar supporting cells which lie adjacent to the inner rods of Corti and surround the inner hair cells are the *inner phalangeal cells*. These are succeeded medially by slender columnar *border cells* of decreasing height which gradually merge medially into the cuboidal epithelium of the sulcus mentioned above. The *outer* hair cells number about 12,000 and are nearly twice as tall as the inner. In the basal coil of the cochlea they are arranged in three regular rows; in the apical coil, in four or five less regular rows.

Part of the vestibular membrane.

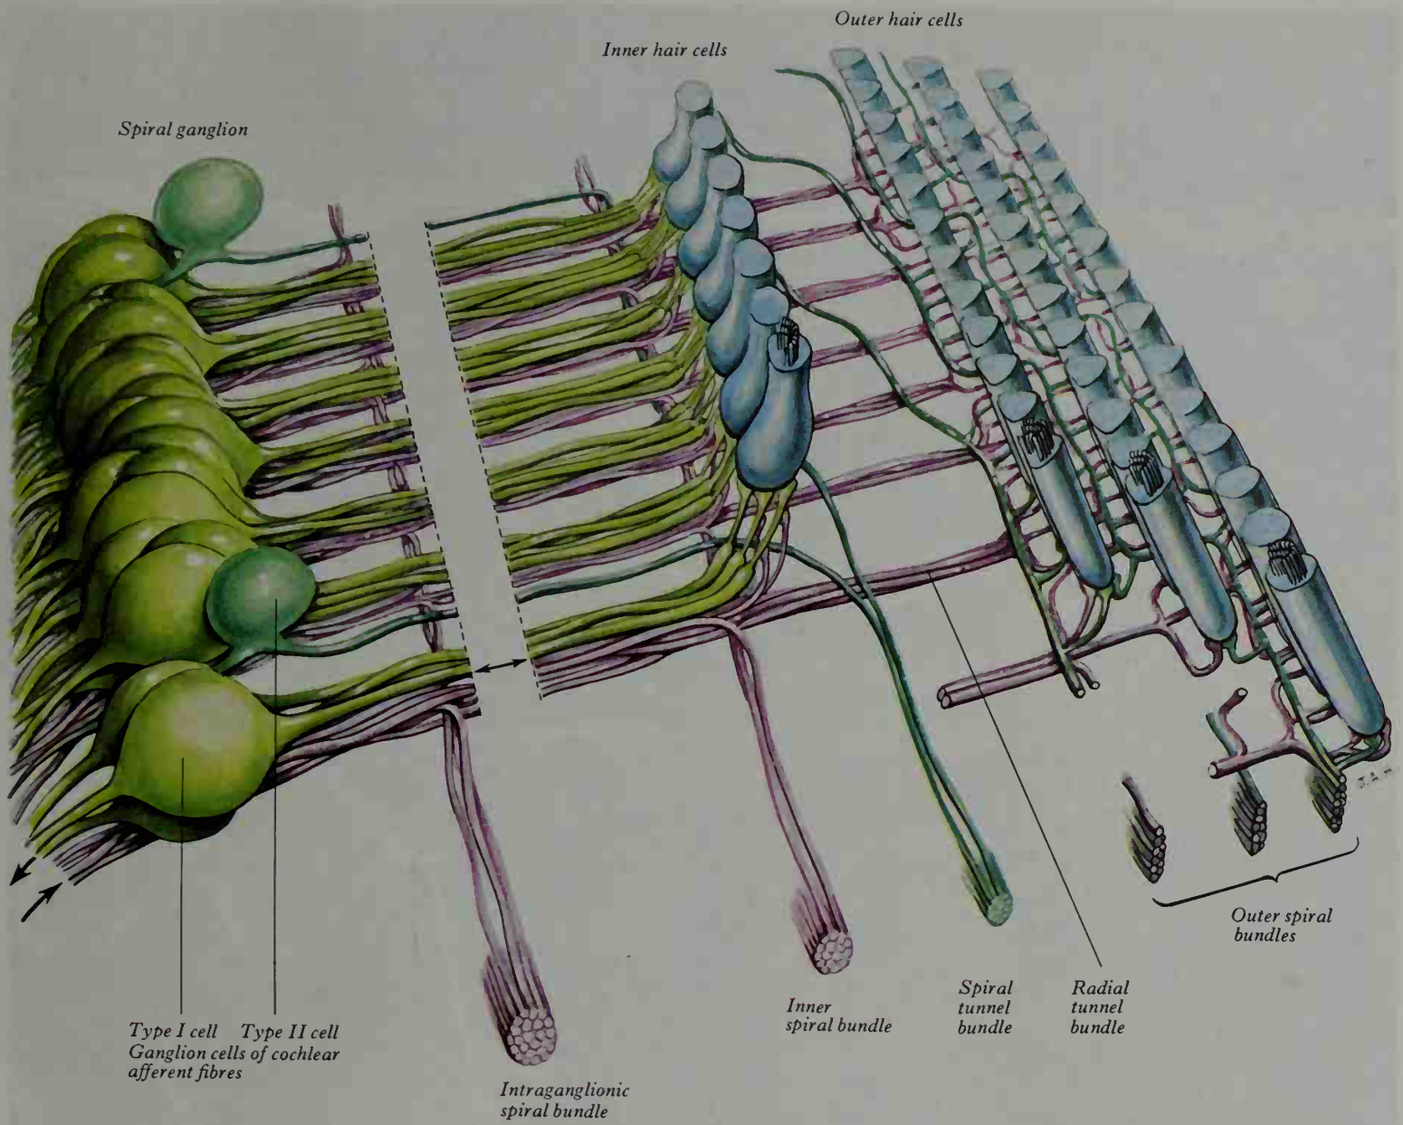
Electron microscopy has added much about the detailed construction of the cochlear hair cells and their supporting structures (see for example Babel *et al.* 1970). Briefly, the **inner hair cells** resemble in some respects the type I vestibular hair cells described previously (p. 1204). Each possesses a relatively short piriform body, the expanded basal region containing a large euchromatic nucleus (7.300, 301); this is surmounted by a constricted 'neck' which on its free apical surface carries 50–60 hairs or stereocilia, but no kinocilium. The cytoplasm contains an abundance of organelles, indicative of a relatively high metabolic rate. These include numerous mitochondria which are particularly abundant in the apical parts of the cell, free polyribosome groups, agranular endoplasmic reticulum, various vesicles and a few lysosomes. Microtubules and microfilaments are also present, notably in the basal regions of the cytoplasm. Immediately beneath the apical surface of the cell there is a thick layer of filamentous and granular material, the *cuticular plate*, forming a continuous cap except at a cuticle-free gap which is present on the region of the apex nearest to the tunnel of Corti. At the lateral margins of the cell the cuticular plate is attached to the intercellular junctions with the neighbouring phalangeal and pillar cells.

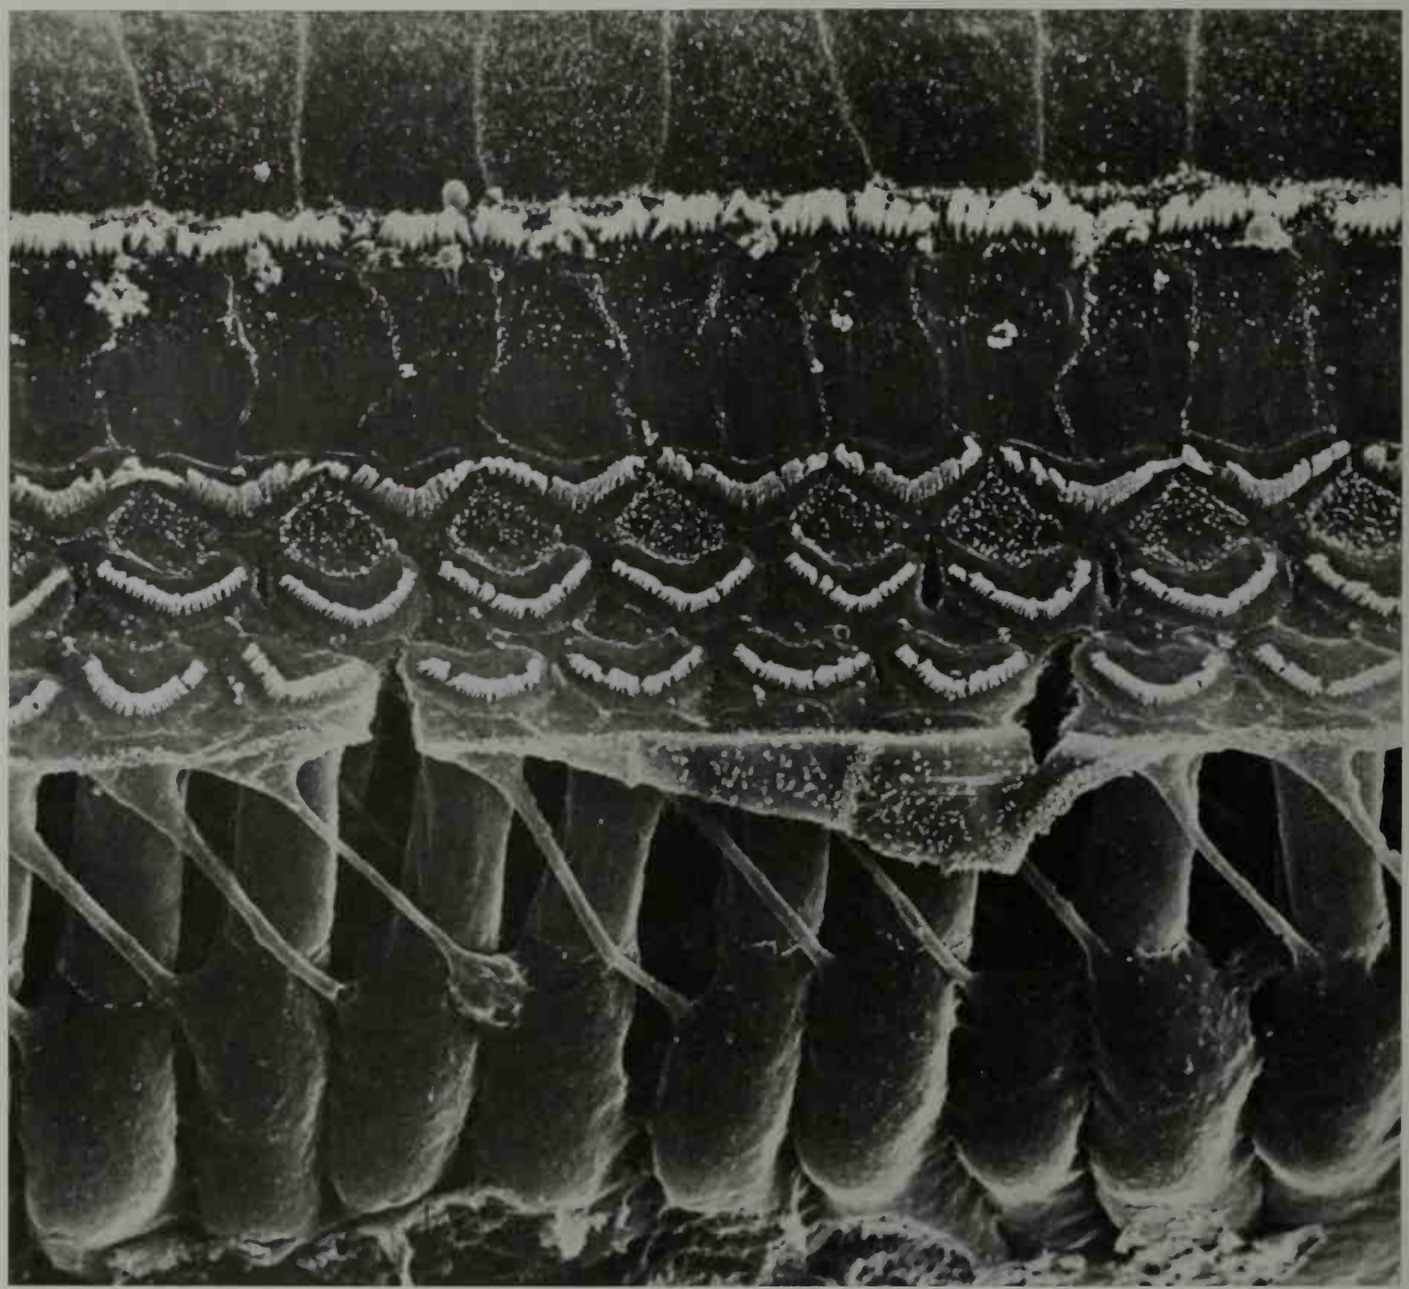


The stereocilia resemble in structure those of vestibular hair cells, being very narrow at their base and expanding to a cylindrical process about 6 μm long at a maximum, and 0·2 μm wide. These structures resemble microvilli in that they are clothed by an extension of the apical plasma membrane of the hair cell, and contain numerous longitudinally directed microfilaments composed of actin. Near their bases an additional dense axial rootlet is present centrally, and this penetrates deep into the cuticular plate to act as an anchoring device. Because of their shape, the stereocilia are able to bend at their narrow basal ends when stimulated by fluid movements or other mechanical disturbances resulting from auditory stimuli arriving at the cochlea (*vide infra*). Unlike the vestibular hair cells, a kinocilium with the typical microtubular interior is not present in mature inner hair cells of the cochlea, although it is found during early development. Its place is taken within the cell by a centriole positioned beneath the apical membrane within the cuticle-free gap, probably as a non-functional vestige.

When viewed from the surface the stereocilia are seen to be arranged in the form of a shallow U with its base pointing towards the centriole, and thus also towards the tunnel of Corti. Each cluster of stereocilia is made up of three or four rows progressively taller towards the tunnel side of the cell; it is not certain if the tips of the longest touch the tectorial membrane, there being no direct evidence for such a contact. The plasma membrane at the basal pole of the cell is in synaptic contact with two types of synaptic boutons derived from cochlear nerve fibres. The terminals of *afferent* fibres contain relatively few mitochondria and microtubules, and a number of clear vesicles of varying diameter. Both the presynaptic (hair cell) and postsynaptic (bouton) membranes are thickened, the latter more markedly, and the presynaptic cytoplasm contains aggregates of both clear and dense-cored synaptic vesicles. *Accessory synaptic structures* which take the form of electron-dense rods, rings or lamellae around which synaptic vesicles are clustered, are commonly present. The terminal boutons of *efferent* fibres, in contrast, contain a number of mitochondria, microtubules and a profusion of synaptic vesicles, the majority of which are small, spherical and clear, but some are larger with dense cores. Although often described as making synaptic contact with the base of the inner hair cells, it has now been shown that the efferent terminals never make such contacts in the cat, and only infrequently in the guinea-pig and man. Much more numerous are contacts between the efferent terminal and the lateral aspect of an *afferent fibre bouton*. Presumably activity in the efferent fibre modulates the transmission characteristics of the afferent fibre terminal. The inner hair cells are, apart from their areas of synaptic contact just described, wholly surrounded by the cytoplasm of the inner phalangeal supporting cells. The superficial rim of the latter, where it encircles the lateral margin of the apical surface of the hair cell, is joined to it by a circular zone which, in section, is seen to consist of a junctional complex (p. 7; 1.5). Similar specialized junctions exist between the outer aspect of the rim of the phalangeal cell and expansions from the inner rod of Corti. These surface specializations make up the 'cuticular membrane' of light microscopy mentioned above.

The outer (external) hair cells are more highly specialized than the internal, though with a number of features in common. They are considerably longer cells, cylindrical in form, with a large basally placed euchromatic nucleus. Numerous mitochondria are found along the lateral walls of the cell close to the plasma membrane, and in the basal cytoplasm below the nucleus. Otherwise, the interior of the cell has far fewer organelles in comparison with the inner hair cell; the most notable structures

7.300A Three-dimensional schema of the structure of the cochlear spiral organ and stria vascularis, showing the arrangement of the various types of cell, and their overall innervation. The organization of the inner and outer hair cells, and their synaptic connexions are depicted below. Sensory nerve terminals are coloured green, and efferent fibres purple. (See text for variant terminology.)

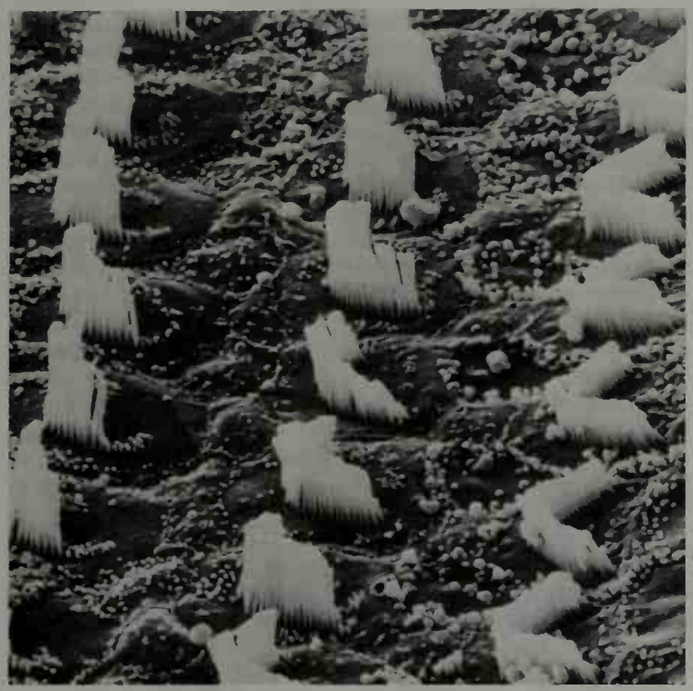


7.300B Diagram of the innervation of the spiral organ, showing the distribution of afferent and efferent fibres. The ganglion cells of the sensory nerve fibres include those related to the inner hair cells (dark green) and others innervating the outer hair cells (light green). Efferent fibres are depicted in purple. Note the great contrast between the multiple, convergent afferent innervation of the inner hair cells (about ten fibres to each cell) and the divergent supply of the outer hair cells (one afferent fibre to about ten cells).

are various complexes of flattened membranous cisternae which are attached by thin peg-like filaments to the lateral walls of the cell, or are present in the apical cytoplasm as concentric whorls (Hensen bodies) which are probably precursors of the lateral cisternae. These membranes are likely to act as strengthening elements helping to retain the cylindrical shape of the cell, although some metabolic functions cannot be ruled out. Other structures within the cell include microtubules and microfilaments, polyribosomes, vesicles, lysosomes and glycogen; however, the great majority of the cytoplasm is filled with a pale matrix containing fine filaments and granules of an unknown composition. A cuticular plate similar to that found in the inner hairs cells forms the apical cap to the cytoplasm, and serves as anchorage to the rootlets of the stereocilia; the latter structures although resembling the inner hair cell stereocilia, are slightly narrower and are arranged in the form of a V or W, the base of the letter pointing away from the tunnel of Corti and towards a centriole in the cuticle-free gap in the apex of the cell. Up to 100 stereocilia have been counted in a single group, arranged in ranks of graded length (7.301 A–C). The groups in the apical portion of the cochlea are taller than those in the base, but in all groups the longest stereocilia are embedded in the lower surface of the tectorial membrane (Hunter-Duvar 1976). Both the inner and outer hair cells are so arranged on the basilar membrane that their centrioles are on the side of the cell which is most distant from the central modiolus. This observation is of considerable functional significance and suggests that transverse shearing forces between the hair cells and tectorial membrane would be the most effective in stimulating the sensory receptors.

The basal pole of each outer hair cell is received into a cup-like depression on the upper end of an outer phalangeal cell of Deiters (*vide infra*), except at the synaptic contacts with cochlear nerve fibres. In this case, however, both the afferent and efferent terminals, which are structurally similar to those of the inner cells, are functionally related directly to the plasma membrane of the hair cell itself (Engström *et al.* 1965).

The external phalangeal cells of Deiters (7.300), are between the rows of the outer hair cells; their expanded bases are planted on the basilar membrane, while the opposite end of each presents, as mentioned above, an asymmetrical cup-like region, partially enveloping the base of a hair cell, and a finger-like *phalangeal process*, which extends up between the hair cells to the reticular membrane to form a plate-like expansion (*vide infra*). The cytoplasm of Deiters' cells contain bundles of microtubules, which arise from basally placed hemidesmosomes, and which continue upwards into the phalangeal process. Immediately to the outer side of Deiters' cells there are five or six rows of columnar cells, the *supporting cells of Hensen* or *external limiting cells* (7.300), and even farther on the outer edge, the cells of *Claudius* or *external supporting cells*. Their free surfaces are also beset with microvilli. Near the lagaena these cells contain fat globules which decrease in number and size as the duct of the cochlea is traced towards the



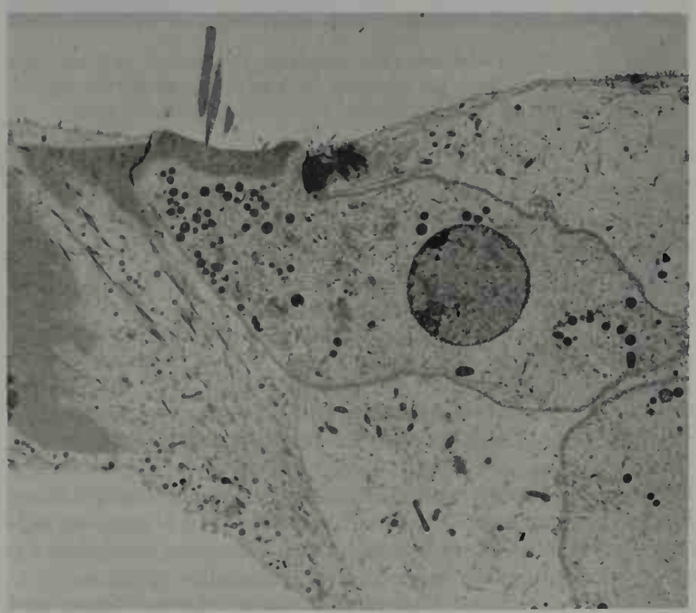
7.301A A scanning electron micrograph of a portion of the spiral organ of Corti (guinea pig) dissected to expose the outer row of outer hair cells and their attendant Deiters' cells with narrow phalangeal processes. Magnification × 2,500.

basal coil. It has been suggested (Hallpike 1931) that these globules provide a graduated loading mechanism, which tunes the region of the lagaena to low tones.

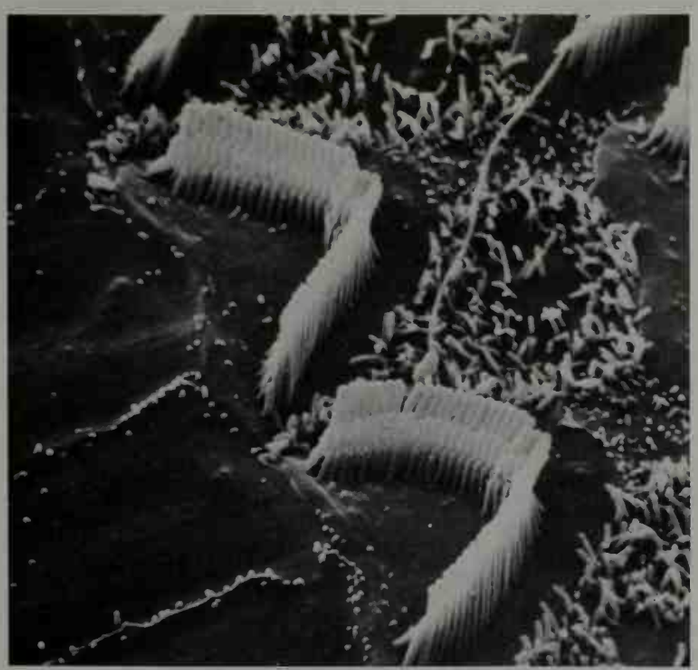
The reticular lamina (7.301), when viewed with a light microscope, appears as a delicate framework perforated by circular holes which are occupied by the free ends of the outer hair cells. It extends from the heads of the outer rods of Corti to the external row of the outer hair cells, and is formed by several rows of minute violin-shaped cuticular structures, called *phalanges*, between which are circular apertures containing the free ends of the hair cells. The innermost row of phalanges consists of the phalangeal processes of the outer rods of Corti; the outer rows are formed by the modified free ends of Deiters' cells. Electron microscopy has now shown that the reticular lamina consists of these horizontal expansions from the outer rods and phalangeal cells which carry bundles of microtubules and tonofibrils in the attenuated veil of dense cytoplasm which they contain. The expansions encircle the uppermost rim of the hair cells, where junctional complexes (occluding zones and desmosomes) are formed, and in which the microtubules end. Beneath this delicate supporting system, the upper two-thirds of the lateral surfaces of the outer hair cells are not in contact with supporting cells, but are bathed by the fluid termed cortilymph (*vide supra*).

The reticular lamina is of great significance in auditory stimulation of the sensory cells because it forms a rigid plate capable of transmitting lateral shearing forces generated by the movements of the basal lamina to the hair cells (*vide infra*). It is also interesting that if any hair cells are lost because of acoustic or drug-induced trauma, the phalangeal processes close together to fill the gap, leaving a disturbance in the regular pattern of the lamina (a *phalangeal scar*).

The membrana tectoria (7.300) overlies the sulcus spiralis internus and the spiral organ of Corti. It consists, in fixed preparations, of delicate fibres embedded in a jelly-like matrix (Iurato 1967; Steel 1978). In electron microscopic preparations filaments of 4 mm diameter are seen; they consist of protein which resembles keratin, associated with mucopolysaccharides. The membrana tectoria is wider and thicker in the apical than in the basal part of the cochlea. Its inner part is thin and is attached to the vestibular lip of the limbus laminae spiralis, the attachment reaching as far as the vestibular membrane. The outer part is thick and padlike, the thickness being greatest over, or slightly to the



7.301B A scanning electron micrograph of a group of outer hair cells arranged in three rows, showing the arrangement of their stereocilia and related phalangeal processes of the Deiters' cells, collectively forming the reticular lamina (see text). Short microvilli are visible on the surfaces of the non-sensory cells. Magnification × 3,000.



inner side of, the upper ends of the rods of Corti. Scanning electron microscopy has shown that a network of fine ridges is present on the upper surface, but the lower surface is relatively smooth, except where the tips of the outer hair cell cilia leave a pattern of W- or V-shaped impressions. Another feature seen in a number of species is a longitudinal ridge running along the under surface near the tunnel of Corti; this structure is visible by light microscopy as *Hensen's stripe*. The *interdental cells* of the vestibular lip to which the tectorial membrane is attached have a well-developed Golgi apparatus, numerous mitochondria, and free polysomes; it is thought that they secrete the membrane. The tips of the outer hair cell stereocilia are embedded in the tectorial membrane, but this attachment is often broken during histological preparation (7.300).

The vestibulocochlear nerve divides near the lateral end of the internal acoustic meatus into an anterior or *cochlear*, and a posterior or *vestibular* component. (The central connexions and proximal parts of these nerves are described on pp. 1073, 1074.)

The vestibular nerve supplies the utricle, the saccule and the ampullae of the semicircular ducts. The *vestibular ganglion*, from the bipolar nerve cells of which the fibres of the nerve take origin, is situated in the trunk of the nerve within the internal acoustic meatus. On the distal side of the ganglion the nerve divides into superior, inferior and posterior vestibular branches. (The nerve sometimes divides on the proximal side of the ganglion, which is then also divided into three parts, one in each branch of the nerve. When this occurs, the ganglion of the posterior division is placed in the foramen singulare.) The filaments of the *superior branch* are transmitted through the foramina in the superior vestibular area, and end in the macula of the utricle and in the ampullary crests of the anterior and lateral semicircular ducts; those of the *inferior branch* traverse the foramina in the inferior vestibular area, and

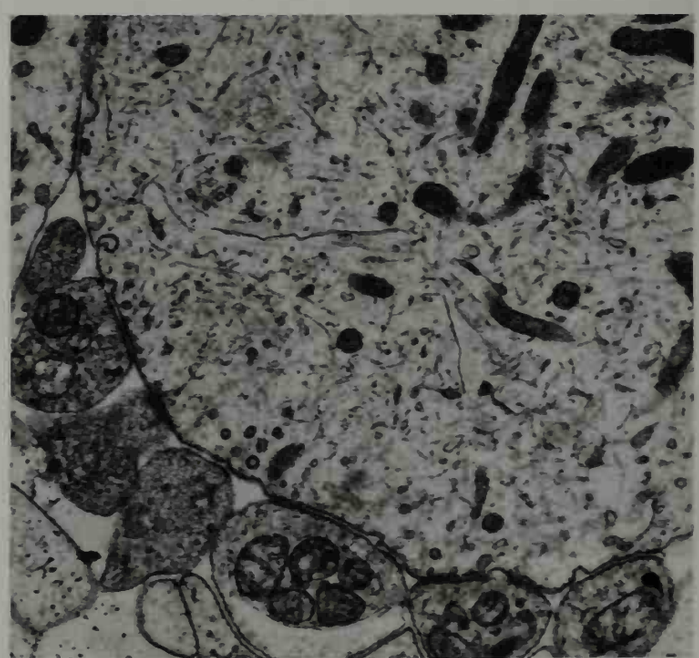
end in the macula of the saccule. The *posterior branch* runs through the foramen singulare at the postero-inferior part of the bottom of the meatus (7.302) and divides into filaments for the supply of the ampullary crest of the posterior semicircular duct.

The cochlear nerve, the nerve of hearing, divides into numerous filaments at the base of the modiolus; those for the basal and middle coils pass through the foramina in the tractus spiralis foraminosus, those for the apical coil through the central canal, and the nerves bend outwards and pass between the lamellae of the osseous spiral lamina. The *spiral ganglion* (7.298), consisting of bipolar nerve cells from which the fibres of the nerve take origin, occupies the spiral canal of the modiolus. Reaching the outer edge of the osseous spiral lamina, the nerve fibres lose their myelin sheaths and pass in bundles through the foramina in the tympanic lip (the *habenulae perforatae*); some end by arborizing around the deep ends of the inner hair cells, while others pass between the rods of Corti and across the tunnel of Corti, and end in relation to the outer hair cells. The latter pass between the cells of Deiters and are often enfolded by them. The hair cells in the basal and middle coils are more richly supplied with nerves than

7.301E A scanning electron micrograph of the surface of Reissner's membrane, viewed from the cochlear duct aspect, showing the regular pattern of simple squamous epithelial cells. Magnification × 2,500.

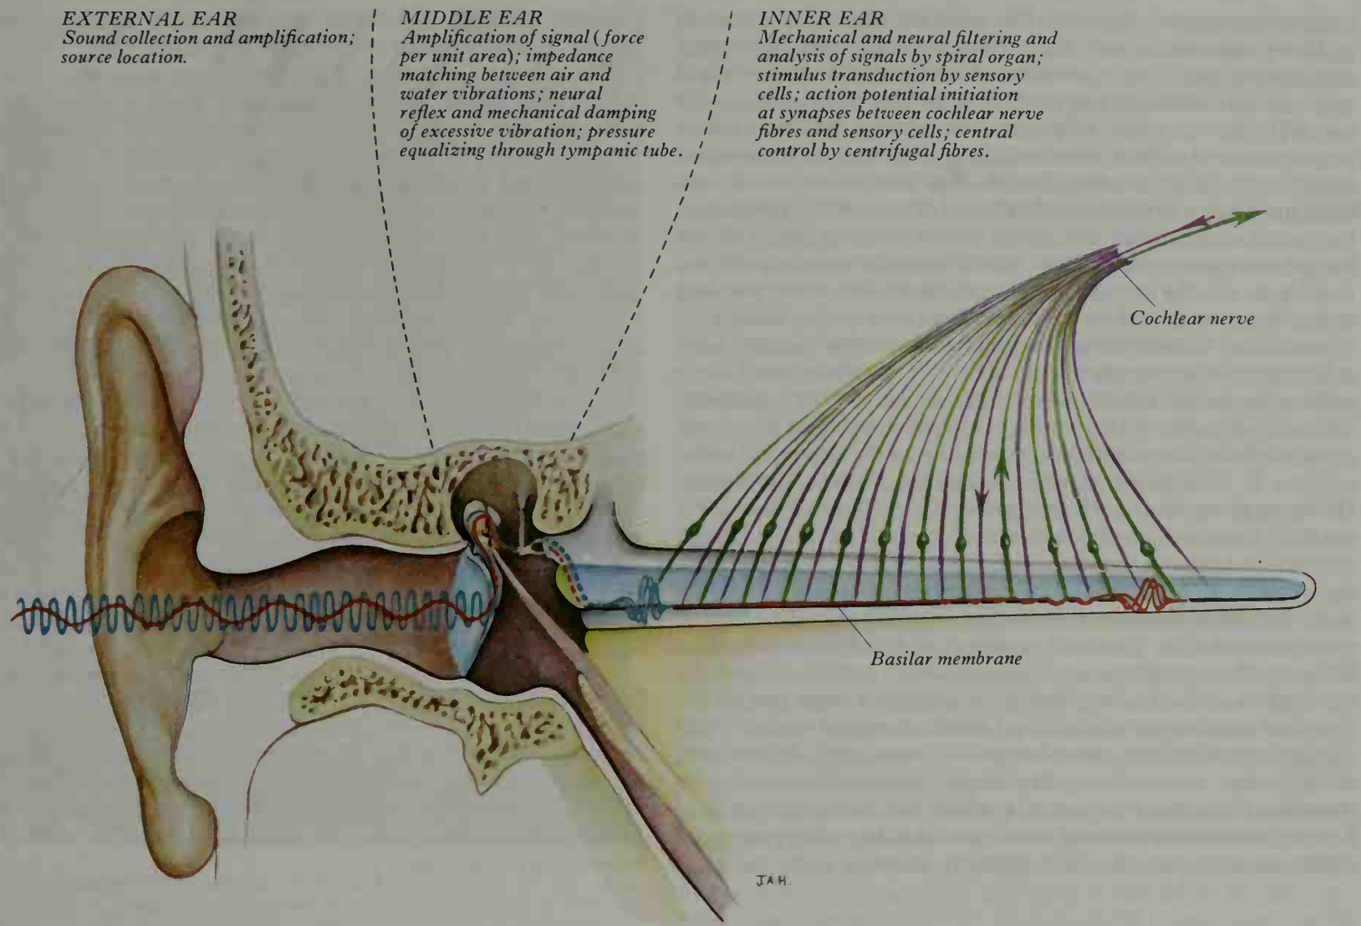
those in the apical coil. The cochlear nerve gives off a vestibular branch to supply the vestibular end of the duct of the cochlea; the filaments of this branch traverse the foramina in the cochlear recess (p. 1201). The cells of the spiral ganglion are also of considerable interest. Two classes (Types I and II) have been described (Spoendlin 1974), the Type I cells being large bipolar elements ensheathed by myelin and giving off large myelinated axons both centrally and peripherally. The Type II cells are smaller and non-myelinated and, oddly, appear to possess only a peripherally directed, non-myelinated process. Various experimental studies have shown that the Type I cells provide the afferent innervation of the inner hair cells, ten ganglion cells being connected to each sensory cell, whereas the Type II ganglion cells are afferent to the outer hair cells, each supplying more than ten sensory cells by extensive branching (Spoendlin 1978).

The structure of the terminal boutons of the efferent and afferent nerve fibres has already been described. The efferent nerve fibres belong to the olivocochlear system first described by Rasmussen (1946). It is now established that this bundle contains both crossed and uncrossed components; the former start from the opposite retrolateral olivary group of neurons, whilst the latter arise from the so-called S-shaped segment of the ipsilateral olivary complex (Whitfield 1967; Iurato 1974). The pharmacology of the pathway is obscure, but it is apparently purely inhibitory in its actions, and alters the threshold level of the outer hair cells, and modifies the transmission through the afferent fibres from the inner hair cells.



The precise distribution of nerve fibres to the inner and outer rows of hair cells is now known in considerable detail. Briefly, the vast majority of the cochlear nerve fibres are distributed to the inner hair cells. The latter each receive the terminals of a number of radially disposed afferent fibres, which are themselves the sites of synaptic terminals from collateral branches of radially disposed inhibitory efferent fibres. The outer hair cells receive the minority of the cochlear nerve fibres. Their efferent fibres are radial in disposition and each fibre establishes inhibitory synapses with a large number of hair cells. The afferent fibres curve into a geometrically organized spiral system of fibres, each of which innervates numerous hair cells. These various fibres form distinct groups with specific orientations and positions within the cochlea, running either radially, or spirally, i.e. parallel to the organ of Corti (Spoendlin 1974). Amongst the different cellular structures of the cochlea lie, firstly, the spiral intraganglionic bundle within the modiolus consisting of non-myelinated fibres thought to be efferent axons; a similar group of efferent *inner spiral fibres* runs immediately beneath the row of inner hair cells, this bundle being pierced by the groups of axons emerging from the habenulae. More peripherally, the *spiral tunnel fibres* lie in the tunnel of Corti running along this space in bundles or as scattered single axons. Individual fibres also run longitudinally in the spaces between the outer pillar cells and the Deiters' cells, forming three distinct rows flanked and partially invaginated by these different supporting cells; these ranks of fibres collectively form the *outer spiral fibres*, and they consist of both afferent and efferent connexions of the outer hair cells, as do the spiral tunnel fibres already mentioned. Autonomic endings have also been observed, but these appear to be restricted to regions of the spiral organ on the modiolar side of the tunnel of Corti. Superimposed on this spiral pattern are the radial fibres afferent to the inner hair cells, and, crossing the space within the tunnel of Corti, to the outer hair cells. A more recent and detailed analysis of cochlear innervation is summarized in illustration 7.300.

The arteries of the labyrinth are: (1) the labyrinthine artery (p. 696), which may arise from the basilar artery, but is more often derived from the anterior inferior cerebellar artery; and (2) the stylomastoid branch of the occipital or posterior auricular artery. The labyrinthine artery divides at the bottom of the internal meatus into cochlear and vestibular rami. The cochlear branch subdivides into twelve to fourteen twigs, which traverse the canals in the modiolus, and are distributed, in the form of a capillary network, in the lamina spiralis and basilar membrane. The vestibular branches are distributed to the utricle, saccule and semicircular ducts.



The veins of the vestibule and semicircular canals accompany the arteries, and, receiving the veins of the cochlea at the base of the modiolus, unite to form the labyrinthine vein, which ends in the posterior part of the superior petrosal sinus or in the transverse sinus. A small vein, from the basal turn of the cochlea, traverses the cochlear canaliculus and joins the internal jugular vein.

THE MECHANISM OF THE AUDITORY RECEPTORS

Many elegant researches have been directed towards an understanding of the role of the different components of the ears, as analysers of the intensity and frequency patterns, and source location, of the sound wave trains which impinge upon them.

7.301F An electron micrograph of a group of efferent nerve endings at the base of an outer hair cell (guinea pig). Note the numerous mitochondria and vesicles within these endings, and the cytoplasmic densities on both the pre- and post-synaptic membranes × 10,000.

7.302 Diagram illustrating the principal activities of the peripheral auditory apparatus. For clarity the cochlea is depicted as though it had been uncoiled. The points of maximal stimulation of the basilar membrane by high frequency (blue) and low frequency (red) vibrations, together with their transmission pathways through the external and middle ear, are also indicated.

These are beyond the scope of a general textbook of anatomy, and monographs and original papers should be consulted.

In outline, sound waves which reach the air column in the external acoustic meatus cause a comparable set of vibrations in the tympanic membrane, and thus in the chain of auditory ossicles. Similar vibrations occur at the foot plate of the stapes, but here the force per unit area of the oscillating surface is increased some twentyfold. These are effective in overcoming the inertia of the perilymph thus producing pressure waves within it, which are conducted almost instantaneously to all parts of the basilar membrane. The latter varies continuously in its width, mass, and stiffness from the basal to the apical end of the cochlea, but its component fibres are *not* under tension. The behaviour of such a mechanical system, when exposed to a periodic oscillating pressure wave in the neighbouring perilymph, varies with the frequency of the oscillations. At very low frequencies, for example 50 Hz, the whole basilar membrane vibrates in phase, and at a similar frequency. As the frequency of the driving fluid pressure waves rises, the different parts of the basilar membrane oscillate less rapidly, and increasingly out of phase, from the basal to the apical end of the cochlea. Consequently, a series of *travelling waves* progresses along the membrane from the base towards the apex. At intermediate frequencies, the *amplitude* of these travelling waves rises slowly as they progress from the basal end, until a maximum amplitude is reached, after which point the amplitude falls rapidly on the apical side of the maximum. With increasing frequency of the driving oscillation, the *position* of the *maximum amplitude* of vibration of the basilar membrane moves progressively from the apical, towards the basal end of the cochlea. The evidence concerning such a distribution of vibration patterns in the basilar membrane stems from three main sources: (1) observation of the excited membrane in cadavers, through drill holes in the bone, using stroboscopic illumination, (2) electrophysiological recording of the *cochlear microphonic potential*, which summates the total electrical activity over short lengths of the hair cell-bearing basilar membrane; and (3) the effects of focal destructive lesions at different points along the membrane.

The vibration pattern of the basilar membrane thus varies with the intensity and frequency of the sound wave train reaching the perilymph. Because of their position and attachment, such oscillations cause a mainly transverse shearing force to be generated between the hair cells carried by the basilar membrane, and the overlying tectorial membrane in which the tips of the stereocilia are embedded. (However, *see* below.) Since at most intermediate frequencies an appreciable length of the basilar membrane is oscillating, it follows that a specific but substantial population of the auditory nerve fibres is active, and it appears that frequency discrimination depends largely upon the topographic limits of the strip of membrane from which these fibres arise. With a just perceptible change in frequency, there is a small shift in these limits, but it must be appreciated that the majority of the nerve fibres active will be common to the two situations. Further, it is considered that at a particular frequency, an increase in the *intensity* of the stimulus is signalled by both an increased *number* of cochlear nerve fibres active, and also by their *rate of discharge* of impulses. For a discussion of these topics consult Tasaki *et al.* (1960); Békésy (1960); Spoendlin (1968); Whitfield (1967). Pye (1979) has studied the dimensional characteristics of the cochlea in most mammalian orders, including primates, and has in particular equated basilar membrane dimensions with the auditory range recorded in many species. However, her results, and others quoted by her, show that there is no simple relation between cochlear spiralling and basilar membrane width, and the frequency range of any particular mammalian group.

The precise roles of the outer and inner hair cells have been much debated in recent years, particularly since it has been realized that the innervation of these two sets of cells is so different. Because of the richness of their afferent supply it has

been proposed that the inner hair cells are the major source of auditory sensation, and this view is supported by much experimental and clinical evidence; for example, animals treated with ototoxic antibiotics to cause specific loss of outer hair cells are still able to hear, although their ability to discriminate between two closely similar sounds is impaired (Harrison and Evans 1979). It is therefore feasible that the mechanism of tone discrimination is twofold, a rather broad detection of frequency of the sound waves being first given by the filtering action of the basilar membrane (*vide supra*) which stimulates maximally the inner hair cells of a particular region of the cochlea corresponding to that frequency; and secondly, a sharpening of the 'tuning' of these cells by the activity of the outer hair cells which appear to be able to inhibit the activity of inner hair cells on either side of those responding to the precise wavelength of the auditory stimulus. This type of contrast-sharpening is of course common in sensory systems where lateral inhibition of sensory cells or second order neurons is often achieved by a second set of neural elements. However, the means by which the outer hair cells are able to carry out their functions is by no means clear, particularly as no definite connection between the outer and inner hair cells has yet been demonstrated (Spoendlin 1978). Another mystery is that the outer hair cells have their stereocilia inserted into the tectorial membrane and are thus well arranged to sense lateral shearing between that structure and the reticular lamina caused by movements of the basilar membrane; indeed a large part of the electrical signal detectable with an electrode placed on the round window stems from the outer hair cells (Evans 1974). In contrast, the inner hair cells lack this attachment, and would appear to be stimulated by some other agent, perhaps the movements of fluid flowing between the tectorial membrane and the underlying spiral organ, an arrangement which perhaps allows a wider range of stimulus strength to be detected, but which needs the more precise tuning provided by the outer hair cells.

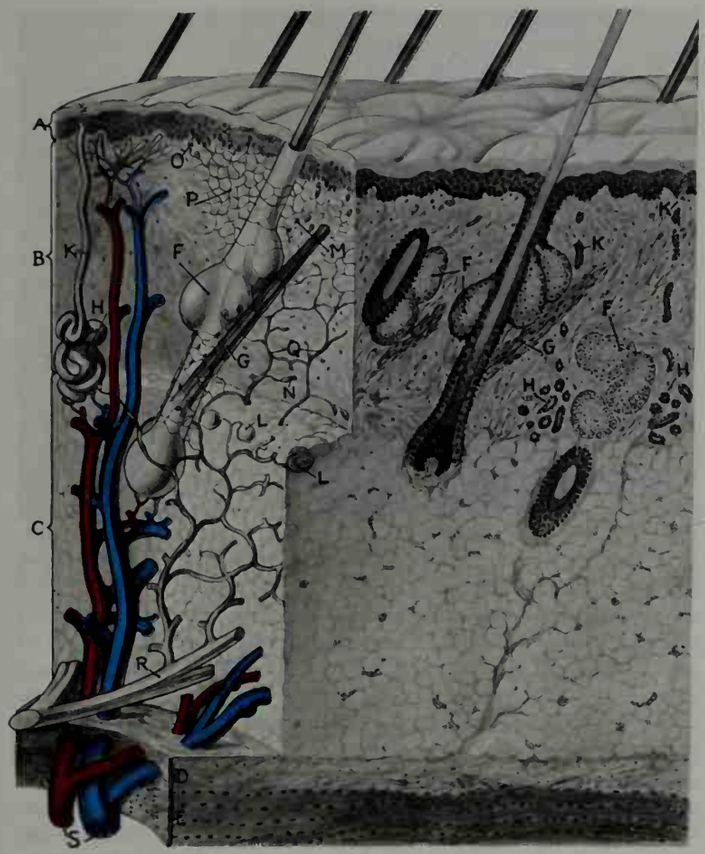
The electrical responses of the cochlea are still rather obscure in their significance, although many of them are readily recorded with relatively crude extracellular electrode techniques (Evans 1974; Yost and Nielsen 1977). The most significant of these is the *endolymphatic potential*, a steady electrical potential recordable between the cochlear duct and the scala tympani, caused by the different ionic compositions of the fluids in these two compartments. Since the resting potential of the hair cells is about 70 mV (negative within) and the endolymphatic potential is positive within the cochlear duct, the total transmembrane potential across the apices of the hair cells is 150 mV, a higher resting potential than that found anywhere else in the body.

When stimulated by sound vibrations as described above, a rapid oscillatory potential, the *cochlear microphonic* is recorded, exactly matching the frequency of the stimulus and of the movements of the basilar membrane. This appears to depend upon some change in the resistance of the hair cell membranes, which probably induces another extracellular potential, the *summating potential*, a steady direct current shift related to the receptor potentials of the hair cells. The cochlear nerve fibres then begin to respond with *action potentials* also recordable from the cochlea.

Recent intracellular recording of auditory responses of inner hair cells (Russell and Sellick 1977) have shown that these sensory cells resemble other receptors in their activities, their steady receptor potentials being related in size to the amplitude of the sound vibrations. Likewise, the afferent nerve fibres are stimulated by synaptic action at the bases of the inner hair cells, firing more rapidly as the vibration of the basilar membrane increases in amplitude.

THE INTEGUMENT

The integument or skin is an anatomically and physiologically specialized boundary lamina which is of major importance in the life of the individual. It forms the entire external surface and is continuous with the mucosal surfaces of the respiratory, alimentary and urogenital tracts at their respective orifices, where the modified skin of the muco-cutaneous junctions occurs. It also lines the external auditory meatus, covers the lateral aspect of the tympanic membrane, and is continuous with the conjunctiva at the margins of the eyelids and with the lining of the lacrimal canaliculi at the lacrimal puncta.



The skin is adapted to serve many different roles, since it is the major interface between the body and its environment (Montagna 1962). It minimizes, within limits, the potentially injurious effects of mechanical, osmotic, chemical, thermal, and photic environmental stresses; it provides a barrier to invasion by micro-organisms, and it limits and regulates the exchange of heat with the environment by special neurovascular mechanisms coupled with thermally insulating properties of layers deep to the skin. The skin is a major sensory surface, containing the receptive fields of a variety of somatic sensory nerve endings; it is capable of limited absorption and excretion, and provides a surface for the conversion of precursor compounds into vitamin D by the action of ultraviolet light; it possesses at its surface good frictional properties, enhancing locomotion and manipulation by its texture and physical structure. Skin also provides a major pathway for social communication, by virtue of vascular responses associated with signalling of emotional states, and muscular responses of expression, creating a complex sign language, and by the equally subtle possibilities of tactile communication. In many primates the skin forms a signalling system related to complicated instinctive behaviour patterns which regulate aggressive, sexual, and other responses of the social group; changes in skin colour and shape in certain areas—the maxillary regions and buttocks for example—often parallel internal changes in hormonal levels, aggressive states and other factors affecting the behaviour of the individual. How far the signals mediated in man by facial expression and other alterations in skin appearance are linked to instinctive behaviour patterns rather than to conditioned behaviour is debatable in adults, although studies on children indicate the fusion of these two elements in a complex fashion.

The Structure of the Skin

The skin is composed of two layers of distinctive structure, properties and embryological origin—the *dermis* or *corium*, a connective tissue layer of mesenchymal origin, which is covered by the *epidermis*, an epithelial layer derived from embryonic ectoderm (7.304). Deep to the dermis lies a layer of loose irregular connective tissue, forming the *superficial fascia*, *hypodermis* or *subcutaneous layer* which in turn is bound to the underlying tissues by a dense fibrous *deep fascia* corresponding to the *epimysium* of muscle blocks, or where a bony or cartilaginous surface is adjacent, to the *periosteum* or *perichondrium*.

The interface between the epidermis and the dermis shows a complex topology, being marked by peg-and-socket or ridge/groove interdigitations between the two (7.304). These arrangements, together with the special anchoring structures linking the epidermis and the dermis, prevent the epithelium from being stripped off the surface of the dermis by shearing forces.

Each of the two layers confers special properties on the skin as a whole. The primary barrier to mechanical damage, desiccation and microbial invasion is the epidermis, particularly the outer horny layers which are highly impermeable to water and chemically rather inert. The epidermis, moreover, has a high capacity for regeneration after damage, and is continually replacing its outer dead cells as they are abraded from the surface. The epidermis also generates the *appendages of the skin*, that is, hairs, nails, sudorific and sebaceous glands. The dermis, in contrast, gives the skin considerable mechanical strength by virtue of the high proportion of collagen fibres intermingled with

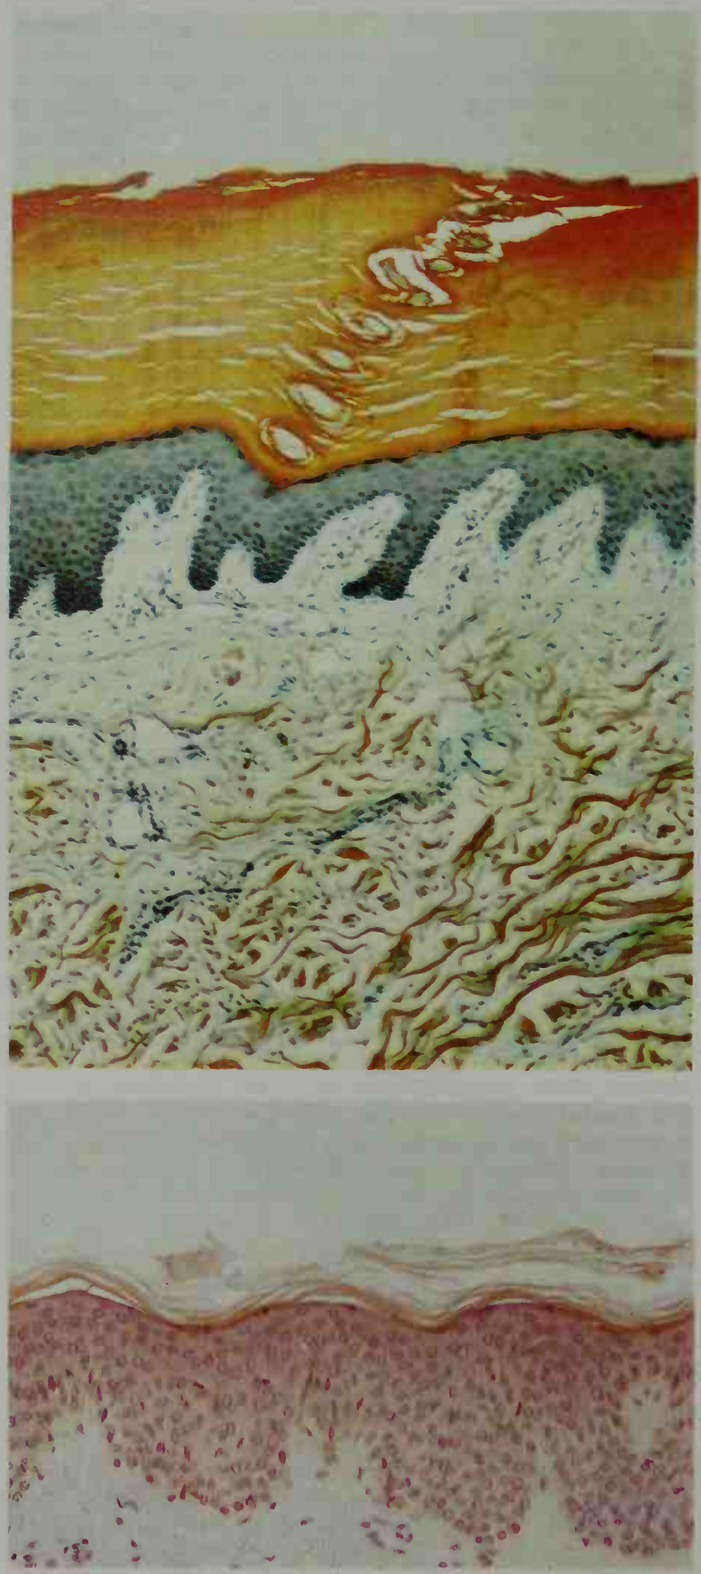
fibres of elastin, and in the various cellular components, provides a reservoir of defensive and regenerative elements capable of combating infection and repairing deep wounds. The vascular supply of the skin is limited entirely to the dermis, and therefore the epidermis relies for its supply of nutrients and metabolic exchange generally on diffusion to and from the capillaries of the most superficial regions of the dermis. The innervation of the skin, however, serves both dermis and epidermis.

Deep to the dermis lie the subcutaneous connective tissue layers of the superficial fascia. In many regions of the body the latter is composed of loosely interwoven irregular connective tissue in the meshes of which lie numerous adipose cells, forming the *panniculus adiposus*. In addition to its mechanical properties as a shock absorber, and its energy-storing capacity, this layer is an important thermal insulator, limiting the flow of heat largely to the channels of the vascular system and thus making thermal regulation by vascular changes possible.

THE EPIDERMIS

The external surface of the epidermis is marked by various furrows, ridges and other irregularities (Montagna and Lobitz 1964). Three principal varieties of surface markings exist (7.305–307): tension and flexure lines and papillary ridges. *Tension lines* form a network of linear furrows of variable size which divide the surface into a large number of polygonal or lozenge-shaped zones. In many areas, such as the back of the hand, they are faint and intersect one another at various angles. Although these lines correspond to variations in the pattern of the fibres in the dermis to some extent, they bear no special relationship to the dermal papillae. *Flexure lines* (*skin joints*) correspond to folds in the dermis associated with habitual joint movements, and to lines of attachment to the underlying deep fascia; they are conspicuous opposite the flexure of joints, particularly on the surfaces of the palms, soles and digits. *Papillary ridges* (*friction ridges*) are confined to the palmar surface of the hands and to the soles of the feet, including their digits, where they form narrow raised ridges separated by fine but distinct parallel grooves, disposed in curved arrays; the precise forms and positions of these ridges are related to the arrangement and size of the underlying dermal papillae interlocking with the base of the epidermis. In thin, hairy skin, the papillae are simple peg-like structures, scattered randomly over the dermal surface; in thick glabrous (non-hairy) skin, the dermal papillae often show complex forms, are large, and are arranged in rows, a single row occupying the position underneath an epidermal papillary ridge. Sweat glands which open in a row along the midline of each ridge grow down during development into the gaps between papillae, dimpling the basal surface of the epithelium to form secondary epidermal pegs (*rete pegs*) or ridges which protrude into the dermis (7.304A). This complex interdigitation no doubt enhances the stability of the junction between the two layers.

The pattern of papillary ridges, and particularly those of the fingers and thumbs are of considerable interest because of their morphological stability throughout life and also because they are slightly different in each individual, as first recognized by Faulds in 1880. The use of fingerprints for purposes of identification is well known and has led to an intensive study of their variation in human populations (the subject of *dermatoglyphics*; *see* Cummins and Midlo 1961; Cummins 1971). It has become clear that only three major patterns occur in human fingerprints (7.307), consisting respectively of loops, whorls and arches, although various combinations of these, and minor pattern variations in orientation, distortion, ridge width and number, continuity, branching and anastomosing provide the enormous pool of variation which makes their precise form unique to the individual. These three major patterns, and many of the minor features, are determined genetically by multifactorial inheritance along Mendelian lines, although prenatal disturbances of metabolism may also alter their character to some extent. Certain genetic disorders may also be reflected in fingerprint and palmar markings, as, in addition they are in the pattern of flexure lines in some cases, so that these markings may form a useful diagnostic tool in certain circumstances (Valentine 1966; Holt 1968).



THE MICROSCOPIC STRUCTURE OF THE EPIDERMIS

Histologically, the epidermis is composed of keratinizing stratified squamous epithelium (p. 41). In such a tissue, two distinct cellular processes are evident: the replacement of cells continually being lost from the surface, by the mitosis of deeper layers; and the transformation of polygonal living cells to dead, flattened, scale-like structures, filled with increasing amounts of the protein keratin, as they age and are removed towards the epithelial surface by the multiplication of the cells beneath them.

Considerable variation occurs over the body surface in the rate and extent of these two processes, so that in some regions, for example the eyelids, lips and other mucocutaneous junctions, the keratinizing layers and indeed the whole epithelium are extremely thin, whilst in others, particularly the palmar and plantar surfaces of the hands and feet, the keratinized layer may be 2 mm or more thick (7.304). In general the epidermis of flexor surfaces of the limbs (apart from the above exceptions) is more delicate than that of extensor surfaces. Because of important differences in the structure of the epidermal layers in various areas, it is customary to distinguish between the epidermis of *thin, hairy skin*, with hairs and sebaceous glands, which covers most of the body surface, and *thick, glabrous skin*, lacking hairs and sebaceous glands, which is restricted to the palms of the hands, the soles of the feet and the flexor surfaces of the digits.

The degree of keratinization is largely under genetic control, since the overall distribution of heavily and lightly keratinized areas is determined before birth. However, intermittent mechanical pressure or abrasion stimulates the adventitious production of keratinized cells, a response of the epidermis which considerably enhances the stress-resisting properties of skin (Rogers 1969).

When suitably macerated, the outer keratinized zone of the epidermis can be stripped from the underlying layers of the epithelial cells, and it has been customary to divide the layers of the epidermis, albeit in a somewhat arbitrary manner, into a deep *germinative zone* and a more superficial *cornified zone* (7.304). For a more detailed treatment of the structure of these layers, the reader is referred to pp. 40, 41, and only certain special aspects of organization will be considered here.

7.304A and B. A Low-power light micrograph of a vertical section through skin from the sole of the human foot: Mallory's triple stain. The finer collagen fibres of the papillary and reticular layers are stained blue, and the coarser collagen of the reticular layer stains red. The epidermis is differentiated into the stratum corneum and stratum lucidum above (red-brown), and the strata basale, spinosum and granulosum, which stain blue-grey. A spiral duct from a sweat gland is also seen in vertical section. The base of the epidermis is irregularly ridged. B A vertical section through the epidermis of the scalp, between hair follicles. Note the reduced keratinized layer (compare with A). Haematoxylin and eosin.

The Germinative Zone

This consists of living cells with little keratin precursor material visible in their cytoplasm. The deeper layers are capable of mitotic division, chiefly in a vertical direction to generate 'stacks' of epidermal cells which are continuous to the epithelial surface. This zone includes a *basal cell layer* (*stratum basale* or *stratum malpighii*) situated adjacent to a basal lamina, where mitotic activity is particularly intense. Superficial to this is a region several cells thick, the *stratum spinosum* (prickle cell layer), marked by the convoluted, interdigitating profiles of the cells, the *keratinocytes* (prickle cells) which are linked by numerous desmosomes attached to internal tonofibrils of the cytoplasm (7.308). This layer probably provides much of the mechanical coherence of the epithelium. Within the germinative zone three other cell types may be present, two of them with extended dendritic processes ramifying among the surrounding keratinocytes, and one with a more rounded profile. The first two types are the epithelial *melanoblast* (*melanocyte*, *dendritic cell*, or *clear cell*), which synthesizes melanin (*vide infra*), and the *Langerhans cell* (Zelickson 1967), the functions of which are the subject of some argument (Breathnach and Wylie 1967). The *melanoblasts* (7.306) are structurally distinct from the surrounding keratinocytes by virtue of their lack of desmosomes, their few internal microfilaments, and the presence of specific *melanin bodies* (*melanosomes*), ellipsoidal structures up to $0{\cdot}7 \times 0{\cdot}2$ μm in their major and minor diameters which show, internally, a regular array of fine (5 nm) granules or fibrils, the latter with regular 5 nm striations. the *Langerhans cells*, in contrast, are devoid of melanin, but contain instead characteristic rod-like *Langerhans granules*, about 0·1 μm long by 0·01 μm wide, having a regular granular interior (Breathnach 1971). Some of these granules are in continuity with the external membrane of the cell. At one time such cells were thought to be degenerating melanoblasts, but the profusion of intracellular organelles and the active DNA synthesis in their nuclei argues against this view; similar cells are known to be present in the dermis, and it is thought by some workers that they are a type of phagocytic cell, similar perhaps to the macrophages of the dermis (Breathnach and Wylie 1967; Zelickson 1971).

There is good evidence that the melanoblasts are of neural crest origin, and that the Langerhans cells come from a different embryonic source.

The other epithelial cell type, found chiefly in hairy skin, is the *Merkel cell* (Zelickson 1971), an element which lies in close association with the tactile sensory nerve endings terminating in the basal parts of the epidermis (*see* p. 852). The cell is marked by an indented nucleus, prominent Golgi complex and numerous dense-cored vesicles each about 80 nm in diameter. These cells appear to play an important role in the sensory process, but the significance of their internal contents is unclear; there is no evidence that the dense-cored vesicles contain catecholamines.

The Zone of Keratinization

In this zone occur the chief cell transformations associated with keratinization (7.304, 308). The *granular layer* (*stratum granulosum*) at its base consists of flattened cells with pyknotic nuclei, surrounded by numerous basophilic granules of the keratin precursor *keratohyalin* (*see* pp. 40, 41). The *clear layer* (*stratum lucidum*) is situated superficially to the granular layer, and appears in sections as a homogenous, slightly striated layer composed of closely packed cells in which traces of flattened nuclei may be seen. This layer is prominent, or indeed visible, only in heavily keratinized areas such as glabrous skin, and contains the keratin precursor *eleidin*. The *cornified layer* (*stratum corneum*) consists of many thicknesses of flattened *squames*, the remnants of cells which have become completely filled with keratin and have lost all other internal structures, including nuclei. At the basal aspect of this layer the cells are closely compacted and adhere to one another strongly, but more superficially they become loosely packed and eventually flake away at the surface. The cells are held together by

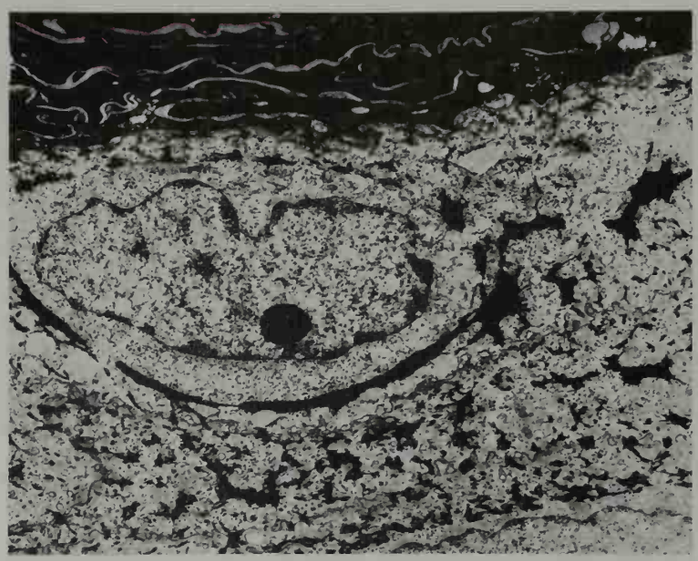
7.306 A similar light micrograph to that shown in 7.305, but taken from hairy skin on the extensor aspect of the forearm; note the pattern of surface grooves (tension lines) and hairs. The oblique direction of the emerging hair shafts points away from the pre-axial border of the limb. Mag. × 6.

an extracellular layer of lipid material which confers strong waterproofing properties on the keratinized layer. This material is synthesized in the stratum spinosum in *lamellated granules*, small vacuoles containing rows of lipid lamellae, which finally discharge when the cells reach the stratum granulosum (Strauss and Matolsty 1977).

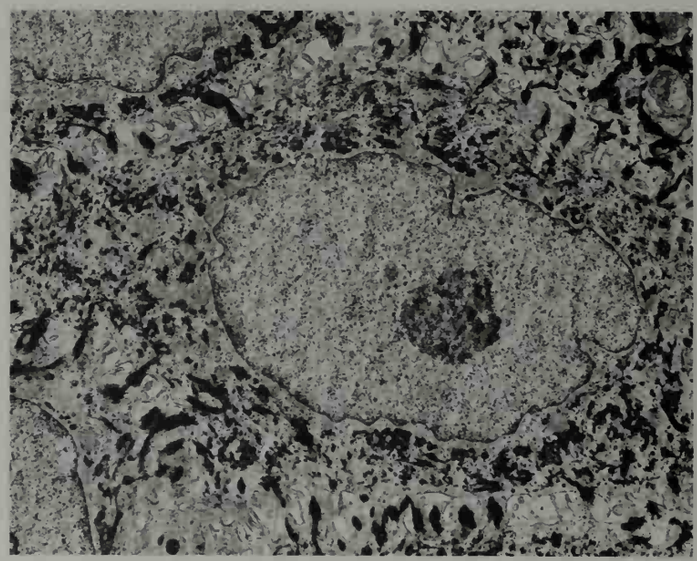
The Pigmentation of the Skin

The final colour of the skin is determined by the presence of at least five pigments at various levels and places in the integument. These are: *melanin*, a brown pigment, situated chiefly in the germinative zone of the epidermis; *melanoid*, a substance similar to melanin, present diffusely throughout the epidermis; yellow to orange *carotene* in the stratum corneum and the adipose cells of the dermis and superficial fascia; and *haemoglobin* (purple) and *oxyhaemoglobin* (red), contained in the vascular supply of the skin, particularly the superficial venous plexuses (*vide infra*). The amounts of the first three of these pigments vary topographically throughout the body, chronologically with the age of the individual, and genetically between individuals. Their relative contributions determine the characteristic racial pigmentation, although considerable genetically-determined differences may occur within a single ethnic group.



Melanin, the brown pigment, is chemically a protein-like polymer of the amino acid *tyrosin*, and possibly of related catecholamines also (Duchon *et al.* 1968; Breathnach 1969; Szabó 1969; Fitzpatrick and Quevedo 1971). Tyrosin is converted by the epidermal melanoblasts into dihydroxyphenylalanine (DOPA) by oxidative enzymes amongst which *tyrosinase* is important. DOPA is further converted to DOPA-quinone, commencing a series of reactions during which polymerization takes place to form the final melanoprotein (melanin). Parts of this enzyme system, and hence the identity of the dendritic melanoblasts which contain them, can be demonstrated histochemically by incubating thin pieces or sections of fresh skin with DOPA, which is converted to melanin within the cytoplasm (*the DOPA reaction*).

Complete absence of skin pigments, excepting those of the vascular system (*albinism*), is a recessive Mendelian character and may occur sporadically in any race; one or more enzymes of the DOPA pathway may be absent in this trait, which may also be associated with other disturbances of tyrosin metabolism.



Each epithelial melanoblast possesses many slender branches terminating in flattened expansions applied to the surfaces of neighbouring keratinocytes (7.313). The melanin granules formed in the perikaryal region of the melanoblast pass along the dendritic branches, and are either secreted at their tips, being subsequently engulfed by keratinocyte cell processes and incorporated into their cytoplasm, or else phagocytosed within dendritic fragments by these cells (Cruickshank and Harcourt 1964; Cohen and Szabó 1968). Similar melanoblasts sometimes

7.307A–C Photographs of the palmar aspect of a terminal phalanx in three different individuals, to show the major types of pattern of the fingerprint ridges. The pattern in A is commonly termed a whorl; B is composed of loops; C is composed of arches. Note interphalangeal flexure lines.

7.308A–C Electron micrographs of human skin in vertical section. A This shows the transition between the stratum spinosum (below), stratum granulosum (middle), and stratum corneum (the dark laminae above). The microfilamentous bundles of the keratinocytes, below, become denser and more compact in the stratum granulosum; finally the cells flatten, becoming scale-like and electron dense. B This shows keratinocytes in the stratum spinosum. The cell outlines are highly convoluted and demonstrate numerous desmosomes; many cytoplasmic bundles of microfilaments are visible. C This shows the bases of the cells of the stratum basale; their cytoplasm contains many ribosomes, but few

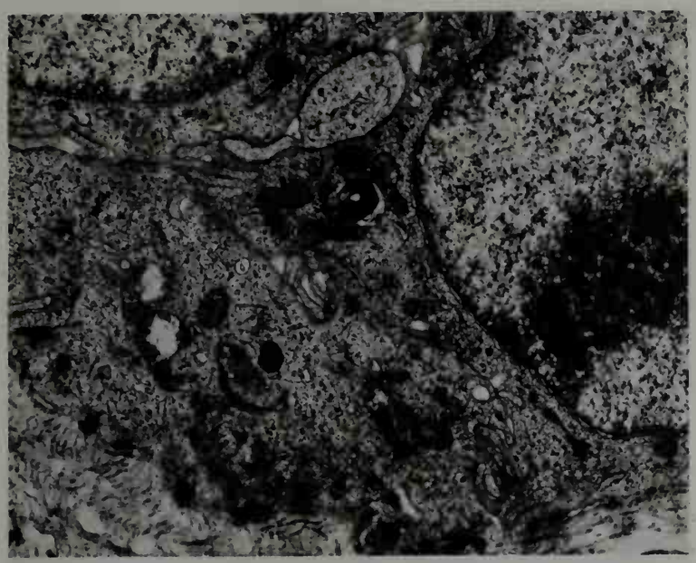
occur in the dermis and may pass on their melanin to macrophages.

The degree of melanization of any particular body region may depend either upon the number of melanoblasts or on the varying activity of individual melanoblasts. Under normal conditions, melanoblasts are often more numerous at the openings of the mucous membranes, on the surface of the penis, face, and limbs than over the trunk and abdomen, varying between 800 and 2,000/mm^3. In newborn infants, up to the age of five months, dermal melanoblasts in the sacral region are responsible for the bluish 'Mongolian Spot' often seen in this vicinity. Melanoblasts are also intimately associated with the bases of hair follicles and provide melanin for incorporation into the cells of hairs (7.313).

In heavily melanized races, the numbers of melanoblasts are about the same as in those with paler skins, so that the difference must lie in the rate of melanin synthesis. However, the melanin content of individual melanosomes is also higher under normal conditions of lighting. In any individual, the rate of melanin synthesis is controlled locally by the incidence of ultraviolet radiation, and systemically by the action of melanocyte stimulating hormone (MSH) from the anterior pituitary gland, amongst other normal and pathological influences. The importance of melanin in protecting the deep, mitosing layers of the epidermis against chromosomal damage by ultraviolet light is seen in the higher incidence of carcinoma of the skin found in Caucasians living in tropical and subtropical regions compared with the indigenous melanized populations. However, melanin also protects the underlying dermis against ultraviolet damage of a more direct nature, that is the inflammatory changes which typically accompany sunburn.

The response of the melanoblasts to varying doses of ultraviolet light are interesting, since at least three distinct phases occur. With brief exposures, the melanin already present in the epidermis darkens appreciably, but later returns to its original colour; with increased exposure, melanin synthesis increases in each melanoblast, and in long exposures the melanocytes themselves increase in number. The extent to which these changes occur depends upon the genetic constitution of the individual as well as upon the dosage.

THE DERMIS



The dermis or corium is tough, flexible and highly elastic. It is very thick in the palms of the hands and soles of the feet; thicker on the posterior than on the anterior aspect of the body, and on the lateral than on the medial sides of the limbs. It is exceedingly thin and delicate in the eyelids, scrotum, and penis.

MICROSCOPIC STRUCTURE OF THE DERMIS

The dermis consists of felted connective tissue, with a varying number of elastic fibres and numerous blood vessels, lymphatic vessels and nerves. The connective tissue is arranged in two layers: a deeper or *reticular*, and a superficial or *papillary*. Nonstriated muscular fibres occur in the superficial layers of the dermis wherever hairs are present; they are also present in the subcutaneous areolar tissue of the scrotum, penis, labia majora and nipples.

The reticular layer consists of strong interlacing bands, composed chiefly of white fibrous tissue, but containing some yellow elastic fibres, which vary in number in different parts. In the deeper part the fasciculi are large, and the wide intervals left by their interlacement are occupied by adipose tissue and sweat glands. Below the reticular layer is the subcutaneous areolar tissue which, except in a few situations, contains fat. The connective tissue bands in the reticular layer lie for the main part in parallel bundles, so that if a *conical* object is stabbed through the skin and then withdrawn it leaves a *linear* wound since the fibres are forced apart without much rupture. The directions taken by the parallel bundles vary in different parts of the body and constitute what are termed the *cleavage lines* of the skin. Surgical incisions made along the direction of cleavage lines heal with minimal formation of scar tissue, whereas incisions across these lines, owing to retraction of the severed fibres, lead to the formation of a broad scar. In general, the cleavage lines are arranged longitudinally in the skin of the limbs and more or less horizontally in the trunk and neck.

With increasing age the yellow elastic fibres atrophy and the skin loses much of its elasticity and becomes wrinkled. If the skin becomes much stretched (as by rapidly growing tumours, fat deposition or pregnancy) the fibres in the reticular layer may undergo partial rupture, followed by scar formation; these areas may show on the surface as white streaks. These are commonly seen on the anterior abdominal wall after pregnancy and are known as *lineae gravidarum*. In many regions the skin is separated from the deep fascia or other structures by loose areolar tissue and in these sites the skin is freely movable over the deeper structures. Elsewhere, however, the skin may be firmly anchored to structures like the periosteum over 'subcutaneous' parts of bones, or to the deep fascia in regions related to movements of underlying joints. In the latter case there may be permanent

C

microfilaments. Their bases are attached to the basal lamina of the epithelium by punctate dense hemidesmosomes; note dermal collagen (below). Magnifications: A and B × 8,000; C, × 20,000.

creases in the skin known as *flexure lines*; they are particularly evident on the palm of the hand and flexor surfaces of the digits, where they are arranged in relation to the movements of the digits (*see* pp. 473 and 1217).

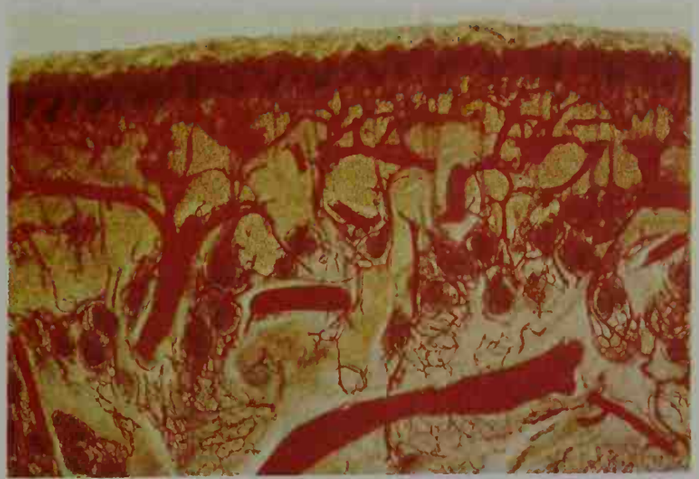
The papillary layer consists of numerous highly sensitive and vascular eminences, termed the *papillae*, which project perpendicularly (7.304, 310). The papillae are minute conical projections, having round or blunted apices, which may be divided into two or more parts, and are received into corresponding pits on the under surface of the epidermis. On the general surface of the body, and especially in areas endowed with slight sensibility, they are few in number and exceedingly minute; but in some situations, as upon the palmar surfaces of the hands and fingers, and upon the plantar surfaces of the feet and toes, they are large, closely aggregated together, and arranged in parallel curved lines, forming the elevated ridges seen on the surface of the epidermis. Each ridge contains two rows of papillae and between the rows the ducts of the sweat glands pass outwards to open on the summits of the ridges. Each papilla consists of very small and closely interlacing bundles of finely fibrillar tissue, with a few elastic fibres; within this tissue there is a capillary loop, and in some papillae, especially in the palms and the fingers, there are tactile corpuscles (7.31).

For a more detailed description of the cutaneous nerve terminals, and patterns of innervation, consult pp. 851–858.

THE VASCULARIZATION OF SKIN

Within the skin, the blood supply and drainage lie along well-determined pathways (7.309), the precise form of which is related to the metabolic requirements of the various cellular components (Montagna and Parakkal 1974). Amongst the highly active areas of the skin are the epidermis and its cellular extensions—hair follicles, sebaceous and sudorific glands—and also the dermal papillae which contain active fibroblasts and the sensory endings of cutaneous nerves; all of these structures are closely related to rich capillary beds in the dermis. The deeper reticular layer of the dermis, in contrast, is highly fibrous and contains few active cells, and the metabolic requirements are low. Although many vessels pass through the reticular layer, they give off few capillaries and are mostly non-nutritive to this layer.

Blood enters the skin through small arteries which penetrate the superficial fascia from its deep aspect and initially ramify in a sheet-like plexus, the *rete cutaneum*, at the interface of the dermis and superficial fascia. From this plexus, some blood vessels run deeply to supply the subcutaneous adipose tissue and, in those regions where they are present at this depth, the bases of hair follicles and sweat glands. Other vessels arising from the rete cutaneum curve in a superficial direction, giving off capillaries around hair follicles, sebaceous glands and sudorific glands as they pass to the junction of the reticular and papillary layers of the dermis; here they form another flat plexus, the *rete subpapillare* or *superficial plexus*. Capillaries extend from this layer towards the base of the epithelium, within dermal papillae, and loop back to a flat venous plexus which lies immediately beneath the rete subpapillare; this in turn drains into a flat intermediate plexus in the middle of the reticular layer of the dermis which further connects with a deep laminar venous plexus at the dermis—superficial fascia junction. Various capillary beds situated in the dermis around glands and hair follicles drain into these three venous plexuses at appropriate levels within the skin.



In the deeper layers of the dermis, arteriovenous anastomoses are common; in glabrous skin some of these are surrounded by thick sphincter-like groups of smooth muscle and pursue a convoluted course. These vessels are termed *glomera*. Since the nonstriated muscle elements are under autonomic control, heat exchange at the epithelial surface can be regulated by the vasoconstriction of the afferent arterioles of the general cutaneous supply, whilst the arteriovenous anastomoses provide for a maintained deep circulation in the skin under thermal conditions which might otherwise reduce the blood supply of the integument to dangerous levels (see also p. 638).

THE LYMPHATIC DRAINAGE OF THE SKIN

Numerous blind-ending lymphatic vessels terminate in the dermis near the base of the epidermis and drain deeply first into a dermal network in the papillary layer, then into another network at the mid-level of the reticular layer and finally into a network at the junction of the dermis and superficial fascia. Deep to this zone, the lymph flows through wider channels provided with valves, into the main lymphatic drainage of the area. The lymphatic drainage of the skin is quite profuse, and free anastomosis appears to occur between vessels at all levels so that there is free interchange of lymph between areas of the skin which are adjacent to each other (Forbes 1938).

THE INNERVATION OF THE SKIN

Skin is richly innervated (7.29) by myelinated and non-myelinated sensory fibres of the cerebrospinal and autonomic nerves, and via non-myelinated efferent autonomic fibres supplying blood vessels, sweat glands and smooth muscle fibres associated with the

7.309 A thick vertical section through palmar skin, the arteries, arterioles and capillaries of which have been injected with red gelatin to demonstrate the pattern of dermal vascularization. At the base of the dermis a broad flat arterial plexus supplies a more superficial papillary plexus, which in turn gives off capillary loops which enter the dermal papillae. Sweat glands and their ducts are numerous in this specimen; they extend basally into the subcutaneous tissues. Magnification × 200.

hairs (pilomotor nerves). The sensory apparatus has already been described in some cytological detail (p. 851), and will be discussed only in relation to the sensory functions of the whole skin (Sinclair 1967; Kenshalo 1968; Sinclair 1973).

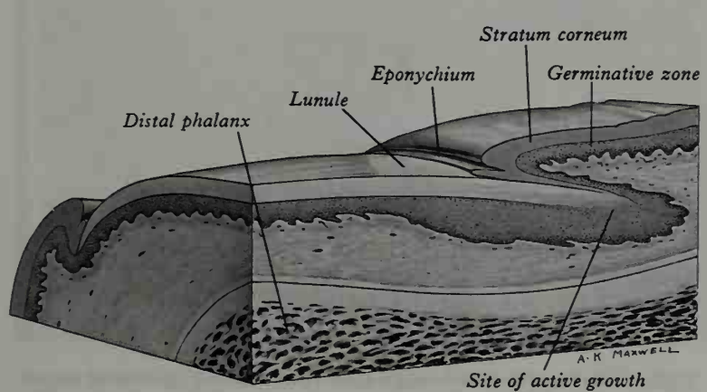
The nerves associated with both efferent and afferent endings penetrate the superficial fascia and ramify through the reticular and papillary layers of the dermis. Conspicuous nerve plexuses are formed around hair follicles and in the papillary layer of the dermis beneath the epithelium where the term *dermal* or *corial plexus* is often applied. Efferent nerves ramify around blood vessels, cutaneous muscle fibres and the bases of sudorific glands. Afferent nerves usually branch to supply a limited area of the skin, or in one type of ending, the Pacinian corpuscle, they may remain unbranched; the area of innervation by a single fibre is often related to the sensitivity threshold of the fibre and inversely to the degree of spatial localization of which it is capable. Each receptive field may overlap with those of other afferent fibres, giving a complex mosaic which creates possibilities of pattern analysis (p. 857).

Since the skin forms the chief interface between the internal and external environments, the elaborate sensory apparatus which it possesses makes it the chief means of comparing physical changes in the two environments and of monitoring their interaction. Information concerning the rate of change of various effective stimuli, their duration, energy content and their spatial and temporal patterning are all being constantly provided by the array of cutaneous receptors. The interpretation and correlation of the various messages arriving in the central nervous system appear to involve the continual analysis of patterns of activity from a wide range of receptor types (p. 851), some of them particularly responsive to certain modalities (e.g. pressure, cold), others responding in a manner determined by their position within the skin, their intrinsic thresholds, and the mechanical characteristics of the non-nervous cells associated with their sensory terminals.

In both hirsute and glabrous skin, the highly branched non-myelinated and myelinated 'free' terminals, which end within the dermis and penetrate the lower layers of the epidermis, form an important sensory component. Some of these fibres subserve mechanoreceptors, others thermoreceptors, whilst yet others are involved in nociception. In hirsute skin, such fibres lie in close association with hair follicles; another type of ending, the Merkel disc is also present in this variety of skin, particularly around the openings of hair follicles, whereas in glabrous skin they are found at the base of the intermediate 'sweat' ridges beneath the papillary ridges of the epidermis. A single myelinated afferent fibre may give rise to several groups of such disc endings, each group corresponding to a 'touch spot' on the surface of the epithelium. Shearing forces applied to the skin surface cause such endings to respond without adapting appreciably to continued stimulation, and it seems likely that the epidermal structures—hair follicles, ridges—to which these endings are attached act as a series of levers, imparting a magnified stress to the associated expanded nerve endings. In hairless skin there are also numerous complex corpuscles, the endings of Meissner, which are situated chiefly within the dermal papillae beneath the papillary ridges (Quilliam 1971). Each Meissner corpuscle receives multiple innervation from the branches of as many as nine separate axons, each of which may also innervate other Meissner corpuscles, so that considerable cross innervation occurs. These endings are some of those responsible for rapidly adapting mechanoreception, and because of their high density on the flexor surfaces of the digits for example, they may be associated with the sensing of rapidly changing, patterned tactile stimuli. Lamellated endings of a somewhat simpler construction are found in other areas such as the mucocutaneous junctions, and mucous membranes (mucocutaneous end organs, genital corpuscles, bulboid endings, lingual end-organs, etc.), where they may have similar functions. Pacinian corpuscles are present chiefly in the deeper layers of the skin, and in the superficial fascia where they are particularly prominent in the flexor surfaces of the digits. Each corpuscle is innervated only by a single axon, and may serve an entire unbranched nerve fibre. The peculiar lamellated structure of the corpuscle appears to possess important properties, making the

7.310 A vertical section through a dermal papilla and adjacent epidermis, showing a capillary loop. Notice the closeness of the vessel to the basal layer of the epidermis. Mallory's triple stain. Mag. × 800.

end-organ responsive to rapidly changing forces such as vibrations. As with the other types of receptor endings, the position within the skin and the mechanical characteristics of adjacent non-nervous cells may create possibilities of stimulus analysis otherwise not feasible, by virtue of the action of the epidermis and dermis as filters, attenuating mechnical and thermal stimuli in different ways as they are transmitted through their successive layers. Sensory endings situated at different levels may therefore form part of a highly ordered sensory system with organization in both horizontal and vertical planes.



In addition to this minute structuring of the sensory apparatus of the skin, large-scale variation also occurs over the whole body surface. Physiologically, such variations are detectable as changes in thresholds to mechanical and thermal stimuli, in point-to-point discrimination of tactile stimuli, and in the ability to identify the precise locality of a stimulus applied to the body surface. In general, both fine discrimination and location of stimuli follow similar gradients, being of a high order at the extremities of the limbs and becoming progressively cruder towards abdomen, thorax and head, although certain areas such as the lips and tongue, for example, create local reversals in this pattern. Discrimination is not entirely bilaterally symmetrical, the right side usually being more discriminative than the left, at least in dextral subjects. Other gradients, for example, of pressure thresholds, may operate in the opposite directions. Sex differences have also been shown, female persons being generally more sensitive to pressure stimuli than male, a finding possibly related to the slightly thinner epidermis typical of female skin.

The anatomical basis of such variations is still far from being satisfactorily explained, a statement which might also be applied to the whole subject of cutaneous sensation.

APPENDAGES OF THE SKIN

THE NAILS

The nails (7.311) are flattened, elastic structures of a horny texture, placed upon the distal parts of the dorsal surfaces of the fingers and toes. The proximal part of the nail, called the *root*, is implanted into a groove in the skin; the exposed part is the *body* of the nail; the distal end forms the *free border*, and a little proximal to it the skin is attached to the under surface of the nail forming the *hyponychium*. The root of the nail is overlapped by a fold of skin, the *nail fold*, the stratum corneum of which is prolonged distally as a thin cuticular fold, the *eponychium*, to cover completely or partially the white opaque crescentic part of the nail called the *lunule*. The greater part of each collateral border of the nail is overlapped by a fold of skin, termed the *nail wall*. The nail itself is analogous to the horny zone of thick skin, although the keratinized squames are hard and highly coherent (Zaias and Alverez 1968; Zelickson 1971); beneath it lies the germinative zone which, together with the subjacent corium, forms the *nail bed*. Under the greater part of the nail the corium is thick and raised into a series of longitudinal ridges which are very vascular, and this accounts for the pink colour seen through the translucent nail. Near the root of the nail, however, the ridges are smaller, irregularly arranged and less vascular; moreover the tissue of the nail is here more opaque, hence this part of the nail is whiter and constitutes the lunule. The lunule is usually visible in the thumb nail, but in the other digits it becomes progressively more covered by the nail fold towards the little finger, in which it is generally hidden altogether. The germinative zone of the nail bed consists functionally of two parts. The part beneath the root of the nail and the lunule (*germinal matrix*) is thicker and actively proliferative, and is concerned with the growth of the nail, the epidermal cells being gradually converted into the nail substance. On the other hand, the part beneath the rest of the nail (*sterile matrix*) is thinner and is not concerned with nail growth but provides a surface over which the growing nail glides. All growth of the nail therefore occurs at its root; the nail increases in thickness from its root to the distal edge of the lunule and the remainder is of uniform thickness. If a nail be removed without severely damaging the germinal matrix, a new nail will grow from this region. Disturbances of growth of the nails may occur in acute illnesses or local trauma, and transverse grooves may develop on the surface which move gradually distally with growth of the nails. Minute air bubbles, giving rise to white flecks, may develop in the substance of the nail. On an average nails grow about 0·5 mm a week; growth is quicker in summer than in winter, and finger nails grow about four times as fast as toe nails. In the hand, nail growth is most rapid in the longest digit (the middle finger), slowest in the little finger and intermediate in the other digits. Nails act as a rigid background for support of the digital pads of the terminal phalanges, and thus may aid tactile mechanisms. From the evolutionary point of view, nails are derived from the more elaborately structured claws which characterize many other mammals and lower tetrapods.

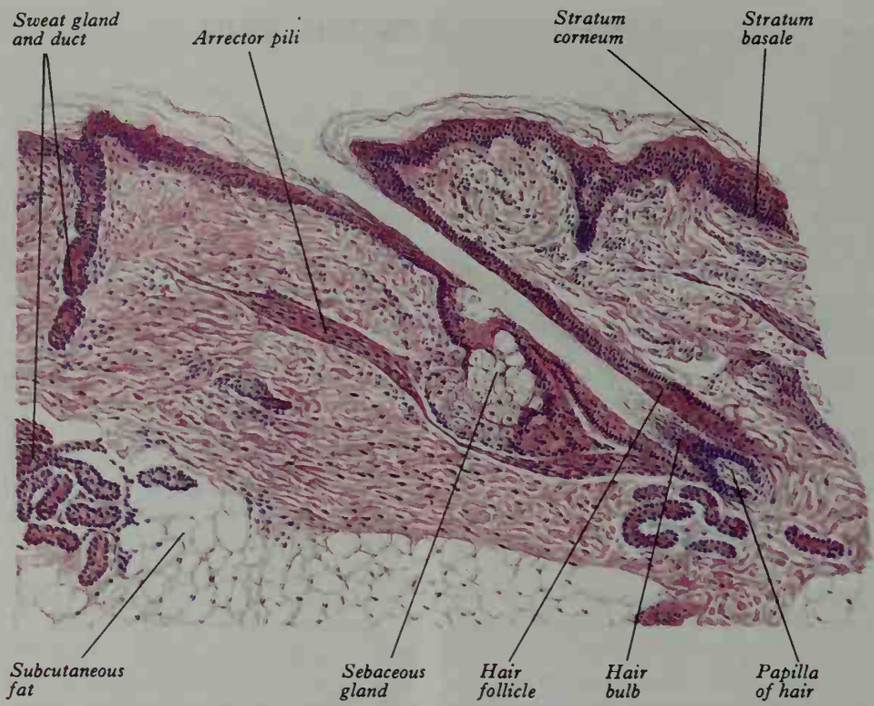
THE HAIRS

The hairs are found on nearly every part of the surface of the body, but are absent from the palms of the hands, the soles of the feet, the dorsal surfaces of the distal phalanges, the umbilicus, the glans penis, the inner surface of the prepuce, the inner surfaces of the clitoris, labia majora and minora. They vary much in length, thickness and colour in different parts of the body and in different races of mankind. In some parts, as in the skin of the eyelids, they are so short as not to project beyond the follicles containing them; in others, as upon the scalp, they may be remarkably long; the eyelashes, the hairs of the pubic region, and the whiskers and beard are remarkable for their thickness. Straight hairs are stronger than curly hairs and present on transverse section a cylindrical or oval outline: curly hairs, on the other hand, are flat. (Some maintain that the form of the hair does not correspond with its shape in cross-section, however.)

A hair consists of a *root*, the part implanted in the skin, and a *shaft* (*scapus*), the portion projecting from the surface.

The *root (radix) of the hair* has a proximal enlargement, the *bulb*, which is set in an invagination of the epidermis and superficial portion of the corium, called the *hair follicle* (7.312, 313). When the hair is of considerable length the follicle extends into the subcutaneous tissue. The hair follicle commences on the surface of the skin with a funnel-shaped opening, and passes inwards in an oblique or curved direction—the latter in curly hairs—to become dilated at its deep extremity, where it corresponds with the hair bulb. The ducts of one or more sebaceous glands open into the follicle near the skin surface. At the bottom of each hair follicle there is a small conical vascular eminence or papilla, similar in every respect to those found upon the surface of the skin; it is continuous with the dermal layer of the follicle, and is supplied with myelinated and non-myelinated nerve endings. It is from the capillaries in the papilla that the hair derives its nutrition.

The hair follicle consists of two coats—an outer or dermal, and an inner or epidermal (7.312, 314).



The *outer coat* is formed mainly of fibrous tissue; it is continuous with the dermis, is highly vascular, and is supplied by numerous, minute nerves.

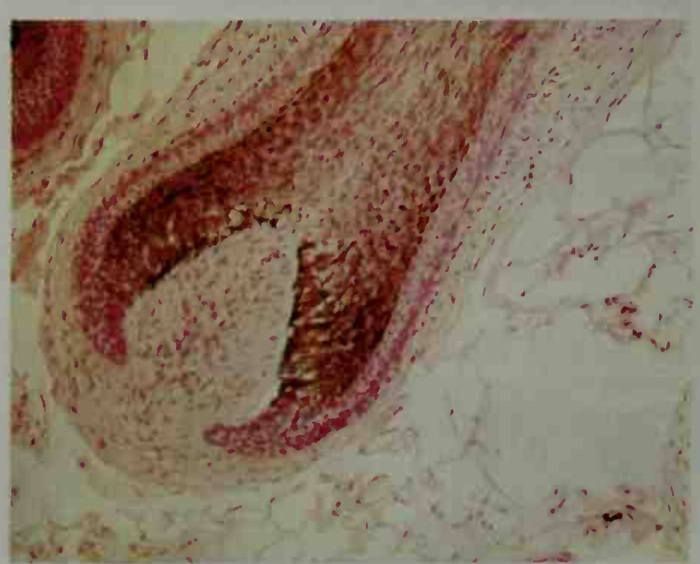
The *inner coat* is closely adherent to the root of the hair, and consists of two strata, named respectively the *outer* and *inner root sheaths*; the outer root sheath corresponds to the stratum spinosum of the epidermis, and resembles it in the rounded form and soft character of its cells; at the bottom of the hair follicle these cells become continuous with those of the root of the hair. The inner root sheath consists of: (1) a delicate cuticle next the hair, composed of a single layer of imbricated scales with atrophied nuclei; (2) one or two layers of horny flattened nucleated cells, known as *stratum epitheliale granuliferum* (*Huxley's layer*); (3) a single layer of cubical cells with clear, flattened nuclei, called *stratum epitheliale pallidum* (*Henle's layer*) (7.314).

The *hair bulb* is moulded over the papilla and composed of polyhedral cells. As they pass upwards into the root of the hair these cells become elongated and spindle-shaped, except those in the centre, which remain polyhedral.

The *shaft of the hair* consists, from within outwards, of the medulla, the cortex and the cuticle. The *medulla* is usually absent from the fine hairs covering the surface of the body, and commonly from those of the head. It is composed of rows of polyhedral cells, with air spaces between, and sometimes within, the cells. The *cortex* constitutes the chief part of the shaft; its cells are elongated and are united to form flattened, fusiform fibres, which contain pigment granules in dark hair, and air in white hair. The *cuticle* consists of a single layer of flat scales which overlap one another from below upwards (Matolsty 1958; Birbeck 1964; Orfanos and Ruska 1968; Zelickson 1971).

Over most parts of the body the hairs are fine and downy and give an appearance of hairlessness. Almost the entire skin of the human at about the middle of fetal life is covered by fine hair, called *lanugo* (primary hairs), and in fact the hairs on the back at

7.312 A section through the skin, showing the epidermis and dermis (corium), a hair in its follicle, an arrector pili muscle, and sebaceous glands opening into the hair follicle. Magnification × 100.



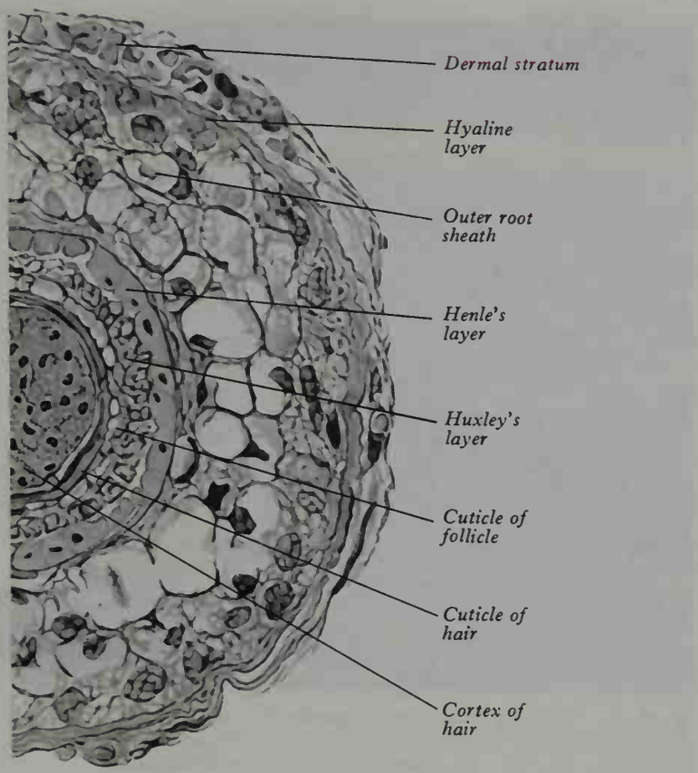
this time are more numerous (per square centimetre) than in the gorilla or chimpanzee of corresponding fetal age. The lanugal hairs are mostly shed by birth and are replaced by fine hairs, termed *vellus* (secondary hairs), in the early months of post-natal life. These are retained in most regions but are replaced by the hairs (*terminal hairs*) of the scalp and eyebrows; also by the axillary and pubic hairs, and those on the face and front of the chest in the male, which appear at puberty, their development and growth being under hormonal control. Hairs on the adult scalp are more numerous (per square centimetre) than in the anthropoid apes. The lanugal and vellous hairs have no medulla. In the male the hairs in the vestibule of the nose and in the external acoustic meatus grow markedly with advancing age.

In furred mammals hair functions in the temperature controlling mechanism by minimizing heat loss; this function in man is served by the subcutaneous fat, and the hairs are concerned largely in the cutaneous sensation of touch (pp. 849, 889). Growth of a hair occurs at the hair bulb, where the cells capping the papilla proliferate and form the *germinal matrix* of the hair. As proliferated cells progressively move towards the surface they become keratinized to form the fibre-like cornified cells of the shaft of the hair. The duration of life of a single hair varies from about four months (eyelashes, axillary hair) to about four years (scalp hair), after which it is shed and is replaced by the sprouting of new cells from the germinal matrix after a period of rest. Rapidly growing hairs are said to be in the *anagen* phase, but when division of the matrix cells ceases, and the hair stops growing, it is termed a *telogen* hair. Growth of a hair varies with its texture, ranging from about 1·5 mm (fine hair) to 2·2 mm (coarse hair) a week. Greying or whitening of hair is due to the collection of minute air bubbles in the cortex (and medulla) of the shaft and to loss of pigment (melanin) formation by cells in the germinal matrix (*see* p. 1218).

Minute bundles of nonstriated muscular fibres, termed the *arrectores pilorum* (7.303, 312), are connected with the hair follicles. They arise from the superficial layer of the corium, and are inserted into the outer coat of the hair follicle, below the entrance of the duct of the sebaceous gland. They are placed on the side towards which the hair slopes, and by their action diminish the obliquity of the follicle and elevate the hair. When they contract, the skin over their origin is depressed, while the skin immediately around the hair is elevated; this results in the appearance of 'goose skin' seen on exposure to cold or in emotional reactions. The sebaceous gland is situated in the angle which the arrector pili muscle forms with the superficial portion of the hair follicle, and contraction of the muscle thus tends to squeeze the sebaceous secretion out from the duct of the gland. The arrector muscles are supplied by sympathetic nerves.

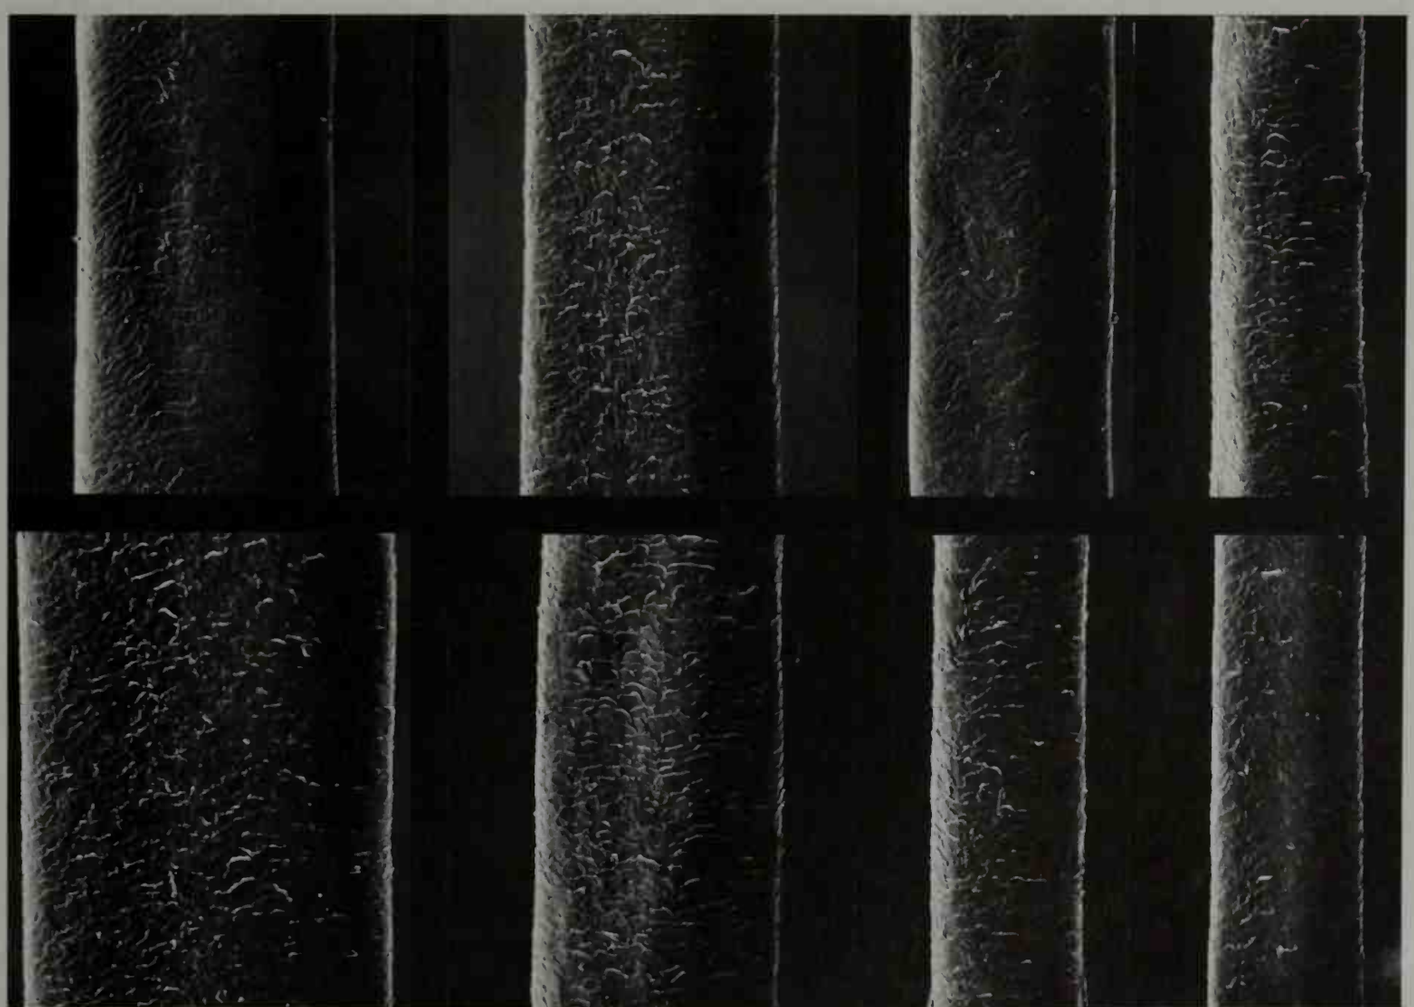
THE SEBACEOUS GLANDS

The sebaceous glands are small, sacculated, and lodged in the substance of the dermis. They occur in most parts of the dermis, but are especially abundant in the scalp and face; they are also very numerous around the apertures of the ear, nose, mouth and anus, but are absent in the palms of the hands and soles of the feet. Each gland consists of a single duct, relatively capacious, which emerges from a cluster of oval or piriform alveoli, usually from two to five, but in some instances as many as twenty in number. Each alveolus is composed of a basement membrane, enclosing a number of epithelial cells. The outer or marginal cells are small



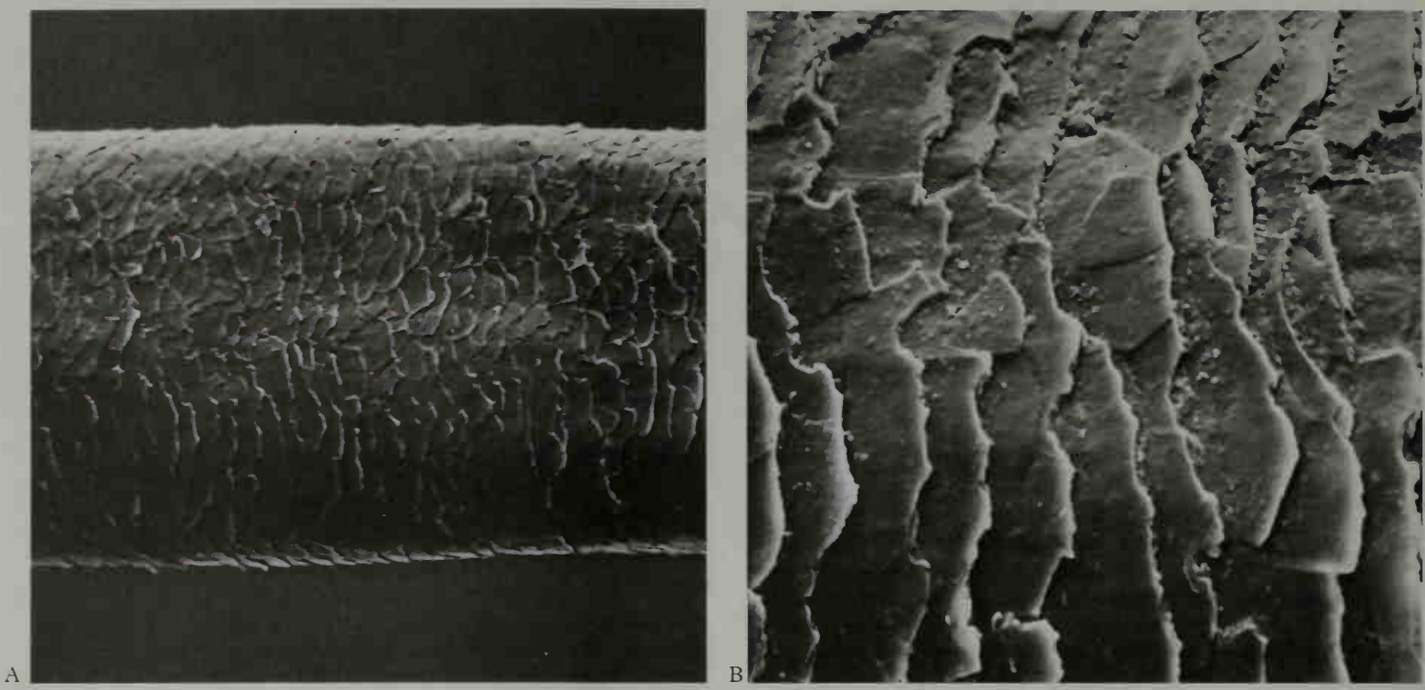
7.313 A vertical section through a hair root, showing the dermal papilla, and numerous melanocyte processes extending into the matrix of the hair. Haematoxylin and eosin. Magnification × 250.

and polyhedral, and are continuous with the cells lining the duct. The remainder of the alveolus is filled with larger cells, containing fat, but in its centre the cells are broken up, leaving a cavity filled with their débris and a mass of fatty matter, which constitutes the *sebum cutaneum* (Charles 1960; Ellis 1967; Zelickson 1971). As the sebaceous glands produce their secretion by complete fatty degeneration of their central cells they are classed as *holocrine* glands. As the central cells disintegrate, they are replaced by proliferation of marginal cells. The ducts open most frequently into hair follicles (the glands being developed as diverticula from the epithelial walls of the follicles themselves) but occasionally upon the general surface, as in the labia minora, glans penis and the free margins of the lips. On the nose and face the glands are of large size, distinctly lobulated, and often become much enlarged from the accumulation of pent-up secretion. The tarsal glands of the eyelids are elongated sebaceous glands with numerous lateral diverticula. Sebum acts as a natural lubricant of the hair and skin protecting skin from the effects of moisture or desiccation and hairs from becoming brittle; it also has some bactericidal action. The secretory activity of the sebaceous glands does not appear to be under nervous control; it is stimulated by hormonal action, particularly androgens.



THE SWEAT GLANDS

Sudoriferous or sweat glands (7.303, 312) occur in almost every part of the skin, and have been classified into two types, *eccrine* and *apocrine* (Biemfica and Montes 1965; Ellis 1968; Zelickson 1971).



The eccrine glands are most numerous and are found in almost every part of the skin. Each consists of a single tube, the

deep part of which is coiled into an oval or spherical ball, which is situated in the deeper layers of the corium or in subcutaneous tissue and is named the *body* of the gland. The superficial part, or duct, traverses the dermis and epidermis and opens on the surface of the skin by an infundibular aperture. In the superficial layers of the dermis the duct is straight, but in the deeper layers it is convoluted or twisted; where the epidermis is thick, as in the palms of the hands and soles of the feet, the part of the duct which passes through it is spirally coiled. The size of the glands varies. They are especially large in those regions where the amount of perspiration is great, as in the axilla and in the groin. Their number varies. They are very plentiful on the palms of the hands and on the soles of the feet, where the orifices of the ducts are exceedingly regular, and open on the curved ridges of the epidermis; they are least numerous in the neck and back. The tube, both in the body of the gland and in the duct, consists of two layers—an outer, of fine areolar tissue, and an inner, of epithelium. The outer layer is thin and is continuous with the superficial stratum of the dermis. In the body of the gland the epithelium consists of cubical or polyhedral cells which may be classified as dark cells and clear cells; the former are rich in ribonucleic acid and mucopolysaccharides and are the main secretory elements. The latter are mostly acidophilic and contain an abundance of glycogen. Electron microscopy reveals canaliculi between the clear cells. Between the basal aspects of these cells and the basement membrane there is an incomplete layer of longitudinally or obliquely arranged elongated, fusiform, myoepitheliocytes. Electron microscopic studies show that their cytoplasm is similar to that of nonstriated muscle cells containing fine (5 nm) filaments and less frequent thicker ones (*see* p. 518). Desmosomes occur where their plasma membranes adjoin those of the secretory cells of the gland. The myoepitheliocytes have been ascribed a contractile role in the expression of secretion from the gland. It is also suggested that they may regulate the flow of metabolites to the secretory cells (Ellis 1965). The ducts are destitute of muscular fibres and are composed of a basement membrane lined by two or three layers of polyhedral cells; the duct passes through the epidermis as a spiral channel which is simply an intercellular cleft between the epidermal cells. When the epidermis is carefully removed from the surface of the dermis, the ducts may be drawn out in the form of short, thread-like processes on its deep surface. The eccrine sweat glands are *merocrine* in nature, i.e., produce their thin watery secretion without demonstrable epithelial cell disintegration.

Apocrine glands occur in the axilla, eyelids, areola and nipple of the breast, in the circumanal region and in association with the external genitalia (Montagna and Parakkal 1974). They are larger than eccrine glands and produce a thicker secretion. In the female they show involution changes related to each menstrual cycle. They are developed in close association with hairs and their ducts typically open into the distal ends of hair follicles.

Apocrine glands are tubular in form, having an extensive coiled secretory portion which may be up to 2 mm across in the larger examples, leading into a narrower straight secretory duct which runs parallel to neighbouring hair follicles. The secretory coils which often anastomose to form a labyrinthine network, are lined with cells being cuboidal to columnar in shape, with pale-staining nuclei, numerous mitochondria and amounts of granular and smooth endoplasmic reticulum varying with their secretory state. Cells often contain large vacuoles of dense material, probably secretory in nature and at the bases of the cells lie numerous longitudinally orientated myoepitheliocytes. The secretions of these glands vary with their anatomical position. In the axilla the glands become distended with a proteinaceous, milky fluid containing various organic compounds including steroids. Bacterial decomposition augments the naturally occurring odour of these secretions to give a characteristic musky, urinous scent. In many mammals similar glands are involved in the production of chemical signals or pheromones which are used in marking territories, in courtship, and in maternal as well as other types of social behaviour. Their existence in humans suggests that these glands may have been important originally in similar types of activity, although their role has been obscured in the exercise of hygiene. The ceruminous glands of the external acoustic meatus are modified apocrine sweat glands. It should be noted that recent work, using the electron microscope, has suggested that the so-called apocrine glands do not lose superficial cytoplasm during secretion and hence all sweat glands may have a merocrine, rather than apocrine, form of secretion.

Eccrine sweat glands are concerned in the temperature control mechanism by surface evaporation of the sweat. They are supplied by sympathetic nerves, though these fibres are cholinergic in nature, and no sweating occurs in a denervated area of skin. Rarely, sweat glands may be congenitally absent, in which case special means have to be adopted to prevent rise of body temperature in hot weather. Apocrine glands are under dual autonomic control, but do not respond markedly to temperature changes, so that strictly speaking they should not be classed as sweat glands at all.

8

SPLANCHNOLOGY

SPLANCHNOLOGY

The grouping together of the organs of respiration, alimentation, urinary excretion, and reproduction, together with the endocrine glands, under the umbrella of 'Splanchnology' is more traditional than rational. There is, perhaps, a certain rough reasonableness in dividing the body's fabric and function into somatic or locomotor and visceral or metabolic moieties, but no effort is customarily exerted to bring osteology, arthrology, myology, angiology and neurology into a corporation. In any case the overlap between all these so-called systems and the miscellany of viscera or *splanchnoi* gathered under the label of 'splanchnology' is most extensive. Again, splanchnology is no sooner formed than it is dismembered into its constituent 'systems', as in this volume. Our only reasons for retaining the term are convenience and tradition.

THE RESPIRATORY SYSTEM

Introduction

The exchange of respiratory gases is a basic essential of the life process, even in its states of suspension, as in seeds or spores, in hibernation or aestivation, when respiration may be greatly diminished but not wholly abolished. In the smallest creatures, such as *Protozoa*, oxygen and carbon dioxide can diffuse directly through the body surface, establishing equilibria along partial pressure gradients with sufficient rapidity to maintain adequate metabolism. In the *Metazoa*, with their greater mass and hence impossibly lengthened diffusion distances, blood transport systems and specific respiratory areas are necessary. The respiratory adaptations assume a dual nature—the transport of respiratory gases and the development, often deep within the animal's body, of specialized areas for gaseous exchange. The breathing tubes or tracheal system of the *Arthropoda* are an example of the former, and it is worthy of note that in the chitinous spirals maintaining patency in such *tracheoles* there is a structural theme which recurs in all vertebrates. In the *Vertebrata*, as in some invertebrate phyla, two major environments, *aqueous* and *terrestrial* (or aerial), have posed different problems of adaptation; but in both habitats there is a basic similarity, in that actual gas exchanges take place between the external environment and circulating blood through a *wet* epithelium, whether in gills, lungs, or through the skin. Cutaneous respiration is limited to some amphibia, and apart from this the respiratory organs of vertebrates are constantly associated with and largely developed from the branchial arch system and the alimentary tube. The first segment of this beyond the mouth is the pharynx, through which water passes to the gills in piscine vertebrates, where the exchanges occur between gases dissolved in water or blood. Diverticula of the pharynx are usual in fishes, and these function as swim-bladders or hydrostatic organs; but in a few extant species they also act as auxiliary respiratory chambers, which can be filled directly from the air. (Such interesting and significant adaptations cannot, unfortunately, detain us here. For these and other aspects of vertebrate life, consult Young 1962; Romer 1970.) It is from such '*lungfish*', or allied forms, that the earliest terrestrial vertebrates, the amphibia, have most probably evolved, the acquisition of an air-breathing habit leading to a host of new forms and adaptations.

It is appropriate to note here that some members of all the terrestrial vertebrate classes—amphibia, reptiles, birds and mammals—have returned wholly or partially to an aquatic existence; but only the larvae of amphibians are able to take oxygen directly from water. (There are a few *adult* amphibians, such as *Salamander atra*, which have this ability.) All the others must temporarily suspend breathing while immersed, coming to the surface to expel the contents of their respiratory organs and to refill them with fresh air. To keep out water and to retain inspired air while such air-breathing vertebrates are submerged, some kind of sphincteric mechanism is obviously necessary at the junction of the lungs, however primitive, and the pharynx from which they develop. Even in fish which merely swallow air to fill their swim-bladders, such a sphincter is necessary; and in the piscine ancestors of the land tetrapods, which were able to 'breathe' from water as well as air, the same need exists, and perhaps also for some form of dilatator mechanism. Hence, a sphincter-dilatator mechanism, which becomes the *larynx*, is probably as basic as the lung-sac itself. In land vertebrates the respiratory cavity, or *lung*, is almost always a bilateral structure; and the interior of these paired pharyngeal diverticula, served by a single air-tube, the *trachea*, becomes highly complicated by folding of its epithelium increasing the area of interchange at which blood is exposed to inspired air. Thus a basic pattern of the respiratory organs is early established, and even in small amphibia the pattern of branching of the trachea—which is typically dichotomous—into smaller divisions, *bronchi* and *bronchioles* and their terminal respiratory air sacs or *alveoli*, has already become quite complex. The specialization into a tracheobronchial 'tree' of air-transporting tubes and the terminal array of thin-walled alveoli where gaseous exchanges occur, is universal in land vertebrates including birds, whose lungs, however, display particular specializations which cannot be entered into here (*see* Portmann 1950). Although the tubes acquire the ability to alter their calibre by contraction or relaxation of nonstriated muscle in their walls, it is in the alveoli that the main volumetric changes of inspiration and expiration occur. As we shall see, the means by which inflation and deflation are effected vary. There is considerable variation—even ignoring avian specialization—in the dimensional characteristics of alveoli and bronchi in different vertebrate groups, including the pattern of branching of the bronchi, lobation of the lungs and so on. Within particular groups, however, this pattern displays considerable constancy in its major features; and recognition of this in man (p. 1246) has proved to be especially valuable in problems of diagnosis and surgical treatment of pulmonary disorders.

Like the lungs the *larynx* also varies greatly in its adaptations in diverse vertebrate groups (Negus 1928, 1949). Although primarily a sphincteric mechanism, it also assumes the functions of *phonation*, even in the first air-breathers, the amphibia, whose pre-nuptial coaxation is all too familiar. As might be expected, the musculature, skeletal elements and neurovascular supplies are derived from the pharynx and branchial apparatus, and numerous allusions to this occur in the appropriate sections of this book (*see*, for example pp. 145, 150, 151, 207).

The amphibia still 'swallow' air, which is drawn in through valvular 'nostrils', opening anteriorly into the roof of the mouth, there being no separate nasal cavity. The floor of the mouth is lowered to inspire, and when it is raised the nostrils are closed, and air is pumped into the pharynx, larynx and lungs. The mouth and pharynx therefore subserve both respiration and feeding. Among reptiles more active forms have evolved, demanding more efficient respiration, which is partly achieved by the development of movable ribs and a change to *aspiration* of air by reduction of pressure in the lungs themselves. This new technique of breathing is finally improved, in the mammals, by the evolution of a muscular diaphragm, leading to the formation of a complete musculo-osseous thoracic cavity, whose elaborated musculature becomes a most efficient means of varying the thoracic and hence pulmonary volume. (It also has an additional advantage in aiding the venous return.) In mammals the oronasal cavity becomes divided into respiratory and alimentary regions by the appearance of a palate; but the former, evolving in continuity with the primitive nares of the upper jaw, is *cranial* or *dorsal* to the mammalian oral cavity—the reverse of the relationship

between pharynx and larynx. Hence the mammalian airway *crosses* the alimentary path in the middle level of the pharynx, and a great variety of adaptations have occurred in the pharynx, palate, and especially the larynx to overcome the difficulties of this curious arrangement, not only in terms of structure but also in the reflexes associated with breathing and swallowing.

The mammalian 'airway' thus includes the nasal cavity, nasal and oral levels of the pharynx, the larynx, trachea, bronchi and their ultimate ramifications in the lungs. Breathing through the mouth is, of course, also possible; but this interferes with the olfactory and 'air-conditioning' functions of the nasal cavity. The separation of a respiratory and olfactory chamber from the mouth has considerable advantages: predatory mammals can still breathe with a mouth obstructed by prey, whose struggles may be prolonged; and their herbivorous prey may still sense warning odours while feeding. In aquatic vertebrates, such as crocodiles, dolphins and whales, a spout-like elongation of the larynx projects into the nasopharynx, more or less completely separating the airway, so that respiration can continue at the water surface even with the mouth submerged, open, and ready for prey. Of course, in the marine mammals other associated specializations occur (Andersen 1969).

In man, typically less specialized in most structural features than many other vertebrates, there is, nevertheless, one outstanding functional elaboration in association with the respiratory system—*speech*. The nasal cavity is still respiratory, olfactory, and an organ of heat and water vapour exchanges, with a small contribution to the sounds of speech. But the larynx, though still an essential sphincter—obviating the entry of swallowed food and other foreign bodies, and a blockade to build up pressure for coughing or as an aid to extreme muscular efforts—is so frequently involved in phonation that this is often regarded as its prime function. It is certainly in this that it has reached unique abilities in mankind. The elaboration of its musculature, and of the neural control which integrates the laryngeal sound production with respiratory, pharyngeal, palatal, lingual and labial muscles in the expert articulation of speech, provide man with this unique ability. Speech, which must of course be heard and interpreted, and which is later expressed in visible, written form, has led to the most complex and abstract symbolology of language (with which mathematical and musical notation may be coupled). In these activities, for which there is no true parallel in the life of any other animal known to us, the highest integrations of the nervous system and locomotor structures are elaborated. The basic function of the respiratory system remains, naturally, vital to mere existence; but its primitive phonational potentiality, leading finally to speech, in all its permutations, would seem to be a fundamental factor in the evolution of human intelligence. It is curious that in the other most 'vocal' vertebrate class, birds, the larynx is commonly a sphincteric mechanism alone, sounds in great variety being produced by the *syrinx*, situated at the tracheal bifurcation. Some birds, of course, are notable imitators of human speech; but there is no evidence of development of true, symbolic language in any vertebrate other than mankind, in whom, presumably, high manual dexterity, large cerebral (especially cortical) development, and emancipated vision have alone provided the adequate milieu for linguistic evolution.

The Larynx

The larynx, which is an organ of phonation, an air passage, and a sphincteric mechanism, extends from the root of the tongue to the trachea. (*See* Terracol *et al.* 1965, and for a detailed recent monograph on laryngeal biomechanics consult Fink and Demarest 1978.) It projects ventrally between the great vessels of the neck, and is covered anteriorly by the skin, the fasciae and the depressor muscles of the hyoid bone (**8**.1A). Above, it opens into the laryngeal part of the pharynx, of which it forms the anterior wall; below, it is continuous with the trachea. In the adult male it is situated opposite the third to sixth cervical vertebrae, but it occupies a somewhat higher position in the child and in the adult female. In infants of between six and twelve months the tip of the epiglottis (the highest part of the larynx) is a little above the level of the cartilaginous disc between the dens and the body of the axis. Its average measurements in the European adult are as follows:

	In males	In females
Length	44 mm	36 mm
Transverse diameter	43 mm	41 mm
Anteroposterior diameter	36 mm	26 mm

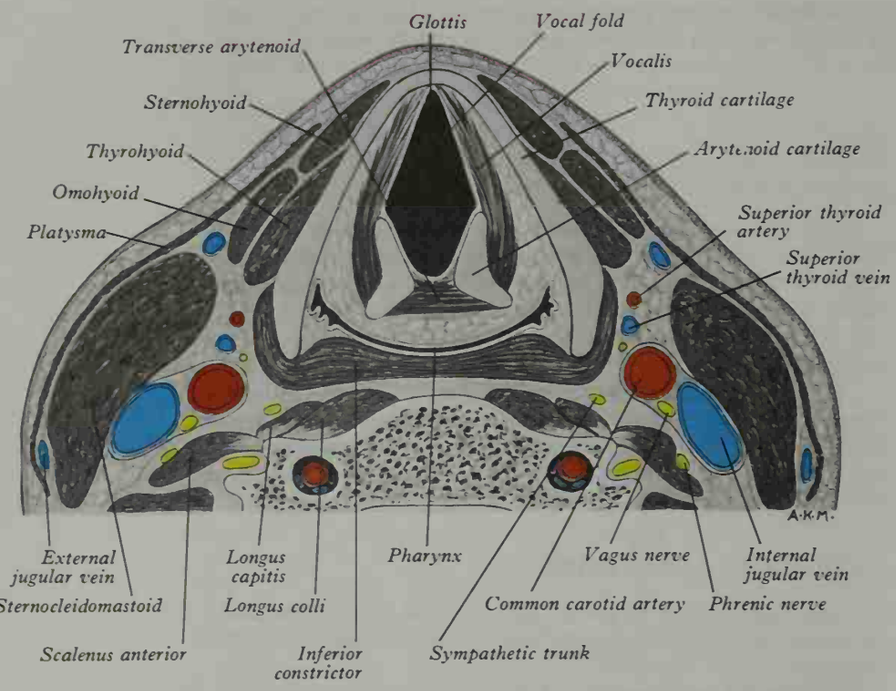
Until puberty the larynx of the male differs little in size from that of the female. In the female its increase at puberty is only small. In the male the increase is considerable; all the cartilages enlarge and the thyroid cartilage projects in the anterior median line of the neck, while the anteroposterior diameter is nearly doubled.

The skeletal framework of the larynx is formed of cartilages, which are connected by ligaments and membranes, and are moved by a number of muscles. Its internal lining is a mucous membrane continuous above and behind with that of the pharynx and below with that of the trachea.

LARYNGEAL CARTILAGES

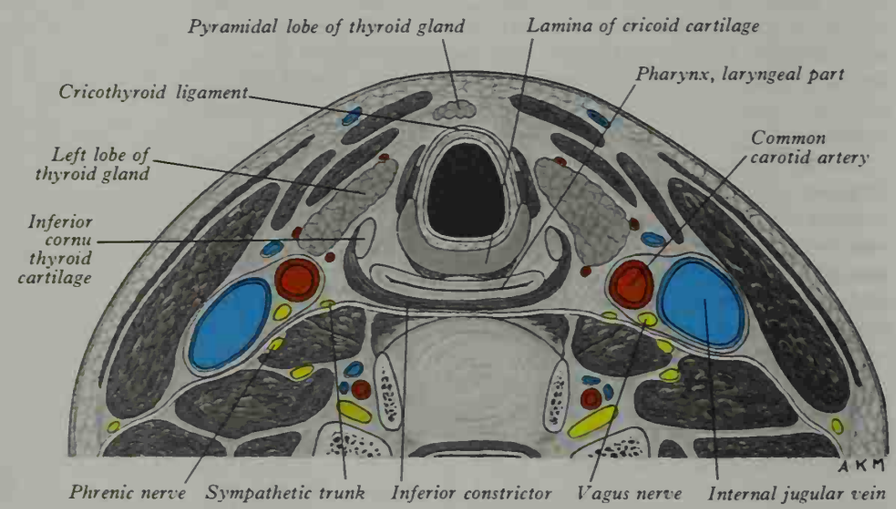
The cartilages of the larynx comprise the thyroid, cricoid and epiglottis, and the paired arytenoid, cuneiform and corniculate cartilages.

The thyroid cartilage (**8**.1, 2, 12) is the largest cartilage of the larynx. It consists of two quadrilateral *laminae*, the caudal parts of the anterior borders of which are fused at an angle in the median plane to form a subcutaneous projection named the *laryngeal prominence*, or 'Adam's apple'. This prominence is most distinct at its upper part, and is well marked in the male but scarcely visible in the female. Immediately above it the laminae are separated by a V-shaped notch, the superior *thyroid notch* or *incisure*. Posteriorly the *laminae* diverge and the posterior border of each is prolonged as two slender processes, the *superior* and *inferior cornua*.



On the *external surface* of each lamina an *oblique line* curves downwards and forwards from the *superior thyroid tubercle*, which is situated a little in front of the root of the superior horn, to the *inferior thyroid tubercle* on the lower border of the lamina. This line provides attachment for the sternothyroid, the thyrohyoid and inferior constrictor of the pharynx. The *internal surface* is smooth: above and behind, it is slightly concave and covered with mucous membrane. In the upper part of the angle formed by the junction of the laminae, the thyro-epiglottic ligament is attached; below this, and on each side of the midline, the vestibular and vocal ligaments and the thyro-arytenoid, thyro-epiglottic and vocal muscles gain attachment.

The *superior border* of each lamina is concave behind and convex in front; it gives attachment to the corresponding half of the thyrohyoid membrane. The *inferior border* is concave behind, and nearly straight in front, the two parts being separated by the inferior thyroid tubercle. In and near the median plane it is connected to the cricoid cartilage by the anterior (median) cricothyroid ligament (*see* p. 1233).



The *anterior* border is fused with that of the opposite lamina, forming with it an angle of about 90° in men, and about 120° in women. In men the greater projection of the laryngeal prominence, the correspondingly greater length of the vocal folds and resultant deeper pitch of the voice are all associated with the smaller thyroid angle. The *posterior border*, thick and rounded, receives the attachments of fibres of the stylopharyngeus and palatopharyngeus. The *superior cornu*, long and narrow, is curved upwards, backwards and medially, and ends in a conical extremity, which gives attachment to the lateral thyrohyoid ligament. The *inferior cornu*, short and thick, curves downwards, with a slight inclination forwards and medially; on the medial surface of its lower end there is a small oval facet for articulation with the side of the cricoid cartilage.

During infancy a narrow, diamond-shaped, flexible strip, named the *intrathyroid cartilage*, occupies the interval between the two laminae anteriorly and is joined to them by connective tissue.

The cricoid cartilage (**8**.3, 5, 6, 7) is smaller, but thicker and

8.1A A transverse section across the ventral region of the neck at the level of the vocal folds. Viewed from the superior aspect.

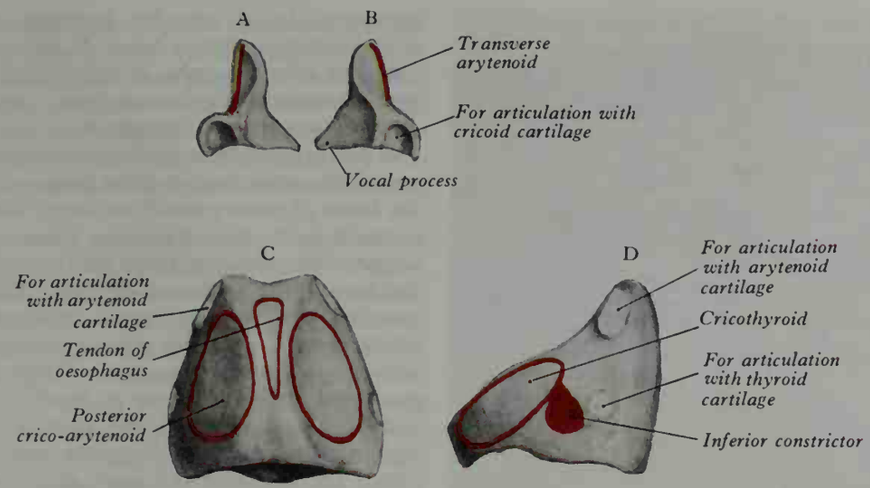
stronger than the thyroid cartilage. It is shaped like a signet ring, and forms the caudal parts of the anterior and lateral walls and most of the posterior wall of the larynx. It comprises a quadrate posterior lamina, and a narrow anterior arch.



The *lamina* of the cricoid cartilage is deep and broad, and measures vertically from 2 cm to 3 cm; the posterior surface is marked by a median vertical ridge, to the upper part of which the two fasciculi of the longitudinal fibres of the oesophagus are attached by a tendon (p. 1317). On each side of the ridge there is a shallow depression for the fibres of the posterior crico-arytenoid. The *arch* is narrow in front, measuring vertically from 5 mm to 7 mm, but widens posteriorly as it approaches the lamina. The external surface affords attachment in front and at the side to the cricothyroid, and behind to part of the inferior constrictor of the pharynx. The arch of the cricoid can be felt easily in the living subject below the laryngeal prominence and separated from it by a slight depression in which can be felt the resilient conus elasticus. On each side, at the junction of the lamina with the arch, there is a prominent circular facet, directed laterally and dorsally, for articulation with the inferior horn of the thyroid cartilage. The *inferior border* of the cricoid cartilage is horizontal, and connected to the highest tracheal cartilage by the cricotracheal ligament. The *superior border* runs obliquely upwards and backwards, giving attachment, anteriorly, to the thick median part and, at the sides, to the membranous lateral sheets of the cricothyroid ligament and the lateral crico-arytenoids. Posteriorly, the lamina presents a shallow median notch, and on its superolateral aspect, on each side, there is a smooth, oval, convex surface, directed upwards and laterally, for articulation with the base of the arytenoid cartilage. (*See*, however, Sellars and Keen, 1978). The *internal surface* of the cricoid cartilage is smooth and lined with mucous membrane.

The paired arytenoid cartilages (8.3, 6, 7) are placed on the lateral part of the superior border of the lamina of the cricoid cartilage, at the back of the larynx. Each is pyramidal, and has three surfaces, a base and an apex.

The *posterior surface*, triangular, smooth and concave, is covered by the transverse arytenoid. The *anterolateral surface* is somewhat convex and rough. On it, near the apex of the cartilage, there is an elevation from which a crest curves at first dorsally and then caudally and ventrally to the vocal process. The lower part of this crest intervenes between two depressions (or foveae), an upper, triangular, and a lower, oblong in shape; the upper gives attachment to the vestibular ligament; the lower to the vocalis and lateral crico-arytenoid. The *medial surface* is narrow, smooth and flat; it is covered with mucous membrane, and its lower edge forms the lateral boundary of the intercartilaginous part of the rima glottidis (p. 1233). The *base* is concave, and presents a smooth surface for articulation with the lateral part of the upper border of the lamina of the cricoid cartilage. Its lateral angle or *muscular process*, rounded and prominent, projects backwards and laterally, and gives attachment to the posterior crico-arytenoid

behind, and to the lateral crico-arytenoid in front. Its anterior angle or *vocal process* is pointed; it projects horizontally forwards and gives attachment to the vocal ligament. The *apex* curves backwards and medially, and articulates with the *corniculate cartilage*.

The corniculate cartilages (8.6, 7, 11) are two small conical nodules of elastic fibrocartilage which articulate with the summits of the arytenoid cartilages and serve to prolong them backward and medially. They are situated in the posterior parts of the aryepiglottic folds of mucous membrane, and are sometimes fused with the arytenoid cartilages.

The cuneiform cartilages (8.7, 11) are two small, elongated, club-shaped pieces of elastic fibrocartilage, placed one in each aryepiglottic fold, where they give rise to whitish elevations on the surface of the mucous membrane, anterosuperior to the corniculate cartilages.

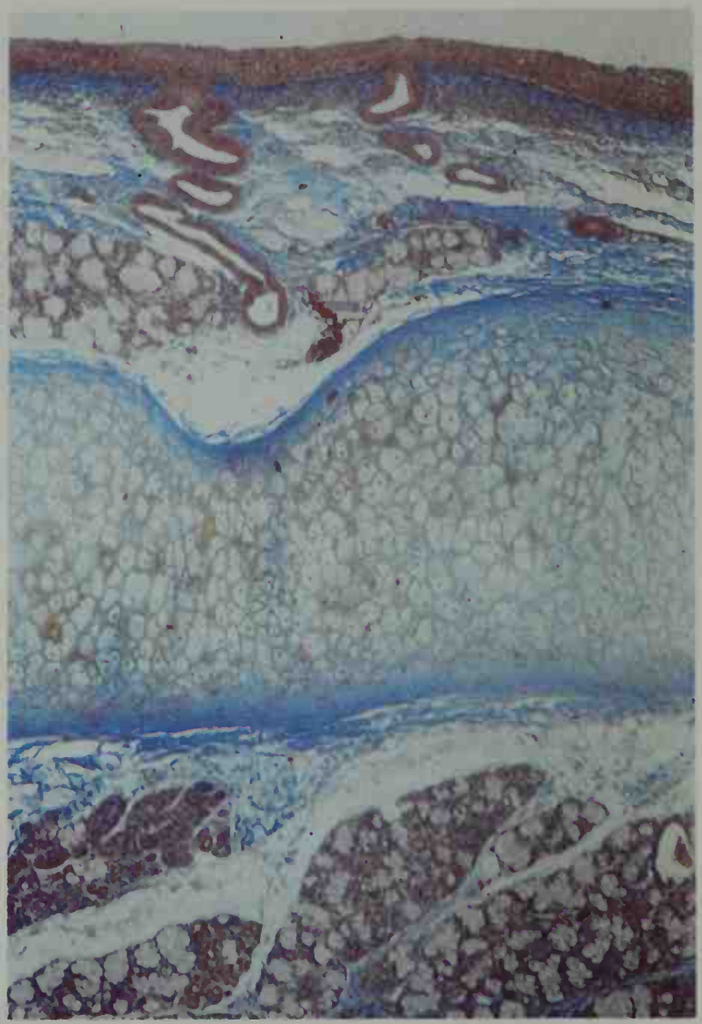
The cartilage of the epiglottis (8.4, 6, 7) is a thin, leaf-like lamella of elastic fibrocartilage, which projects obliquely upwards behind the tongue and the body of the hyoid bone, and in front of the entrance to the larynx. The free extremity, broad and rounded, is directed upwards; the attached part or stalk is long, narrow, and connected by an elastic ligament, named the *thyro-epiglottic ligament*, to the angle formed by the two laminae of the thyroid cartilage, a short distance below the thyroid notch. The sides of the epiglottis are attached to the arytenoid cartilages by the aryepiglottic folds of mucous membrane (p. 1233).

The upper part of the *anterior surface* of the epiglottis is free, and covered with mucous membrane, which is reflected on to the pharyngeal part of the tongue and on to the lateral wall of the pharynx, forming a *median glosso-epiglottic fold* and two *lateral glosso-epiglottic folds*. The depression on each side of the median glosso-epiglottic fold is named the *vallecula*. The lower part of the anterior surface lies behind the hyoid bone and the thyrohyoid membrane, and is connected to the upper border of the hyoid bone by an elastic *hyo-epiglottic ligament*; it is separated from the thyrohyoid membrane by some fatty tissue.

The *posterior surface* of the epiglottis is smooth, concave from side to side, concavoconvex from above downwards, and covered with mucous membrane; its lower part projects backwards as an elevation, known as the *tubercle*. When the mucous membrane is removed, the cartilage is seen to be indented by a number of small pits into which mucous glands project. The cartilage is perforated by branches of the internal laryngeal nerve.

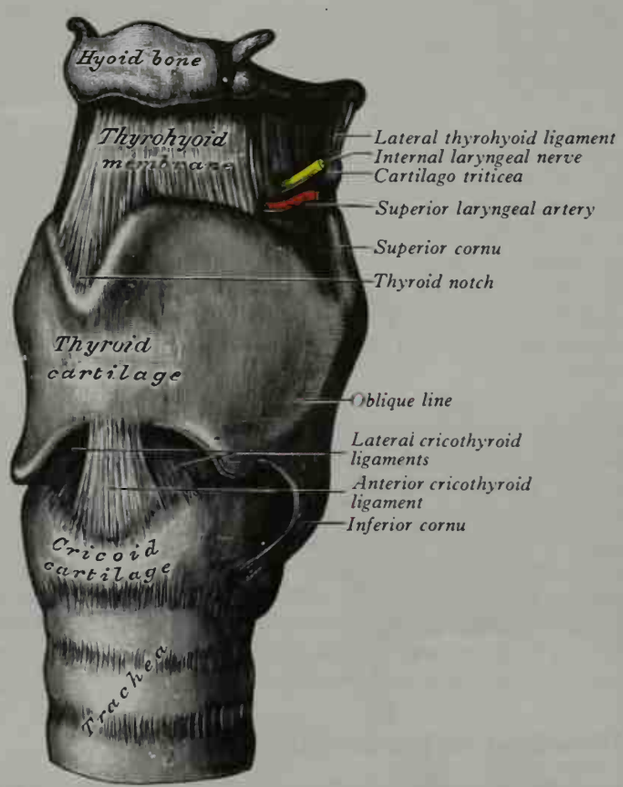
8.4A The epiglottis, posterior aspect. Note its pitted surface.

Functions of the Epiglottis



During deglutition (p. 1313) the epiglottis moves upwards and forwards and is squeezed between the base of the tongue and the rest of the larynx, the bolus slipping over its anterior surface as it bends over to close the inlet of the larynx. In man, it is degenerate in function and is separated from the soft palate by a long interval; it is not essential for deglutition, which can take place normally even if the epiglottis is destroyed by disease; neither is it essential for respiration or phonation. Some mammals are keen scented even when the mouth is open for feeding. In these, the epiglottis is large and projects into the nasal part of the pharynx *above* the soft palate; when eating, the epiglottis is drawn downwards and forwards (by the hyo-epiglottic muscle, represented in man by the hyo-epiglottic ligament) against the *upper* surface of the soft palate, so keeping the nasal airway clear and the buccal airway closed. Thus, the function of the epiglottis in these animals is to preserve the integrity of the olfactory sense even when the mouth is open.

Structure of the Laryngeal Cartilages



The corniculate and cuneiform cartilages, the epiglottis, and the apices of the arytenoids consist of *elastic* fibrocartilage, which shows little tendency to calcification. The thyroid, cricoid, and the greater part of the arytenoids consist of hyaline cartilage, and become more or less ossified as age advances. Ossification commences about the twenty-fifth year in the thyroid cartilage, and somewhat later in the cricoid and the arytenoids; by the sixty-fifth year these cartilages commonly show, in radiographs, patchy calcification and may even become ossified.

LARYNGEAL ARTICULATIONS

The joints between the inferior cornua of the thyroid cartilage and the sides of the cricoid cartilage are synovial, and each is

8.4B A low magnification light micrograph of a transverse section of the epiglottis, showing stratified squamous epithelium covering the anterior surface, mucous glands and fibro-elastic cartilage. 8.5 The ligaments of the larynx. Anterolateral aspect.

enveloped by a capsular ligament, which is strengthened posteriorly by a fibrous band. At these joints the cricoid rotates upon the inferior cornua of the thyroid cartilage around an axis passing transversely through both joints; to a limited extent the cricoid also glides in different directions on the thyroid cornua.

A pair of synovial joints exists between the facets on the lateral part of the upper border of the lamina of the cricoid cartilage and the bases of the arytenoid cartilages; each joint is enclosed by a capsular ligament, and a strong *posterior crico-arytenoid ligament* connects the cricoid cartilage with the medial and posterior part of the base of the arytenoid cartilage. These joints permit of two varieties of movement: one is arytenoid rotation about an axis which is not vertical but runs obliquely from dorsomediocranial to ventrolaterocaudal positions (Frable 1961), whereby the vocal process is moved laterally or medially, and the rima glottidis increased or diminished; the other is a gliding movement, and allows the arytenoid cartilages to approach or recede from each other; the direction and slope of the articular surfaces allows lateral gliding accompanied by a forward and downward movement. The two movements of gliding and rotation are associated, the medial gliding being connected with medial rotation, and the lateral gliding with lateral rotation (von Leden and Moore 1961). The posterior crico-arytenoid ligaments limit the forward movements of the arytenoid cartilages on the cricoid cartilage. (For dimensional details of the crico-arytenoid articulation consult Sonesson 1959 and Sellars and Keen 1978.)

Sometimes a synovial joint exists between the apex of each arytenoid cartilage and the corresponding corniculate cartilage but the junction is usually by cartilage.

Numerous lamellated (Pacinian) corpuscles, a few Ruffini endings and free nerve endings are present in the capsules of the laryngeal joints. In the cat these receptors respond to mechanical stimulation and are involved in the normal coordination of activity in the laryngeal muscles during respiration and phonation (Kirchner and Wyke 1965). The articular supply in man is derived chiefly from the recurrent laryngeal nerves, by independent rami or by branches from the muscular rami of the nerve (Psenicka 1966).

LARYNGEAL LIGAMENTS AND MEMBRANES

Extrinsic Ligaments

The *thyrohyoid membrane* (**8**.5, 6) is a broad, fibroelastic layer, attached below to the cranial border of the thyroid cartilage and to the front of its superior cornua, and above to the *upper* margin of the posterior surface of the body and greater cornua of the hyoid bone. As it ascends, it passes behind the concave posterior surface of the body of the hyoid bone, and is separated from it by a bursa which facilitates the upward movement of the larynx during deglutition. The median and thicker part of the membrane is termed the *median thyrohyoid ligament*; on each side the lateral and thinner part is pierced by the superior laryngeal vessels and the internal laryngeal nerve. Its outer surface is contiguous with the thyrohyoid, sternohyoid and omohyoid, and with the body of the hyoid bone. Its inner surface is related to the epiglottis and the piriform fossa of the pharynx. The *lateral thyrohyoid ligaments* are round elastic cords which form the posterior borders of the thyrohyoid membrane, and connect the tips of the superior cornua of the thyroid cartilage to the posterior ends of the greater cornua of the hyoid bone. A small cartilaginous nodule, termed the *cartilago triticea*, occurs frequently in each ligament.

The epiglottis is attached to the hyoid bone by the hyo-epiglottic ligament and to the thyroid cartilage by the thyro-epiglottic ligament (p. 1231).

The *cricotracheal ligament* unites the lower border of the cricoid cartilage with the first tracheal cartilage. It is continuous below with the fibrous membrane which invests the tracheal cartilages.

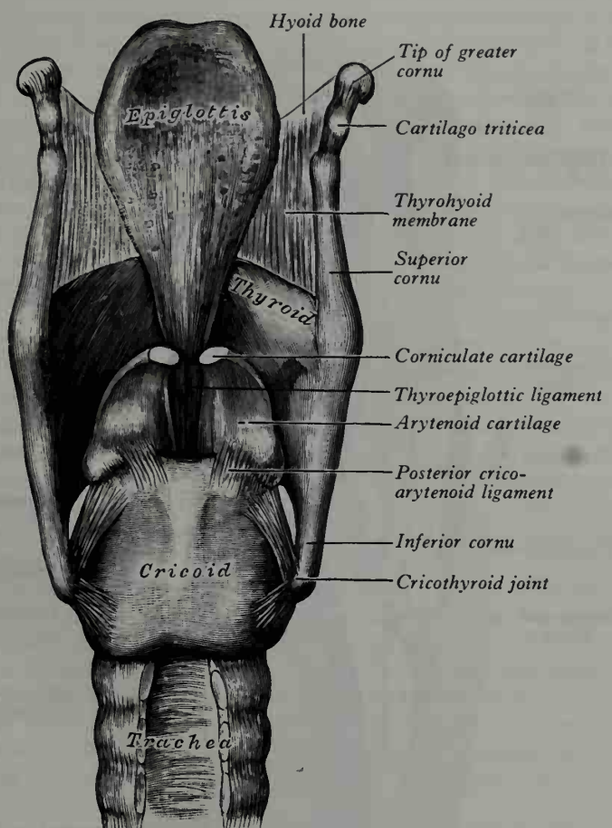
Intrinsic Ligaments

Beneath the mucous membrane of the larynx there is a broad sheet of fibrous tissue which contains many elastic fibres, and is termed the *fibroelastic membrane of the larynx*. It is interrupted on each side by the interval between the vestibular and vocal ligaments;

the upper portion, called the *quadrangular membrane*, extends between the arytenoid cartilage and the cartilage of the epiglottis, and is often poorly defined; the lower part is a well-marked membrane forming, with its fellow of the opposite side, the *cricothyroid ligament* (*cricovocal membrane*), which connects the thyroid, cricoid and arytenoid cartilages. The joints between the individual cartilages are also provided with ligaments, already described.

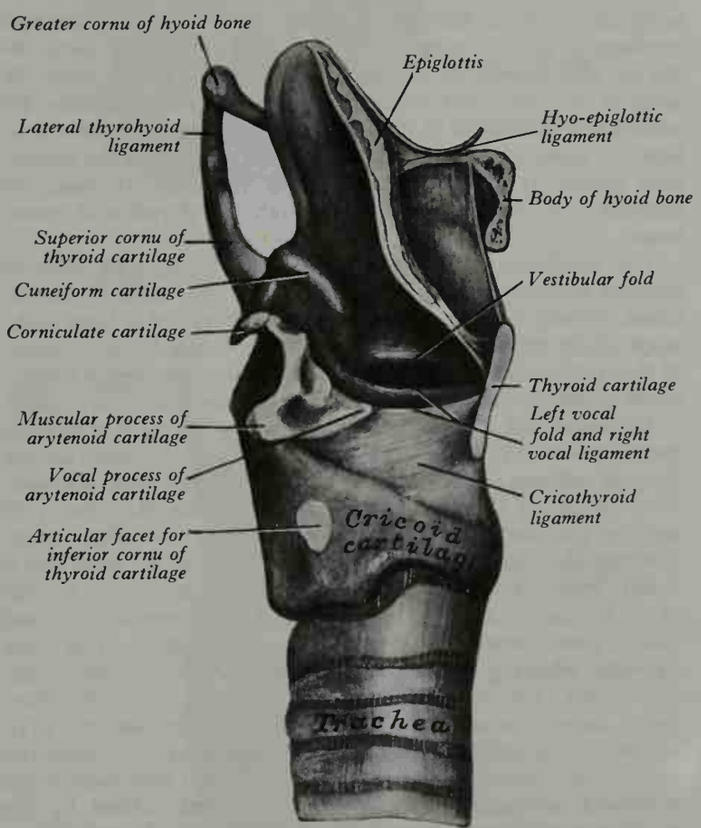
The cricothyroid ligament (**8**.5, 7) is the inferior, larger part of the fibro-elastic laryngeal membrane. Composed mainly of elastic tissue, it is described as showing distinctive anterior and lateral parts. The *anterior* (*median*) *cricothyroid ligament* is thick, broad below, narrower above, and connects adjacent margins of the cricoid and thyroid cartilages. An anastomosis between the two cricothyroid arteries arches across it and supplies perforating rami to the larynx. The *lateral cricothyroid ligaments* (sometimes termed cricothyroid or cricovocal membranes, are thinner, lined internally by laryngeal mucous membrane and covered externally by the lateral crico-arytenoid and thyro-arytenoid muscles. From the internal rim of the superior border of the cricoid cartilage they ascend and converge, and their free superior edges, which extend from the dorsal aspect of the thyroid angle (just caudal to its midpoint) to the apices of the vocal processes of the arytenoid cartilages, form the basis of the vocal folds (**8**.9). These two thickened edges of the cricothyroid ligamentous complex are distinguished from the rest of it as the *vocal ligaments* (**8**.7). (The picturesque but ill-defined term, *conus elasticus*, is commonly applied to the entire complex sometimes only to its anterior part.)

The cavity of the larynx (**8**.8, 9) extends from the laryngeal inlet, by which it communicates with the pharynx, to the level of the lower border of the cricoid cartilage, where it is continuous with the cavity of the trachea. It is divided into three parts by an upper and a lower pair of folds of mucous membrane which project from the sides of the cavity into its interior. The upper pair are named the *vestibular folds*, and the fissure between them is called the *rima vestibuli*. The lower pair are concerned in the production of the voice, and are therefore named the *vocal folds*, and the fissure between them is called the *rima glottidis*, commonly called the *glottis*.



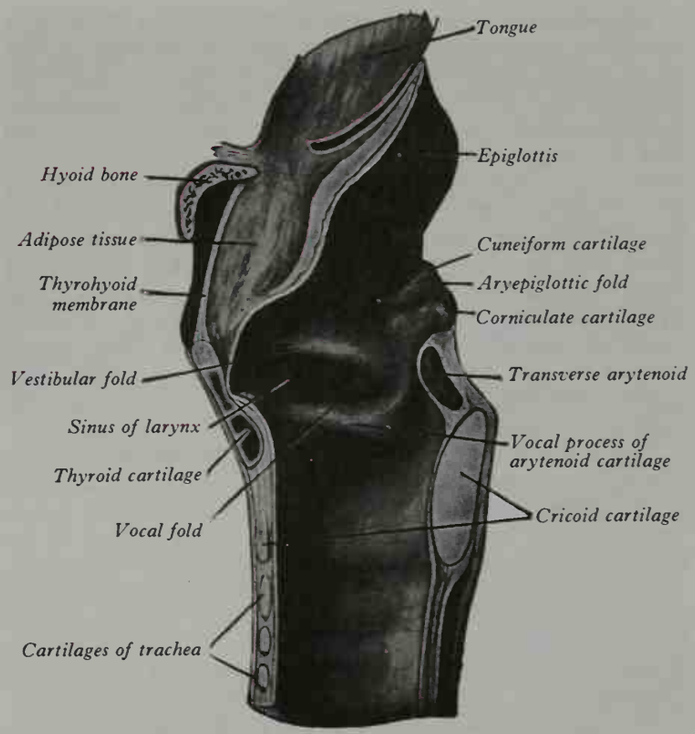
The *inlet of the larynx* or 'aditus laryngis' (**8**.10) is the aperture through which the laryngeal cavity opens into the pharynx. The plane of the aperture is directed backwards and somewhat upwards, for the anterior wall of the larynx is much longer than its posterior wall and slopes downwards and forwards in its upper part (**8**.8). The opening is bounded anteriorly by the upper edge of the epiglottis, posteriorly by the mucous membrane stretching between the arytenoid cartilages, and on each side by the free edge of a fold of mucous membrane which stretches between the side of the epiglottis and the apex of the arytenoid cartilage and contains ligamentous and muscular fibres; this is the *aryepiglottic fold*, and in the posterior part of its free margin there are two oval elevations, an anterosuperior due to the cuneiform cartilage, and a postero-inferior due to the corniculate cartilage. These are separated by a shallow vertical furrow, which is continuous below with the opening into the sinus of the larynx (*vide infra*).

The *vestibule of the larynx* (**8**.8, 9) is the part between the laryngeal inlet and the level of the vestibular folds; it is wide above, and narrow below. Its anterior wall is much longer than its posterior wall and consists of the posterior surface of the epiglottis, the lower part of which projects backwards as its *tubercle* (p. 1231). Its lateral walls, deep in front and shallow behind, are formed by the medial surfaces of the aryepiglottic folds; its posterior wall consists of the mucous membrane connecting the arytenoid cartilages, above the level of the vestibular folds.



The *middle part* of the laryngeal cavity is the smallest. It reaches from the level of the rima vestibuli to that of the rima glottidis. On each side it opens, through a slit between the vestibular and vocal folds, into a recess which is named the sinus of the larynx.

The *sinus of the larynx* (**8**.8, 9) is a fusiform recess which lies between the vestibular and vocal folds, and ascends for a short distance lateral to the vestibular fold. It is lined with mucous membrane, clothed on the outside by the corresponding thyro-arytenoid. From the anterior part of the sinus a narrow opening leads upwards into the saccule of the larynx.



The *saccule of the larynx* (**8**.9) is a pouch which ascends from the anterior part of the sinus, between the vestibular fold and the inner surface of the thyroid cartilage, occasionally extending as

8.8 A sagittal section showing the medial aspect of the right half of the larynx.

high as the upper border of the cartilage; it is conical in form, and curved slightly backwards. On the surface of its mucous membrane there are the openings of sixty to seventy mucous glands, which are lodged in the submucous areolar tissue. The saccule is enclosed in a fibrous capsule continuous below with the vestibular ligament. Its medial surface is covered by a few muscular fasciculi, which arise from the apex of the arytenoid cartilage and, passing forwards between the saccule of the larynx and the mucous membrane of the vestibule, disappear in the aryepiglottic fold; laterally it is separated from the thyroid cartilage by the thyro-epiglottic muscle. The muscles compress the sac and express the secretion of its mucous glands upon the surfaces of the vocal folds. In most apes the saccules are remarkably developed in the form of air sacs, which may extend into the superficial tissues of the neck and even into the axillae; they appear to affect the resonance of the voice. In man, the saccules occasionally protrude through the thyrohyoid membrane.

The *vestibular folds* (**8**.7, 8, 9) are two thick, pink folds of mucous membrane, each enclosing a narrow band of fibrous tissue, termed the *vestibular ligament*, which is fixed in front to the angle of the thyroid cartilage immediately below the attachment of the epiglottic cartilage, and behind to the anterolateral surface of the arytenoid cartilage, a short distance above the vocal process.

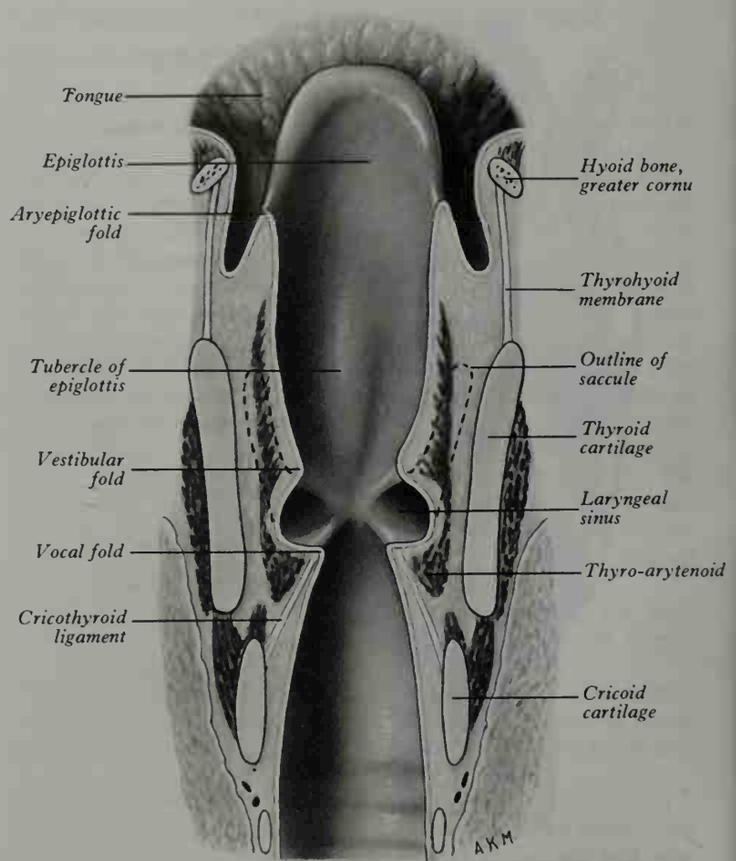
The *vocal folds* (**8**.7, 8, 9) are two sharp, white folds of mucous membrane which stretch from the middle of the angle of the thyroid cartilage to the vocal processes of the arytenoid cartilages. They form the lateral boundaries of the rima glottidis in its anterior part and are concerned in the production of the voice. The stratified squamous epithelium which covers the vocal fold is closely bound down to the underlying vocal ligament. As a result of the absence of a submucous layer and blood vessels, the vocal fold is pearly white in colour in the living subject. The *vocal ligament*, which is continuous below with the lateral part of the cricothyroid ligament (p. 1232), consists of a band of yellow elastic tissue, related, on its lateral side, to the vocalis (p. 1235).

The *rima glottidis* or *glottis* (**8**.11) is a fissure between the vocal folds anteriorly, and the bases and vocal processes of the arytenoid cartilages posteriorly; it is limited behind by the mucous membrane passing between the arytenoid cartilages, at the level of the vocal folds. The region between the vocal folds is named the *intermembranous part*, and measures about three-fifths of the length of the entire aperture; that between the arytenoid cartilages is named the *intercartilaginous part*. The average sagittal diameter of the glottis, in the adult male, is 23 mm; in the adult female, 17 mm. It is the narrowest part of the larynx, but its width and shape vary with the movements of the vocal folds and arytenoid cartilages during respiration and phonation (*see* p. 1236).

The *lower part* of the laryngeal cavity extends from the level of the vocal folds to the lower border of the cricoid cartilage. Its upper part is elliptical in form, but its lower part widens, assumes a circular shape, and is continuous with the cavity of the trachea. It is lined with mucous membrane, and its walls consist of the cricothyroid ligament above, and the inner surface of the cricoid cartilage below.

LARYNGEAL MUSCULATURE

The muscles of the larynx are divisible into two groups: (1) *extrinsic and* (2) *intrinsic*.



(1) The extrinsic muscles pass between the larynx and neighbouring structures, and are described in the section on Myology (p. 539).

(2) The intrinsic muscles are: the *cricothyroid, posterior crico-arytenoid, lateral crico-arytenoid, transverse arytenoid, oblique arytenoid* and its subsidiary part the *aryepiglotticus, thyro-arytenoid* and its subsidiary part the *vocalis*, and *thyro-epiglotticus*. With the exception of the transverse arytenoid these muscles are paired.

The cricothyroid (**8**.12), triangular in form, arises from the front and lateral part of the outer surface of the cricoid cartilage; its fibres diverge, and are arranged in two groups. The lower fibres constitute the '*oblique*' *part* and slant backwards and laterally to the anterior border of the inferior cornua, while the superior fibres form the '*straight*' *part* and run upwards and backwards to the posterior part of the lower border of the lamina of the thyroid cartilage.

The medial borders of the two muscles are separated by a triangular interval occupied by the conus elasticus.

The posterior crico-arytenoid (**8**.13) arises from the inferomedial region of the broad depression on the corresponding

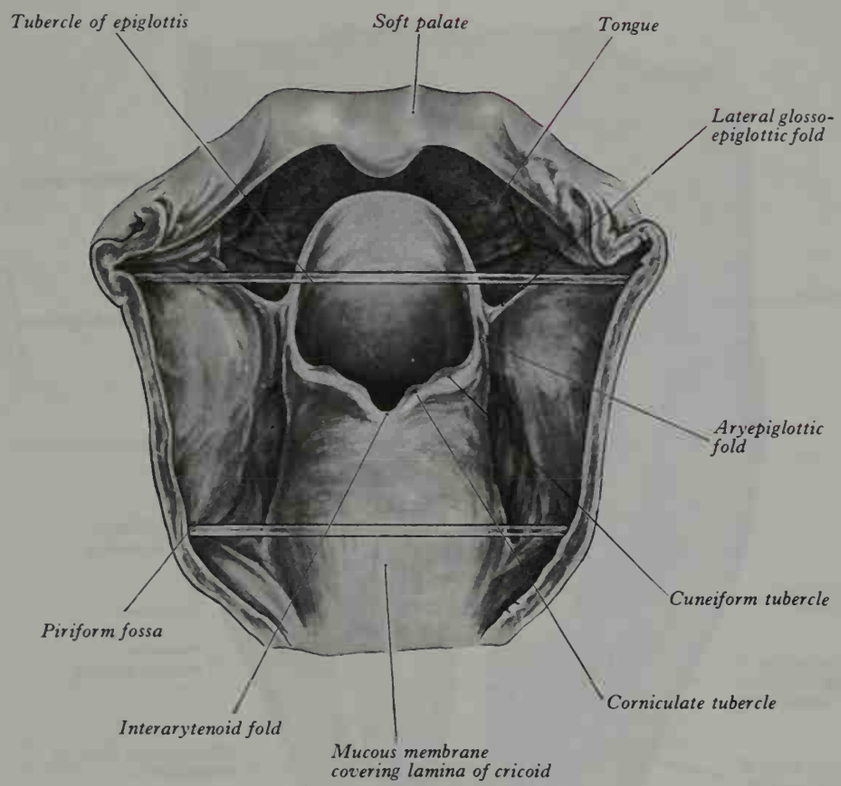
8.9 A coronal section through the larynx and the cranial end of the trachea. Posterior aspect.

half of the posterior surface of the lamina of the cricoid cartilage; its fibres, directed upwards and laterally, converge to be inserted into the back of the muscular process of the arytenoid cartilage. The highest fibres are nearly horizontal, the middle oblique and the lowest almost vertical; some of the latter fibres are inserted into the anterolateral surface of the arytenoid cartilage.

The lateral crico-arytenoid (8.14) is smaller than the preceding muscle; it arises from the upper border of the arch of the cricoid cartilage, and, passing obliquely upwards and backwards, is inserted into the front of the muscular process of the arytenoid cartilage.

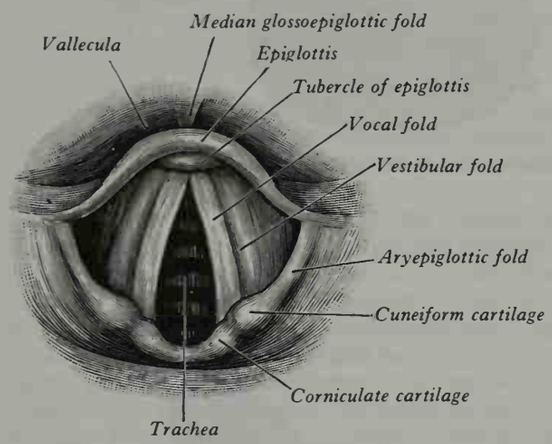
The transverse arytenoid (8.13) is a single muscle which bridges the interval between the arytenoid cartilages and fills the posterior concave surfaces of these cartilages. It arises from the back of the muscular process and lateral border of the arytenoid cartilage of one side, and is inserted into the corresponding parts of the cartilage on the opposite side.

The oblique arytenoid (8.13), superficial to the transverse arytenoid, consists of two fasciculi which cross each other like the limbs of the letter X. Each passes from the back of the muscular process of one arytenoid cartilage to the apex of the opposite cartilage. Some of the fibres are continued round the lateral side of the apex of the arytenoid cartilage, and are prolonged into the aryepiglottic fold; they constitute the *aryepiglottic* muscle.



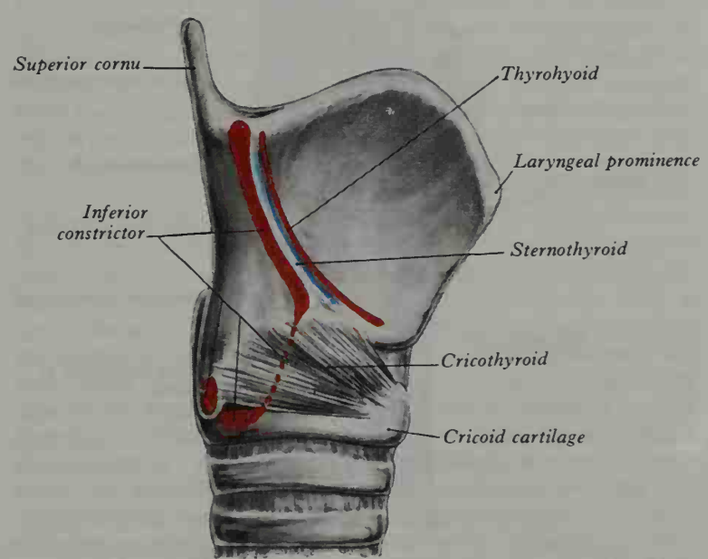
The thyro-arytenoid (8.14) is a broad, thin muscle, which is situated lateral to the vocal fold, the cricothyroid ligament, the sinus and the saccule of the larynx. It arises in front from the lower half of the angle of the thyroid cartilage, and from the crico-thyroid ligament. Its fibres pass backwards, laterally and upwards, to be inserted into the anterolateral surface of the arytenoid cartilage. The lower and deeper fibres of the muscle form a band which, in a coronal section, appears as a triangular bundle, and is attached to the lateral surface of the vocal process and to the inferior impression on the anterolateral surface of the arytenoid cartilage. This muscular bundle is named the **vocalis**, and is parallel with, and just lateral to, the vocal ligament; it is said to be thicker behind than in front, because many deeper fibres start from the vocal ligament, and so do not extend so far forwards as the thyroid cartilage. Other observers do not substantiate this usually accepted description; they consider that all its fibres loop in an arched and plaited manner from the thyroid cartilage to the arytenoid (Tautz and Rohen 1967). A considerable number of the fibres of the thyro-arytenoid are prolonged into the aryepiglottic fold, where some of them cease, while others are continued to the margin of the epiglottis, forming the **thyro-epiglotticus**. A few fibres extend along the wall of the sinus from the lateral margin of the arytenoid cartilage to the side of the epiglottis. The **superior thyro-arytenoid** (8.14), which is not always present, is a small muscle, lying on the lateral surface of the main mass of the thyro-arytenoid and extending obliquely from the angle of the thyroid cartilage to the muscular process of the arytenoid cartilage.

Actions. The muscles of the larynx may be conveniently divided into three groups according to their main actions (Negus 1947): (1) those which vary the glottis—the *posterior* and *lateral crico-arytenoids* and the *oblique* and *transverse arytenoids*; (2) those regulating the tension of the vocal ligaments—the *cricothyroids*, the *posterior crico-arytenoids*, the *thyro-arytenoids* and the *vocales*; (3) those which modify the inlet of the larynx—the *aryepiglottici* and the *thyro-epiglottici* (8.15). It is to be noted that, under normal conditions, the corresponding muscles of the two sides usually act in concert.

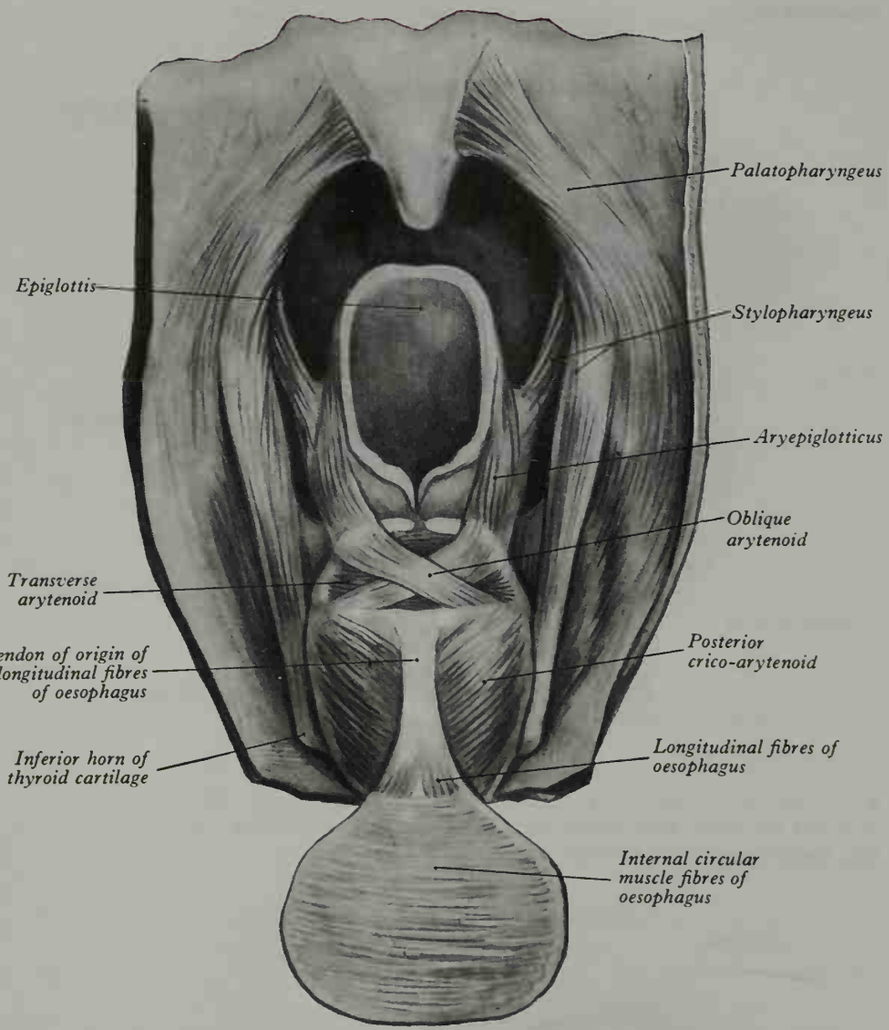


The *posterior crico-arytenoids* open the glottis, by rotating the arytenoid cartilage laterally around an axis passing through the crico-arytenoid joints (*see* p. 1232), so that the vocal processes and the attached vocal folds are separated. They also pull back the arytenoids, thus assisting the cricothyroids in making the vocal folds tense. The most lateral fibres of the muscle draw the arytenoids laterally, so that the entire rima glottidis becomes triangular (not rhomboid) when the posterior crico-arytenoids contract.

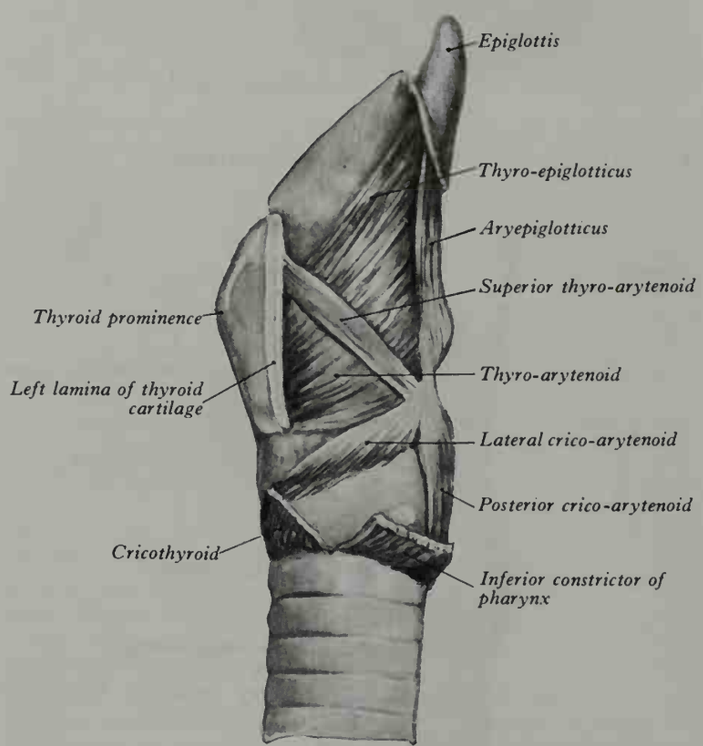
The *lateral crico-arytenoids* close the glottis, by rotating the arytenoid cartilages medially so as to approximate the vocal processes.



The *transverse arytenoid* approximates the arytenoid cartilages,



8.10 The inlet of the larynx, viewed from the posterior aspect. The posterior wall of the pharynx has been divided in the median plane and two glass rods have been inserted to keep the cut portions apart.



8.11 A laryngoscopic view of the interior of the larynx.

8.13 The muscles of the larynx. Posterior aspect.

8.14 The muscles of the larynx. Most of the left lamina of the thyroid cartilage has been removed. Left lateral aspect.

and thus closes the opening of the glottis, especially in its posterior part.

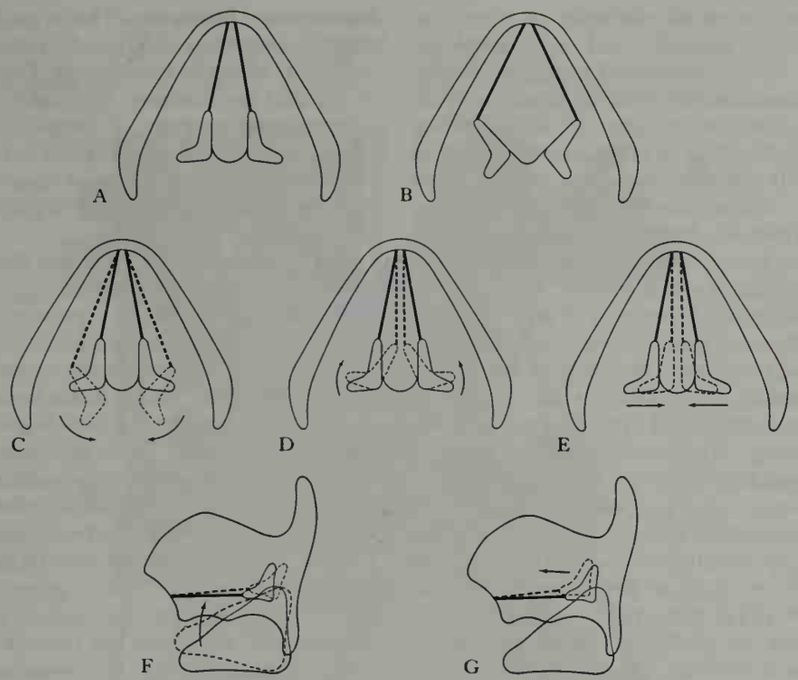
The *cricothyroids* produce tension and elongation of the vocal ligaments by drawing up the arch of the cricoid cartilage and tilting back the upper border of its lamina; the distance between the vocal processes and the angle of the thyroid is thus increased, and the vocal ligaments are consequently put on the stretch. They also pull the thyroid cartilage forward, increasing the distance between the angle of the thyroid cartilage and the arytenoids; this action also renders the vocal folds tense. The latter action of the muscle is probably the principal one, because during phonation the lamina of the cricoid is held immovably against the vertebral column by the action of the cricopharyngeus (p. 1311). During swallowing, the cricopharyngeus relaxes and allows the cricoid to be tilted forwards during closure of the inlet of the larynx.

The *thyro-arytenoids* draw the arytenoid cartilages towards the thyroid cartilage, and thus shorten and relax the vocal ligaments. At the same time they rotate the arytenoid cartilages medially and approximate the vocal folds. The deeper fibres, forming the *vocales*, produce relaxation of the posterior parts of the vocal ligaments, while the anterior part is tense, the effect being to raise the pitch of the voice. For a critique and expansion of the above simplified views of arytenoid movements, based upon dissection and electrical stimulation, consult Sellars (1978).

The *oblique arytenoids* and the *aryepiglottici* act as a sphincter of the inlet of the larynx, by bringing the aryepiglottic folds together, and by approximating the arytenoid cartilages to the tubercle of the epiglottis.

The *thyro-epiglottic* muscles widen the inlet by their action on the aryepiglottic folds.

Neuromuscular spindles are present in all the muscles of the human larynx (Keene 1961), and their numbers in individual muscles have been assessed (Voss 1966). The maximal count (23) was in the transverse arytenoid.



MOVEMENTS OF THE VOCAL FOLDS

In the condition of rest (**8**.15), e.g. in quiet respiration, the intermembranous part of the rima glottidis is triangular, its apex being in front and its base behind, the base being represented by a line (about 8 mm long) connecting the anterior ends of the vocal processes of the arytenoids; the intercartilaginous part is rectangular since the medial surfaces of the arytenoids are parallel.

In forced inspiration, the vocal folds undergo extreme abduction; the arytenoid cartilages are rotated laterally and their vocal processes move widely apart. The glottis is thus rhomboid; both intermembranous and intercartilaginous parts are triangular, the widest part of the aperture being opposite the attachments of the folds to the vocal processes of the arytenoids.

The movements of the vocal folds during phonation have been studied by high-speed cinematography (Pressman 1942). Preparatory to phonation the intermembranous and intercartilaginous parts of the glottis are reduced to a linear chink by adduction of the vocal folds, and adduction and medial rotation of the arytenoid cartilages. This is followed by tightening of the folds, the degree of tension determining the pitch of the sound. As the pitch rises, the tension of the folds increases and they may lengthen by as much as 50 per cent in the highest notes. The photographs suggest that the lengthening affects both extremities of the folds, indicating that the cricothyroids act not only on the cricoid cartilage as described above but also tilt the thyroid cartilage downwards and forwards. In whispering, the intermembranous part of the glottis is closed, but the intercartilaginous part remains widely patent, so that there is free escape of air during the process.

Fink (1975, 1978) has developed an interpretation of 'laryngeal biomechanics' which depends particularly upon the behaviour of the various *folds* which project into the cavity of the larynx to a highly variable degree dependent upon its activities in respiration, general bodily physical effort, and phonation. In addition to the well-recognized bilateral vocal, vestibular, and aryepiglottic folds, he identifies two further median folds, which he designates as the *median thyrohyoid fold* and the *interarytenoid*

8.15A–G A series of diagrams to show different positions of the vocal folds and arytenoid cartilages.

A Position of rest in quiet respiration. The intermembranous part of the rima glottidis is triangular and the intercartilaginous part is rectangular in shape.

B Forced inspiration. Both parts of the rima glottidis are triangular in shape.

C Abduction of the vocal folds. The arrows indicate the lines of pull of the posterior crico-arytenoid muscles. The abducted vocal folds and the abducted, retracted and laterally rotated arytenoid cartilages are shown in dotted outline. The entire rima glottidis is triangular.

D Adduction of the vocal folds. The arrows indicate the lines of pull of the lateral crico-arytenoid muscles. The adducted vocal folds and the medially rotated arytenoid cartilages are shown in dotted outlines.

E Closure of the rima glottidis. The arrows indicate the line of pull of the transverse arytenoid muscle. Both the vocal folds and the arytenoid cartilages are adducted, but there is no rotation of the latter.

F Tension of the vocal folds, produced by the action of the cricothyroid muscles which tilt the anterior part of the cricoid cartilage cranially and so carry the arytenoid cartilages dorsally.

G Relaxation of the vocal folds, produced by the action of the thyro-arytenoid muscles, which draw the arytenoid cartilages ventrally.

fold. The latter consists of the transverse arytenoid muscle, the mucous membrane anterior to which is bulged or *folded* into the larynx when the muscle approximates the two arytenoid cartilages. (It obviously helps to obliterate the intercartilaginous part of the rima glottidis in phonation.) The median thyrohyoid fold is a more complex entity. As can be seen in Fig. **8**.8, the lower part of the epiglottis is attached to the hyoid bone and thyroid cartilage by elastic ligaments, which are separated from the median thyrohyoid ligament by a wedge of adipose tissue; these are the hyo-epiglottic and thyro-epiglottic ligaments (p. 1231). Anterior to the adipose tissue is another elastic ligament, the anterior part of the thyrohyoid membrane including the median thyrohyoid ligament. During swallowing (p. 1313) a marked approximation of the thyroid cartilage and hyoid bone occurs (in addition to the general elevation of pharynx, larynx, and trachea). This approximation causes the structures defined above to bulge posteriorly into the aditus to the larynx as a transverse fold, helping considerably to narrow the entrance to the larynx proper during swallowing. During inspiration the reverse action occurs, and all the folds enumerated above are reduced to a minimum. The intrusion of all the folds, and not just the vocal folds, is also important in phonation since the cavity of the vocal tract (*vide infra*) is thereby altered, thus modifying the resonant properties of the tract. (The *median thyrohyoid fold*, as defined above, contains the so-called '*pre-epiglottic space*' of laryngeal surgery, an important region in the spread of supra-epiglottic tumours. *See* Maguire and Dayal 1974.)

The movements of the larynx, and the manner in which its inlet is closed during deglutition, are described on p. 1313.

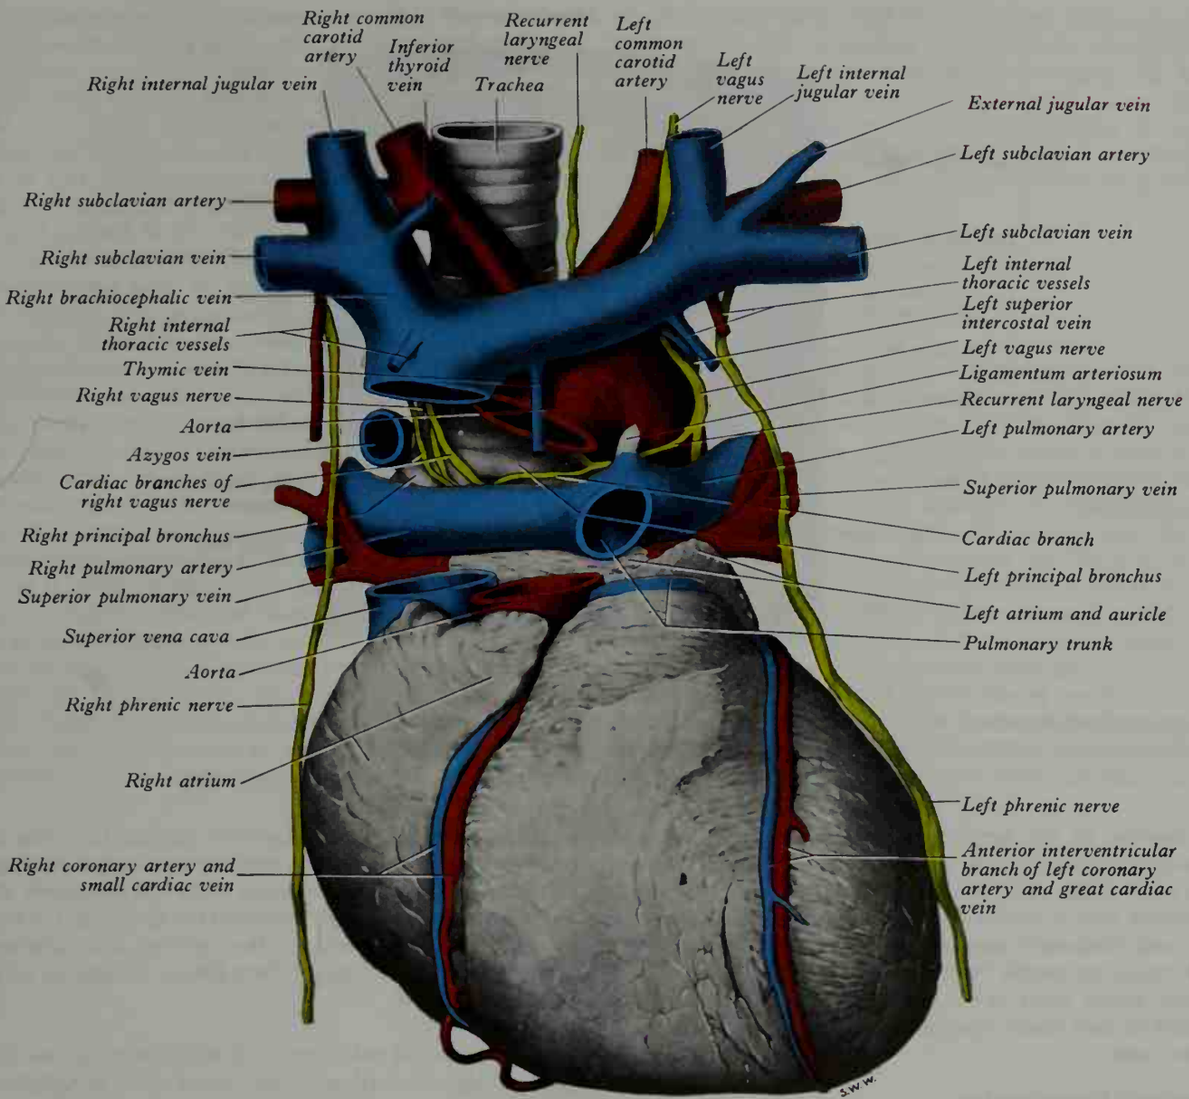
THE ANATOMY OF SPEECH

Though the respiratory function of the larynx is basic, its adaptation to speech is paramount to the emergence of human society and culture; the mute, the deaf, the illiterate are at a marked disadvantage. The intelligence, skill, and enterprise of the gregarious primates, especially mankind, is obviously dependent upon clear intercommunication. Language, in all its infinite permutations—firstly in speech, for immediate tribal integrations of effort, and then in recorded ideas and experience, with all the consequent power for accumulation and transmission of knowledge through time and space—is indispensable to human pre-eminence. The acquisition of language is perhaps the most complex sensorimotor development in the individual's life. Large cerebral territories are involved in the sensory, perceptual, and motor aspects of speech (p. 1014), in addition to the auditory system and the intricate assembly of structures producing speech. This assembly includes not only the larynx and other parts of the respiratory system, but also a most extensive array of muscles, from abdominal wall to lips. These muscles, apart from those of the larynx, are described elsewhere. Here we are concerned with the larynx and its associated respiratory spaces.

The larynx is the primary source of the complicated and endlessly varying chains of sounds which are the basis of speech. It is in this context, therefore, that its structure must now be considered, including the associated respiratory spaces—the pharynx, mouth and nasal cavities—which together with it constitute a 'vocal tract'. The physics of this in phonation, the production of sounds and their articulation into *phonemes*, the basic units of speech, has attracted less attention than other aspects of linguistics. These latter have engendered a vast literature, further augmented in recent years by a growing interdisciplinary approximation between workers in such diverse fields as 'hemispheric' anatomy, neurophysiology, and the 'psychological' aspects of speech. Such investigations are outside the compass of this volume; but the acoustics of speech, in terms of the structure of the vocal tract, must be briefly considered.

As in the case of most musical instruments, the speech

mechanism consists of three essential elements: a source of energy, structures capable of periodic and also aperiodic oscillations, and a resonator. Energy is derived from the velocity of the stream of expired air, oscillation primarily from the vocal folds, resonance from the multiform 'column' of air extending from the folds to the lips and nostrils. The physical activities in all three are intricate and rapidly variable, and must require most complex neural integration. These activities are, nevertheless, subject to the same physical laws as, for example, an organ pipe. They can hence, in principle, be similarly analysed, though not with the same metrical simplicity or precision as the more regularly constructed and unvarying organ pipe. The vocal folds vibrate in accordance with the same interactions of length, mass, and tension as a vibrating reed or string. The available increase in length, almost 50 per cent, does not suffice for the octaves of frequencies, on average, characteristic of speech (and certainly not for the range used in singing). Ranges vary with age and sex, the total range for human speech being of the order of 60 to 500 cycles per second, with average central speech frequencies of about 100 for males, 200 for females, and 250 for children. The individual range is achieved by variations in *tension* and *mass*, as well as length. Tensor muscles such as the cricothyroid and posterior crico-arytenoid (p. 1234) affect nor only tension, but also length. Changes in mass are probably due to the thyro-arytenoid muscles, a slip of each of which, its *pars vocalis* (p. 1235), is partly attached to its vocal ligament, and may thus play a complex role in adjustments of length, tension and mass. Other intrinsic muscles are of course involved; the geometry of their attachments (p. 1234) is an indication of their effects. Unfortunately, electromyographic and photographic techniques have not provided precise data, and it is as yet unprofitable to attempt detailed analyses of their contribution to phonational mechanics.



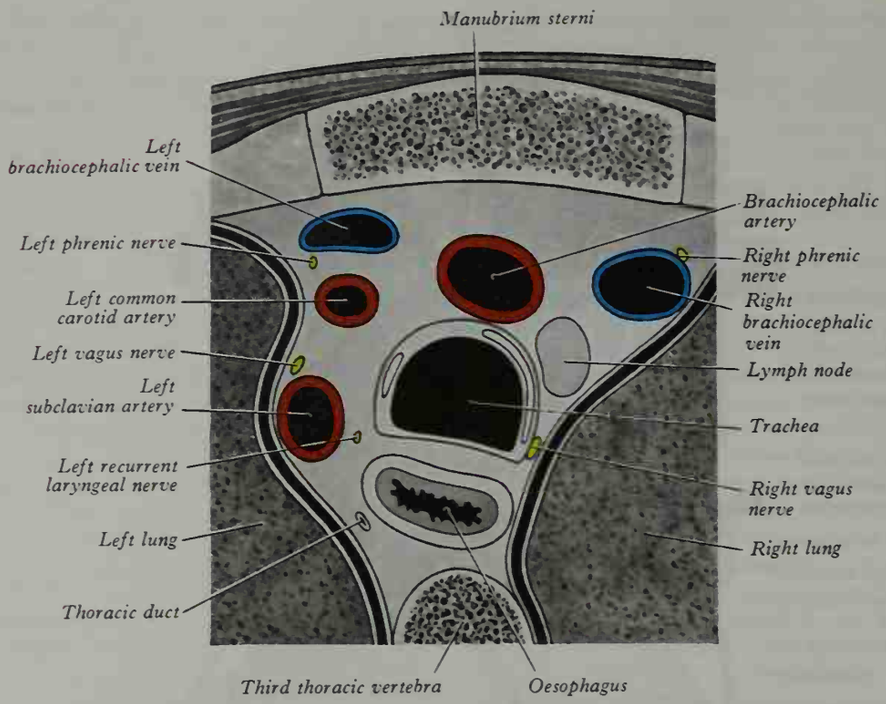
The modes of vibration of the vocal folds are not simple (consult Van den Berg 1968, Wyke 1974, Hinchcliffe and Harrison 1976, and Fry 1979, for modern accounts). Not only are numerous harmonics produced above any fundamental tone or frequency, but also the orientation of waves in the vocal folds is complex. High-speed cinematography reveals the occurrence of transverse and longitudinal waves, and the distribution of these over the surface of the folds varies even during a single act of phonation. Commonly, at the start of phonation the glottis closes to a linear chink (rima glottidis) both in its intramembranous and intercartilaginous parts (**8**.15), the latter being approximated by rotation of the arytenoid cartilages. The vocal folds come into complete contact, though this varies in the precise areas apposed, and the parameters of the apposition may vary during production of a single 'sound'. As expiratory air pressure is increased below the approximated folds, these are suddenly forced apart, returning by their own elasticity, because pressure momentarily drops. This cycle of events is repeated at a fundamental frequency (and its harmonics) dependent upon the factors stated above, and upon the velocity and pressure of the air current. Re-apposition of the folds may be aided by muscular effort and also by the 'Bernouilli effect', a kind of suction due to the sudden decrease in pressure as the folds open. The periodicity of these events is measured in milliseconds. They impart pressure waves of like frequencies to the column of air above the vocal folds, which acts as a selective resonator. To describe this as a 'column' is, of course, an oversimplification, for it is not only most variable in its shape and dimensions from level to level, and tortuous in its axis, but also adjustable within wide limits in respect of these same properties and in the tension of its walls. The positioning of the tongue, of the fauces, the soft palate, and changes in other dimensions, all greatly modify the parameters of the vocal tract. The sound impressed upon the resonator, in all the dynamic variation of fundamental tones and their accompanying harmonics, is thus subjected to a second stage of modification, some harmonics being dampened and others enhanced. Techniques are available for the analysis of this ultimate amalgam or 'spectrum' of frequencies in any particular sounds, which may be represented graphically against the coordinates of frequency and amplitude. Such investigations have shown that the vocal tract acts as an intricately selective filter and resonator, which propagates a remarkably similar pattern or 'envelope', irrespective of the fundamental frequency. This is essential to speech, for it ensures that, despite the continuously varying tone of voice, a constant *quality* or *timbre* is maintained. The term *formant* is also used, as in musical instruments; for example, a flute sounds like a flute over a wide register of frequencies, because the formant is characteristic throughout. Each voice similarly has an individual and identifiable formant or quality; if this were constantly varying, especially in the tones given to vowel sounds, linguistic intelligibility would be lost.

So far we have considered only the production of *tones*, however complex, and these do not constitute speech, in which the phonetic permutation of a limited repertoire of vowels is vastly enriched by the imposition of consonants, or *articulation*. Consonants are associated with particular anatomical sites, from which they usually take their designations in the terminology of phonetics. For example, we speak of *labials* (*p* and *b*), *dentals* (*t* and *d*), *nasals* (*m* and *n*) and so on. These sites have two similarities: (*a*) a partial obstruction or constriction at some level of the vocal tract, and (*b*) the production of aperiodic vibration, i.e. noise, which is superimposed upon or interrupts the flow of laryngeal tones. The subject is complex and can only be touched upon here. It is easy to ascertain subjectively that in pronouncing dental consonants the tip of the tongue is apposed to the back of the teeth. This momentarily constricts the passage of escaping air, modifies the resonant parameters of the 'vocal tract', and also generates local noise. The vocal tract is considered to be divided anatomically, in this instance, into a long column stretching from vocal folds to lingual tip and a very short section from teeth to lips. The 'resonator' may similarly be divided by appositional constructions into less unequal moieties by approximation of the tongue to the palate (hard or soft), and at other levels. Each 'setting' of the anatomical resonator, like those of the vocal folds, adds a characteristic to the total acoustic product which must be identifiable as an event of significance in the stream of speech if this is to be intelligible.

It is important to appreciate that these anatomical changes in the larynx and its resonating vocal tract are effected in small fractions of a second, with a speed, adroitness, and subtlety which are difficult to convey in verbal description. The multiplicity of laryngeal, pharyngeal, hyoid, palatal, lingual, and circumoral muscles, combined in rapidly changing combinations in the mechanics of phonation and articulation, reflects the extreme complexity of speech. It is perhaps not surprising that one philospher (Chomsky 1965) has suggested that the cerebrum, and particularly its 'dominant hemisphere', is genetically programmed for language (p. 1024). Quite apart from these wider implications, phonetics is in its own right a larger study, which can only be superficially considered here, even its strictly anatomical connexions. But enough has been said, perhaps, to demonstrate the usefulness of the anatomy of speech to phoneticians and others, and to stimulate the anatomist to a deeper interest in the phonetic functions of the larynx and vocal tract.

LARYNGEAL MUCOUS MEMBRANE

The mucous membrane of the larynx is continuous above with that of the pharynx and mouth, below with that of the trachea. It is loosely attached to the anterior surface of the epiglottis, and to the subjacent tissues in the valleculae. It covers the aryepiglottic folds, which limit the inlet of the larynx; in these folds there is a considerable amount of fibro-areolar tissue. It lines the cavity of the larynx, forms, by its reduplication, the chief parts of the vestibular folds, and is continued into the sinus and saccule of the larynx. It is firmly attached to the posterior surface of the epiglottis and to the laryngeal surfaces of the cuneiform and arytenoid cartilages. The parts covering the vocal ligaments are thin and intimately adherent to them. On the anterior surface and the upper half of the posterior surface of the epiglottis, the upper part of the aryepiglottic folds, and the vocal folds, the epithelium of the mucous membrane is stratified squamous (**8**.4B); other areas of stratified squamous epithelium also occur above the plane of the glottis. The rest of the epithelium of the laryngeal mucous membrane is ciliated columnar in type.



8.16 A dissection to show the relations of the bifurcation of the trachea and the principal bronchi. Parts of the great vessels have been resected. Vessels containing oxygenated blood are shown in red; those shown in blue contain de-oxygenated blood.

Glands. The mucous membrane of the larynx is furnished with numerous mucous glands; they are very plentiful upon the epiglottis, where they are lodged in little pits; many are present in the margins of the aryepiglottic folds in front of the arytenoid cartilages, where they are termed the *arytenoid glands*. They are large and numerous in the saccules of the larynx and secretion has been observed to flow down over the vocal folds periodically during phonation. The free edges of the vocal folds are devoid of glands. The stratified epithelium covering the vocal folds is, of course, vulnerable to drying, and it is essential that the secretion of neighbouring glands should spread over the folds and be retained. Scanning electron microscope observations have recently demonstrated the existence not only of microvilli, but also of so-called micro-ridges (microplicae) on the surface cells of the epithelium of the folds and elsewhere in the larynx (Andrews 1975; Tillmann *et al*. 1977). Such features have been noted in other epithelia subjected to drying out (e.g. the corneal epithelium), and microplicae are regarded as conducive to retention of surface secretions. Drying of the vocal epithelium interferes with phonation and may lead to superficial necrosis.

Taste buds, similar to those in the tongue, are scattered over the posterior surface of the epiglottis, in the aryepiglottic folds, and less regularly in other parts of the larynx. Their centripetal pathway is through the vagus nerve.

LARYNGEAL VESSELS AND NERVES

The chief *arteries* of the larynx are the laryngeal branches of the superior and inferior thyroid arteries. The *veins* accompanying the superior laryngeal artery join the superior thyroid vein, which opens into the internal jugular vein; those accompanying the inferior laryngeal artery join the inferior thyroid vein, which opens into the left brachiocephalic vein. The *lymph vessels* are divisible into two sets, a superior above the vocal folds, and an inferior below; the superior vessels accompany the superior laryngeal artery, pierce the thyrohyoid membrane, and end in the deep cervical lymph nodes situated near the bifurcation of the common carotid artery; some of the inferior lymph vessels pierce the cricothyroid ligament and open into a lymph node lying in front of that ligament or in front of the upper part of the trachea, while others emerge below the cricoid cartilage and pass to the deep cervical lymph nodes and to the lymph nodes alongside the inferior thyroid artery. The *nerves* are derived from the internal and external branches of the superior laryngeal nerve, from the recurrent laryngeal nerve and from the sympathetic. The internal laryngeal branch is probably entirely sensory and autonomic though some claim that special visceral motor fibres in it innervate the transverse arytenoid (Williams 1951). The nerve enters through the postero-inferior part of the thyrohyoid membrane above the superior laryngeal artery, and divides into branches which supply both surfaces of the epiglottis, the aryepiglottic fold, and the interior of the larynx down as far as the level of the vocal folds. The external laryngeal branch supplies the cricothyroid by entering its lateral surface. The terminal part of the recurrent laryngeal nerve accompanies the laryngeal branch of the inferior thyroid artery, and passes upwards deep to the lower border of the inferior constrictor of the pharynx, immediately behind the cricothyroid joint. It supplies all the

8.17 A transverse section through the mediastinum at the level of the body of the third thoracic vertebra. Viewed from the superior aspect.

intrinsic muscles of the larynx except the cricothyroid, and distributes sensory branches to the laryngeal mucous membrane below the level of the vocal folds. Before entering the larynx it usually divides into a motor and a sensory branch—not into 'adductor' and 'abductor' rami as has sometimes been asserted (Williams 1954). As might be expected in such highly skilled musculature, motor units in the larynx are small; a ratio of 30 muscle fibres to each motor neuron has been estimated (English and Blevins 1969).

Laryngoscopic Examination

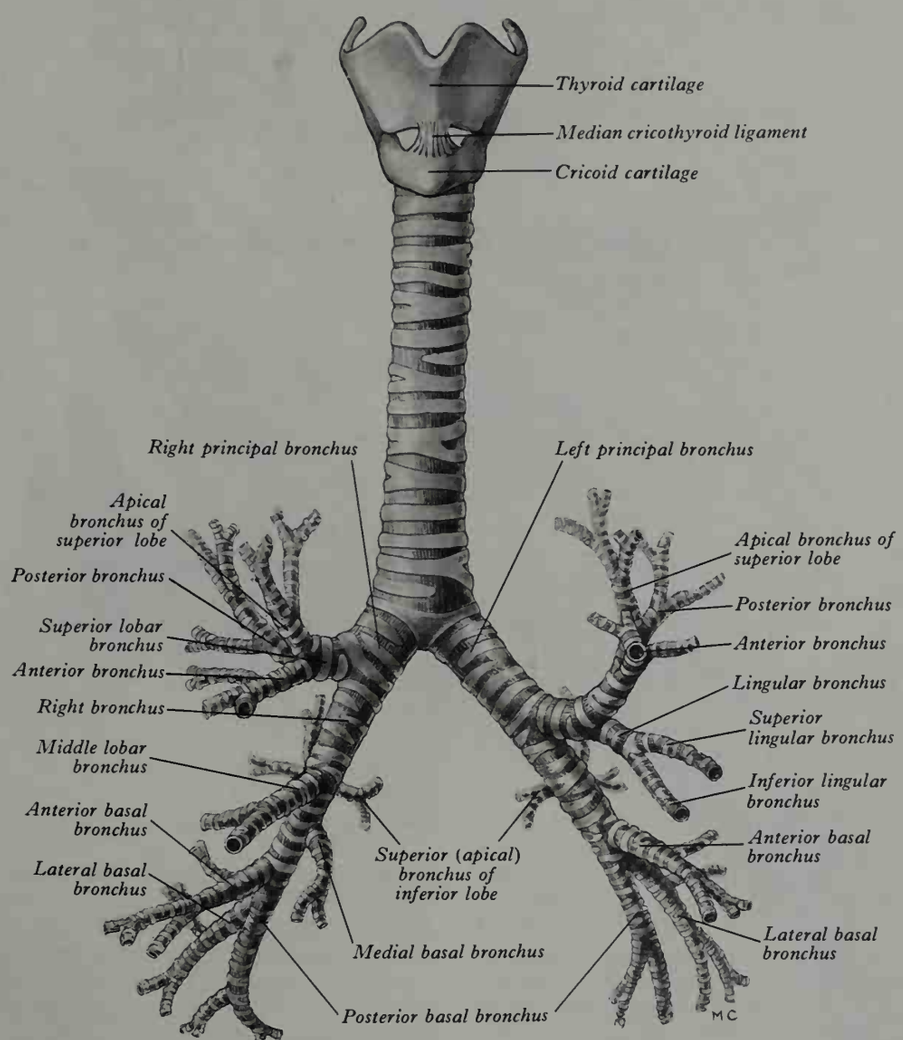
The inlet of the larynx, the structures surrounding it, and the cavity of the larynx can be inspected with a laryngoscopic mirror (**8**.11). The epiglottis is seen much foreshortened, but its tubercle can be seen in the median plane. From the margins of the epiglottis the aryepiglottic folds can be traced backwards and medially and, at their posterior extremities, the elevations produced by the cuneiform and the corniculate cartilages can be recognized. The pink vestibular folds and the pearly white vocal folds are visible within the cavity of the larynx and, when the rima glottidis is opened widely, the mucosa and cartilages of the trachea are visible. The piriform fossae can also be inspected.

Radiography

In lateral cervical radiographs, in addition to the ossified parts of the laryngeal cartilages, the epiglottis, aryepiglottic folds, arytenoid, corniculate and sometimes the cuneiform cartilages, and the laryngeal sinus are all visible.

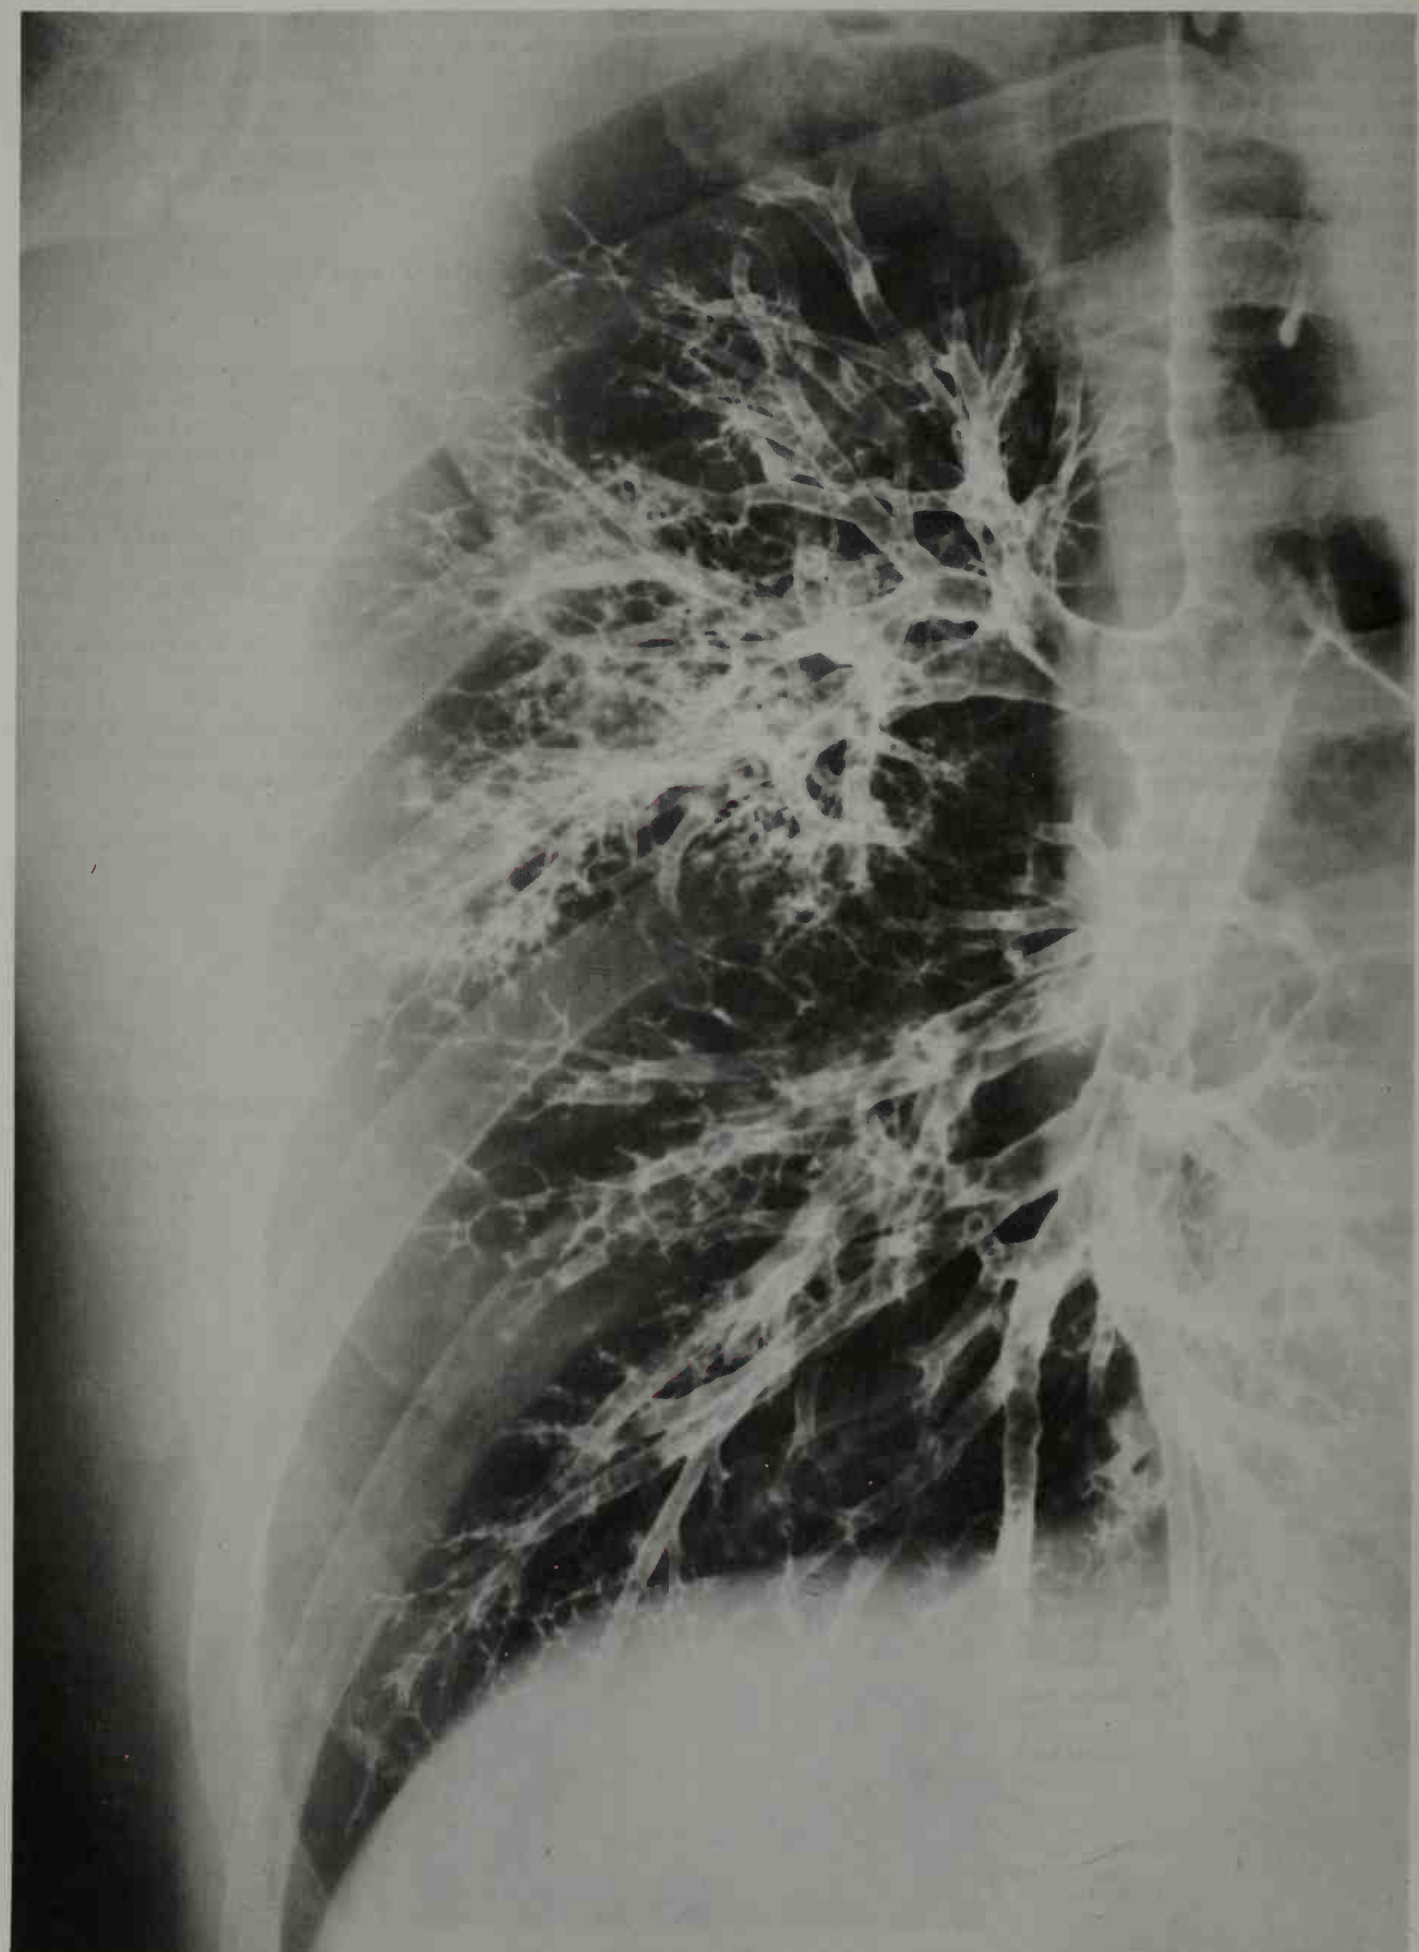
Surface and Applied Anatomy

In or near the midline of the neck the following structures are readily identified (**5**.33). The laryngeal prominence can be felt



8.18 A transverse section through the mediastinum at the level of the upper part of the body of the fourth thoracic vertebra. Viewed from the superior aspect.

easily; it is visible in men but not always in women. The anterior parts of the upper borders of the laminae of the thyroid cartilage and the thyroid notch are palpable. (The vocal folds are approximately level with the mid point of the anterior border of the thyroid.) Above the thyroid, the body of the hyoid and its greater cornua can be palpated, the latter most readily by gripping the throat at this level between the thumb and finger. The thyrohyoid membrane lies in the depression between the thyroid cartilage and the hyoid. Below the thyroid, the arch of the cricoid can be felt; it is on a level with the lower part of the cricoid lamina and lies opposite the body of the sixth cervical vertebra. The depression between the cricoid and thyroid marks the cricothyroid ligament. Below the cricoid the first tracheal cartilage can be felt. Foreign bodies may become impacted in the inlet of the larynx or in the rima glottidis and cause suffocation by mechanical obstruction. Small masses may descend into the trachea or bronchi, or lodge in the laryngeal sinus and, by irritating the mucous membrane, cause reflex spasm of the glottis with consequent suffocation. Inflammation of the upper part of the larynx may cause considerable swelling of the mucous membrane through effusion of fluid into the abundant lax submucous tissue; this condition is called 'oedema of the glottis'. The effusion does not involve, or extend below, the vocal folds, since the mucous membrane is closely adherent to the vocal ligaments without the intervention of any submucous tissue. In the above cases, an incision into the larynx below the vocal folds through the cricothyroid ligament (laryngotomy) or into the trachea (tracheotomy) may be necessary to restore a free airway. The mucous membrane of the upper part of the larynx is extremely sensitive, and contact with foreign bodies causes an immediate explosive cough. In suicidal cut-throat the wound is usually through the thyrohyoid membrane damaging the epiglottis, superior thyroid vessels, external and internal carotid arteries and internal jugular veins; less frequently it is above the hyoid with damage to the tongue muscles and the lingual and facial vessels. (For results of damage to the laryngeal nerves, *see* p. 1082.)



The Trachea and Bronchi

THE TRACHEA

The trachea is a cartilaginous and membranous tube, about 10 or 11 cm long continued downwards from the lower part of the larynx (**8**.19, 20). In the cadaver it reaches from the level of the sixth cervical vertebra to that of the upper border of the fifth thoracic vertebra, where it divides into two principal bronchi, one for each lung. The trachea lies mainly in the median plane, though its point of bifurcation usually lies a little to the right of this. In the living subject during deep inspiration the bifurcation descends and may reach the level of the sixth thoracic vertebra. The trachea is very mobile and can extend and shorten very rapidly. It is not quite cylindrical, being flattened posteriorly; its external diameter from side to side is about 2 cm in the adult male, and 1·5 cm in the adult female. In the child the trachea is smaller, more deeply placed and more movable than in the adult. In the living the lumen is smaller than in the cadaver, its diameter in the adult being about 12 mm. In the first year of life the diameter does not

exceed 3 mm, while during childhood the diameter in millimetres corresponds approximately with the age in years. The shape of the lumen in transverse section is very variable, especially in later decades. Thus it may be rounded, lunate, or flattened (Campbell and Liddelow 1967). For an extensive study of tracheobronchial dimensions (in Chinese subjects), *see* Wang and Tai (1965). In this study the lumen of the trachea averaged 16·17 mm, (range 9·5–22·0 mm).

Relations of the Trachea

The *cervical part* of the trachea (**6**.43) is covered anteriorly with the skin and the superficial and deep fasciae. It is crossed by the jugular arch connecting the anterior jugular veins and overlapped by the sternohyoids and sternothyroids. The second, third and fourth tracheal cartilages are crossed by the isthmus of the thyroid gland; immediately above the isthmus an anastomosing vessel connects the two superior thyroid arteries; below the isthmus it is related, in front, to the pretracheal fascia, the inferior thyroid veins, the remains of the thymus, and the arteria thyroidea ima (when that vessel exists). In the child, the brachiocephalic artery crosses obliquely in front of the trachea at, or a little above, the level of the upper border of the manubrium sterni, and the left brachiocephalic vein may extend a little above the upper border of the manubrium. Posteriorly the trachea is related to the oesophagus, which intervenes between it and the vertebral column; the recurrent laryngeal nerves ascend, one on each side, in, or just in front of, the grooves between the sides of the trachea and the oesophagus. *Laterally* the trachea is related to the lobes of the thyroid gland, which descends to the level of the fifth or sixth tracheal cartilage, and to the common carotid and inferior thyroid arteries.

The *thoracic part* of the trachea (**8**.16, 17, 18) descends through the superior mediastinum. *Anteriorly*, it is related to the manubrium sterni, the origins of the sternohyoids and sternothyroids, the remains of the thymus, the inferior thyroid veins, the left brachiocephalic vein, the arch of the aorta, the brachiocephalic and left common carotid arteries, the deep part of the cardiac plexus of nerves, and some lymph nodes. Owing to the divergence of the brachiocephalic and left common carotid arteries as they ascend in the neck, the former vessel comes to lie on the right, and the latter on the left of the trachea. *Posteriorly*, it is related to the oesophagus, by which it is separated from the vertebral column. On the *right* it is related to the right lung and pleura, the right brachiocephalic vein, the superior vena cava, the right vagus nerve, and the azygos vein; on the *left* to the arch of the aorta, the left common carotid and left subclavian arteries. The left recurrent laryngeal nerve, in its upward course, lies at first between the trachea and the arch of the aorta, and then in, or just in front of, the groove between the trachea and the oesophagus.

THE RIGHT PRINCIPAL BRONCHUS

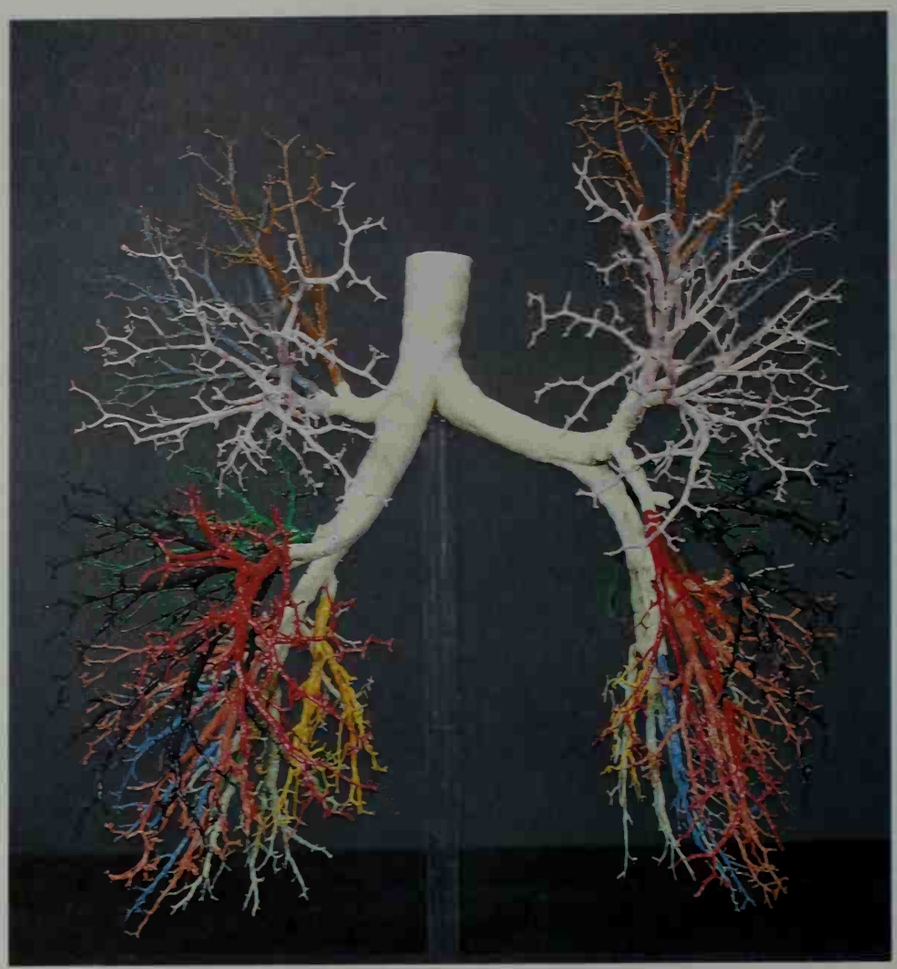
The right principal bronchus (**8**.19, 20), wider, shorter and more vertical than the left, is about 2·5 cm long, and enters the right lung opposite the fifth thoracic vertebra. Its greater width and more vertical course result in a greater frequency of foreign bodies passing into the right than into the left principal bronchus. The azygos vein arches over its superior aspect; the right pulmonary artery lies at first inferior and then anterior to it. After giving off the *superior lobar bronchus* which arises posterosuperior to the pulmonary artery, the right principal bronchus crosses the posterior aspect of the artery to enter the hilum of the lung, postero-inferior to the artery, where it divides into a *middle* and *inferior lobe bronchus*.

The right superior lobar bronchus arises from the lateral aspect of the parent bronchus and runs superolaterally to enter the hilum of the lung. About 1 cm from its origin it divides into three segmental bronchi. One of these, the *apical segmental bronchus*, continues superolaterally towards the apex of the lung, to which it is distributed. Shortly after its origin it divides into an apical and an anterior branch. The second, the *posterior segmental bronchus*, serves the postero-inferior part of the superior lobe of the lung and is directed posterolaterally with a slight superior inclination. Soon after its origin it divides into a lateral and a posterior branch. The third, the *anterior segmental bronchus*, runs antero-inferiorly to supply the rest of the superior lobe; not far from its origin it divides into a lateral and an anterior branch which are of equal size.

The middle lobar bronchus arises about 2 cm below the origin of the superior lobar bronchus, from the anterior aspect of the parent trunk and descends anterolaterally. It soon divides into a *lateral segmental bronchus* to the lateral part of the middle lobe and a *medial segmental bronchus* to its medial part.

The right inferior lobar bronchus is the continuation of the principal stem beyond the origin of the middle lobar bronchus. At or a little below this point, a large *superior* (apical) *segmental bronchus* arises from the posterior surface of the inferior lobar bronchus and runs posteriorly to be distributed to the cranial part of the inferior lobe of the right lung. This bronchus subsequently divides into medial, superior and lateral branches, the former two usually arising from a common stem.

Thereafter, the right inferior lobar bronchus continues to descend posterolaterally. The *medial basal segmental bronchus* is given off from its anteromedial aspect, and runs inferomedially to serve a small region below the hilum of the lung. The inferior lobar bronchus continues downwards and then divides into an *anterior basal segmental bronchus* which descends anteriorly, and a trunk which divides almost immediately into a *lateral basal segmental bronchus* which descends laterally, and a *posterior basal segmental bronchus* which descends posteriorly.

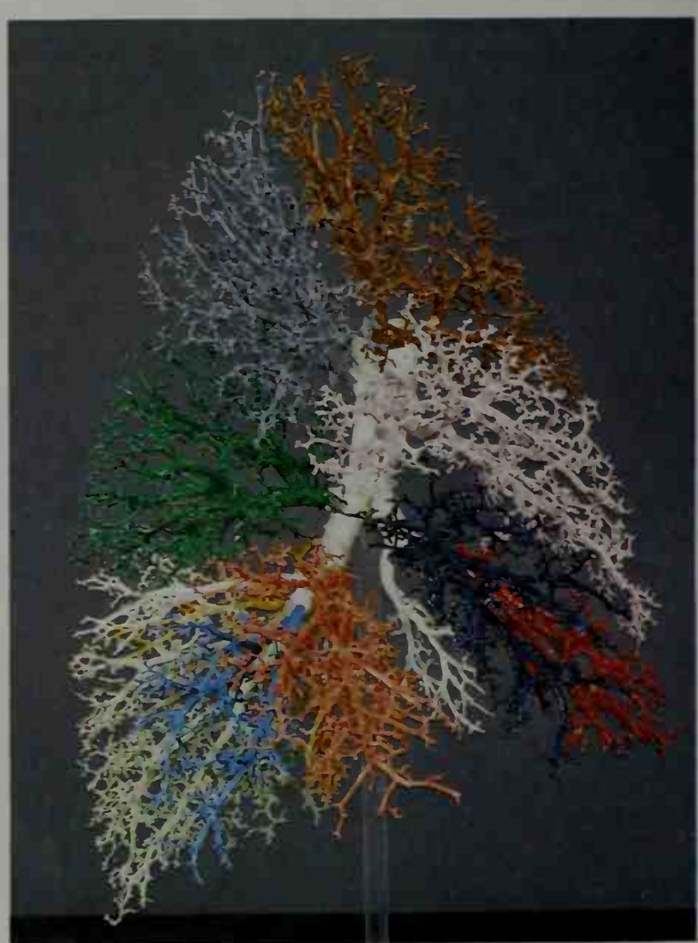


In over 50 per cent of right lungs a *subsuperior* (subapical) *segmental bronchus* arises from the posterior surface of the right inferior lobar bronchus between 1 and 3 cm below the superior segmental bronchus. This is distributed to the region of lung between the superior and posterior basal segments.

THE LEFT PRINCIPAL BRONCHUS

The left principal bronchus (**8**.19, 20), narrower, and more transverse than the right, is nearly 5 cm long and enters the root of the left lung opposite the sixth thoracic vertebra. It passes to the left inferior to the aortic arch, and crosses anterior to the oesophagus, thoracic duct and descending aorta; the left pulmonary artery lies at first anterior, and then superior to it. Having entered the hilum of the lung it divides into a superior and an inferior lobal bronchus.

The left superior lobar bronchus arises from the antero-lateral aspect of the parent bronchus. It curves laterally for a short distance and then divides into two bronchi, which correspond to the branches of the right principal bronchus to both the superior and middle lobes of the right lung. They are both distributed to the superior lobe of the left lung, which does not possess a separate middle lobe. The cranial division ascends for about 1 cm before giving off an *anterior segmental bronchus*, and then continues its cranial course for a further 1 cm as the *apicoposterior segmental bronchus*, before dividing into apical and posterior branches. The apical, posterior and anterior segmental bronchi are distributed, for the most part, in a similar manner to the corresponding bronchi of the superior lobe of the right lung. The caudal division of the left superior lobar bronchus descends anterolaterally to be distributed to the antero-inferior part of the superior lobe of the left lung. The latter is termed the *lingula*; unlike the bronchus to the middle lobe of the right lung which divides into medial and lateral segmental bronchi, the *lingular bronchus* divides into *superior lingular* and *inferior lingular segmental bronchi*.



The left inferior lobar bronchus continues to descend posterolaterally for about 1 cm. At this point the *superior* (apical) *segmental bronchus* arises from its posterior surface and is distributed in essentially the same manner as in the right lung. The inferior lobar bronchus continues for a further 1–2 cm before dividing into two stems, an anteromedial and a posterolateral. The *medial basal segmental bronchus* arises in common with the *anterior basal segmental bronchus* from the former; the *lateral basal segmental bronchus* arises in common with the *posterior basal segmental bronchus* from the latter. The territories supplied by these basal segmental bronchi is similar to those on the right. The medial basal segmental bronchus arises independently from the

The segmental bronchi and their main branches have been coloured: (1) apical—brown; (2) posterior—grey/blue; (3) anterior—pink; (4) lateral (middle lobe) and superior lingular—dark blue; (5) medial (middle lobe) and inferior lingular—red; (6) superior (apical) of inferior lobe—dark green; (7) medial basal—yellow; (8) anterior basal—orange; (9) lateral basal—blue; (10) posterior basal—light green.

B Corrosion cast, left lung, lateral view; colour coding as above.

C Corrosion cast, right lung, lateral view; colour coding as above. (Note that in the final preparation of such specimens large amounts of finer detail have been carefully removed to reveal the major arrangement of the bronchial 'tree'.)

8.21A–D (above) Specimens of human lungs in which the segmental bronchi have been injected with coloured gelatin. Unfixed specimens of the human lungs were obtained at post-morten. The bronchial trees were washed out with water, and individual segmental bronchi, identified by dissection, were cannulated separately and injected with gelatin of contrasting colours. The lungs were subsequently fixed in 10 per cent formaldehyde solution. A costal surface of left lung; B costal surface of right lung; C mediastinal surface of left lung; D mediastinal surface of right lung. Approximately the same colour convention has been used as for the corrosion cast shown in **8.20A**. In these specimens, however, in the right lung a subsuperior segment is present in the inferior lobe, and is coloured white. (All specimens were prepared by Dr. M. C. E. Hutchinson and photographed by Mr. Kevin Fitzpatrick, of the Department of Anatomy, Guy's Hospital Medical School.)

inferior lobe bronchus in up to 10 per cent of lungs, and this, together with the fact that the territory it supplies is similar to that on the right side, lends support to the recognition of this as a separate segmental bronchus. A *subsuperior* (subapical) *segmental bronchus* arises from the posterior surface of the left inferior lobe bronchus in as many as 30 per cent of lungs.

BRONCHOPULMONARY SEGMENTS

Each of the primary branches of the right and left *lobar bronchi* described above are termed *segmental bronchi* because each divides into ramifications that are distributed to self-contained, functionally independent units of lung tissue called *bronchopulmonary segments* (**8**.21). The main segments are *named* and *numbered* as follows:

Right

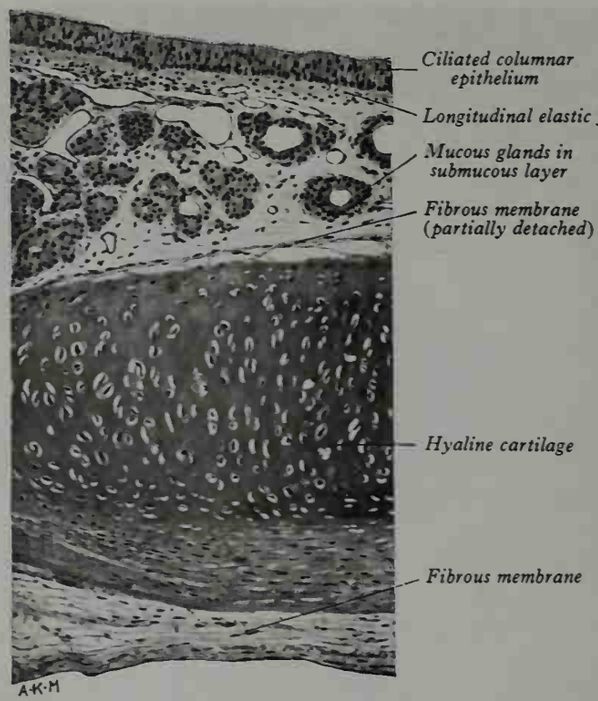
Superior lobe:	(1) apical, (2) posterior, (3) anterior.
Middle lobe:	(4) lateral, (5) medial.
Inferior lobe:	(6) superior (apical), (7) medial basal, (8) anterior basal, (9) lateral basal, (10) posterior basal.

Left Lung

Superior lobe:	(1) apical, (2) posterior, (3) anterior, (4) superior lingular, (5) inferior lingular.
Inferior lobe:	(6) superior (apical), (7) medial basal, (8) anterior basal, (9) lateral basal, (10) posterior basal.

Each bronchopulmonary segment is surrounded by connective tissue, continuous with that of the visceral pleura, and forms a separate respiratory unit of lung. (For the vascular and lymphatic arrangements of the segments *see* pp. 800, 1265, and for further details of bronchopulmonary segmentation and the bronchial tree consult Brock 1942, 1943, 1944, 1954; Boyden 1955; Bloomer *et al.* 1960; Volpe *et al.* 1969.)

Applied Anatomy. While pathological conditions such as bronchiectasis and certain infective processes may be restricted to one or more bronchopulmonary segments, malignant neoplasms and tuberculosis break through from one segment to adjacent ones.

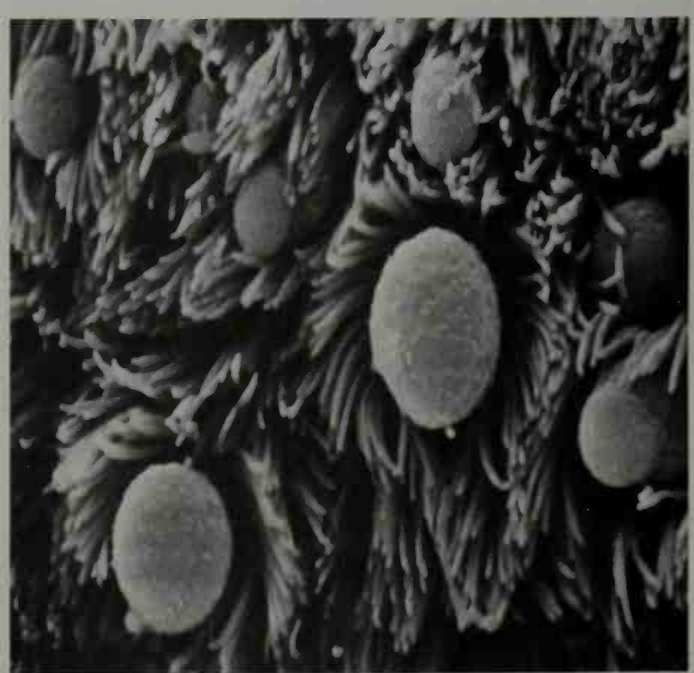


A knowledge of the mode of branching of the bronchial tree is necessary during bronchoscopy and for the proper interpretation of bronchograms. A similar knowledge is necessary when determining the appropriate postures to be adopted by patients for promoting drainage of infected areas of lung. The superior (apical) segment of the lower lobe is a common site for a lung abscess to occur following aspiration of material when the patient is lying supine. Foreign bodies when inhaled may obstruct a main, lobar, segmental or smaller bronchus according to their size. The interpretation of their effects and the nature of surgical treatment necessarily involve considerations of the pattern of bronchial branching.

When appropriate, surgical resection of a single bronchopulmonary segment can be undertaken; more radical surgical procedures include the removal of a number of segments, of a whole pulmonary lobe (lobectomy), or of the complete lung (pneumonectomy).

STRUCTURE OF TRACHEA AND MAJOR BRONCHI

The trachea and extrapulmonary bronchi consist of a framework of incomplete rings of hyaline cartilage, united by fibrous tissue and nonstriated muscle (**8**.22A). They are lined by mucous membrane (**8**.22B).



The cartilages of the trachea vary from sixteen to twenty in number. Each is an imperfect 'ring' which occupies about the anterior two-thirds of the circumference of the trachea; behind, where the 'rings' are deficient, the tube is flat, and is completed by fibrous and elastic tissue and nonstriated muscular fibres. The cartilages are placed horizontally one above another, and are separated by narrow intervals. They measure about 4 mm vertically and 1 mm in thickness; cranio-caudally their external

8.22A A transverse section through a part of the wall of a human trachea.

surfaces are flattened, but their internal surfaces are convex. Two or more of the cartilages often unite, partially or completely, and are sometimes bifurcated at their extremities. They are highly elastic, but may become calcified in advanced life. In the extrapulmonary bronchi the cartilages are shorter, narrower, and rather less regular than those of the trachea, but in general have the same shape and arrangement.

The first and last tracheal cartilages differ from the others (**8**.19). The *first cartilage* is broader than the rest, and often divided at one end; it is connected by the cricotracheal ligament with the lower border of the cricoid cartilage, with which or with the succeeding cartilage it is sometimes blended. The *last cartilage* is thick and broad in the middle, where its lower border is prolonged into a triangular hook-shaped process which curves downwards and backwards between the two bronchi forming a

8.22B A surface view of the ciliated epithelium of the trachea (rat). Mucus-secreting goblet cells occur between the ciliated cells. (Magnification × 5,100.) (Prepared by Mr. Michael Crowder, Department of Anatomy, Guy's Hospital Medical School, London.)

ridge called the *carina*. It forms on each side an imperfect ring which encloses the commencement of the bronchus. The cartilage above the last is somewhat broader at its centre than the others.

Distally, the irregularity of the cartilaginous plates in the extrapulmonary bronchi increases, and as the major bronchi approach their lungs and lobes, the plates encroach on their dorsal aspects, almost, but never completely, encompassing the bifurcations. In the intrapulmonary bronchi, the plates of cartilage become smaller, progressively forming less and less of the bronchial wall, until they disappear at the commencement of bronchioles. (For details *see* **8**.19A, 28A and consult Reid 1976.)

The Fibrous Membrane

Each of the cartilages is enclosed in a perichondrium, which is continuous with a sheet of dense irregular connective tissue forming a fibrous membrane between adjacent hoops of cartilage and at the posterior aspect of the trachea and extrapulmonary bronchi where the cartilage is incomplete. The fibrous layer of the perichondrium and the fibrous membrane are composed mainly of collagen with some elastin fibres intermingled; the fibres cross each other diagonally, allowing changes in diameter of the enclosed airway, and the elastic component provides a measure of elastic recoil when the membrane is stretched.

Nonstriated muscle fibres occur within the fibrous membrane at the posterior aspect of the tube; most of these fibres are transverse, inserting into the perichondrium at the posterior extremities of the cartilages, and forming a transverse sheet in the gaps between these skeletal elements. Contraction of these transverse muscle fibres can therefore alter the cross-sectional area of the trachea and bronchi. A few longitudinal muscle fibres are also present external to the transverse fibres. The nonstriated muscle of the intrapulmonary bronchi is independent of the cartilage plates, and where the latter become less frequent, i.e. in the smaller bronchi, muscular contraction may actually obliterate the lumen (Reid 1976).

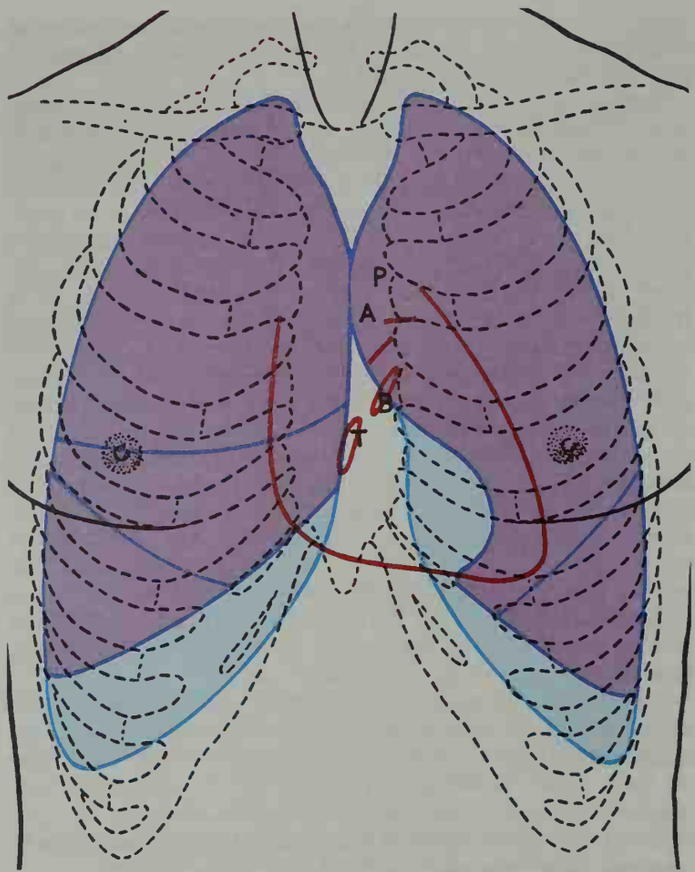
The Mucous Membrane

The mucous membrane is continuous with and similar to that of the larynx above and the intrapulmonary bronchi below. It consists of a layer of pseudostratified ciliated epithelium interspersed with goblet cells, both cell types being situated on a basal lamina (**8**.22). Some of the pseudostratified cells possess exceptionally large nuclei and are thought to be polytene in their chromosomal content. Numerous lymphocytes are usually present in the lower parts of the epithelium. The cilia beat the overlying layer of mucus upwards towards the laryngeal aditus (*vide supra*). Deep to the epithelium and its basal lamina are firstly a lamina propria rich in longitudinal elastic fibres, secondly a submucosa of loose irregular connective tissue in which are situated the larger blood vessels, nerve trunks and most of the tubular glands and patches of lymphoid tissue, and thirdly, deep to the submucosa, the perichondrium and fibrous membrane described above. Around the cartilages of the trachea and bronchi, and their fibrous membranes, is the deep fascia merging with the fascial planes of the surrounding muscles, the oesophagus, and other associated structures.

Vessels and Nerves

The trachea is supplied with blood mainly by the inferior thyroid *arteries*. Its thoracic end is supplied by the bronchial arteries, which give off branches ascending to anastomose with the inferior thyroid arteries; all these vessels also supply the oesophagus. The *veins* end in the inferior thyroid venous plexus. The *lymph vessels* pass to the pretracheal and paratracheal lymph nodes. The *nerves* are derived from the vagi and the recurrent laryngeal nerves, and from the sympathetic trunks; they are distributed to the tracheal muscle and to the mucous membrane. The sympathetic nerve endings, when active, cause bronchodilatation by releasing catecholamines, whilst parasympathetic activity causes bronchoconstriction. Many small ganglia occur in the autonomic plexuses of both the tracheal and bronchial walls (Feyler 1965). In cats, paraganglia consisting of chromaffin cells and arteriovenous anastomoses have been observed in the bronchial wall (Muratori 1965). For a quantitative technique of assessing the amounts and distribution of the tissues in the bronchial walls, normal or pathological, *see* Hale *et al.* (1968).

Surface and Applied Anatomy. The *trachea*, about 2 cm wide, extends from the cricoid cartilage almost vertically downwards in the median plane as far as the sternal angle; it inclines very slightly to the right as it descends. The *right bronchus* runs from the lower end of the trachea downwards and to the right for 2·5 cm to reach the hilum of the lung opposite the sternal end of the right third costal cartilage. The *left bronchus* runs at a smaller angle from the lower end of the trachea for 5 cm to the left and downwards to reach the hilum of the lung behind the left third costal cartilage, 3·5 cm from the median plane. The trachea may be opened by a median vertical incision, either above the isthmus of the thyroid gland (high tracheotomy) or below it (low tracheotomy). The low operation is more troublesome because the trachea recedes from the surface as it descends and because of the anterior relations of this part of the tube, namely the inferior thyroid veins, the anastomosis between the anterior jugular veins, the arteria thyroidea ima (when present), and (in the child) the brachiocephalic artery, the left brachiocephalic vein and the thymus. The trachea may be compressed by pathological enlargements of structures related to it, e.g. the thyroid gland, the thymus and the arch of the aorta. (The radiological appearances of the trachea, bronchi and lungs are dealt with on p. 1267.)

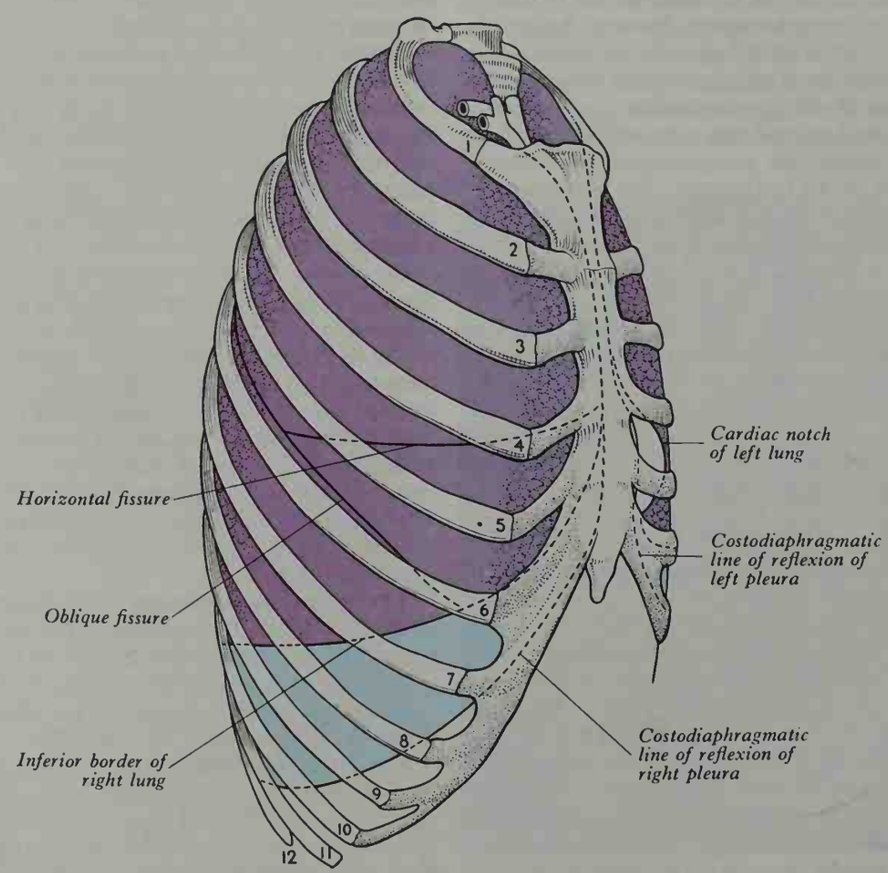


Bronchoscopy. By means of a bronchoscope, passed through the mouth and larynx, after the application of a local anaesthetic, the interior of the larynx, trachea and bronchi with the proximal parts of their main branches supplying the bronchopulmonary segments (pp. 1243–1246) may be examined, pathological states studied and biopsies taken for microscopy; foreign bodies may be removed, or accumulations of fluid removed by suction.

The Pleurae

Each lung is invested by a serous membrane arranged in the form of a closed invaginated sac termed the *pleura*. A part of this serous membrane covers the surface of the lung and lines the fissures between its lobes; it is called the *visceral* or *pulmonary pleura*. The rest of the membrane lines the inner surface of the corresponding half of the chest wall, covers a large part of the diaphragm, and is reflected over the structures occupying the middle part of the thorax; this portion is termed the *parietal pleura*. The pulmonary and parietal pleurae are continuous with each other around and below the root of the lung; in health they are in contact in all phases of respiration, the potential space between them being known as the *pleural cavity*. When the lung collapses or when air or fluid collects between the pulmonary and parietal pleurae, the pleural cavity becomes apparent. The right and left pleural sacs are distinct from each other, and come into immediate contact for just a short distance behind the upper half of the body of the sternum (**8**.23A), although they are separated only by a narrow interval behind the oesophagus in the mid-thoracic region. The interval between the two sacs is named the *interpleural space* or *mediastinum*. The right pleural cavity is wider than the left, because the heart extends further to the left than to the right side. The upper and lower limits of the pleural sacs are approximately the same, but the left sac sometimes descends to a lower level in the mid-axillary line.

The pulmonary pleura is inseparably connected with the lung. It is adherent to all the surfaces, including those which bound the fissures between the lobes of the lung; it is absent, however, over an area where the lung root enters, and along a line extending downwards from this and marking the attachment of the so-called pulmonary ligament (**8**.27).

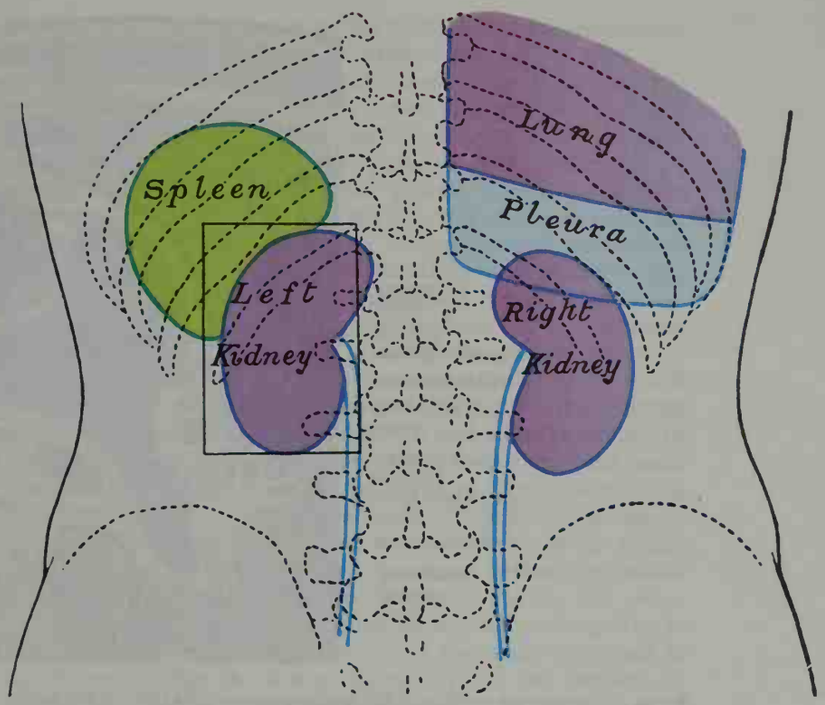


The parietal pleura. Different regions of the parietal pleura have distinctive names; the part lining the internal aspect of the ribs, transversus thoracis (p. 548) and sides of the vertebral bodies is the *costovertebral pleura*; that clothing the thoracic surface of the diaphragm is the *diaphragmatic pleura*; that ascending into the neck over the summit of the lung is the *cervical pleura* (or *dome of the pleura*) and that applied to the structures occupying the interpulmonary region is the *mediastinal pleura*.

8.23A Ventral aspect of the thorax, showing surface projections. Skeletal, pulmonary (purple), pleural (blue), and cardiac (red outline). A. Orifice of aorta. B. Left atrioventricular (mitral) orifice. P. Orifice of pulmonary trunk. T. Right atrioventricular (tricuspid) orifice.

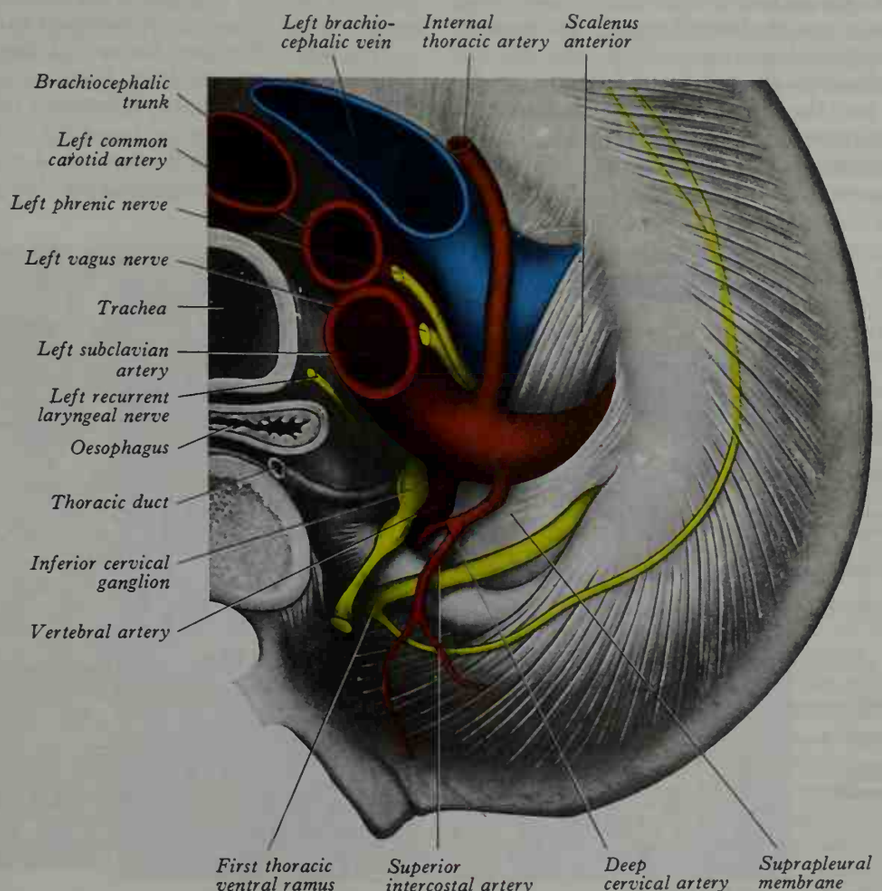
The *costovertebral* (or '*costal*') *pleura* (**8**.23A–C) lines the sternum, ribs, the constituent parts of the transversus thoracis, and the sides of the bodies of the vertebrae, and is easily separated from them. Outside the costal pleura there is a thin layer of loose areolar tissue, called the *endothoracic fascia*; it corresponds to the transversalis fascia of the abdominal wall. In front, the costal pleura begins behind the sternum where it is continuous with the mediastinal pleura. The line of junction of the mediastinal with the costal pleura extends from behind the sternoclavicular joint downwards and medially to a point near the median plane behind the sternal angle. From here the right and left costal pleurae descend in contact with each other as far as the level of the fourth costal cartilages, below which the line differs on the two sides. On the right side it is continued down to the posterior surface of the xiphisternal joint. On the left it diverges laterally and descends, at a distance of 2 to 25 mm from the margin of the sternum (Woodburne 1947), to the level of the sixth costal cartilage. On each side the costal pleura sweeps laterally, lining the inner surfaces of the costal cartilages, ribs and the constituent parts of the transversus thoracis; at the back of the thorax it passes over the sympathetic trunk and its branches, and on to the side of the bodies of the vertebrae, where it again becomes continuous with the mediastinal pleura. Above, the costal pleura is continuous with the cervical pleura at the inner margin of the first rib. Below, it is continuous with the diaphragmatic pleura along a line which may differ slightly on the two sides. On the right side this *costodiaphragmatic line of reflexion* of the pleura begins dorsal to the xiphoid process, and passes dorsocaudally behind the seventh costal cartilage, reaching the eighth rib in the mid-clavicular line, then reaching the mid-axillary line at the level of the tenth rib; from here the line ascends slightly, and, crossing the twelfth rib, reaches the level of the upper border of the spine of the twelfth thoracic vertebra (**8**.23C). On the left side the line follows at first the ascending part of the sixth costal cartilage, and in the rest of its course may be slightly lower than that on the right side.

The *diaphragmatic pleura* is thin, and covers part of the upper surface of the corresponding side of the diaphragm. The outer



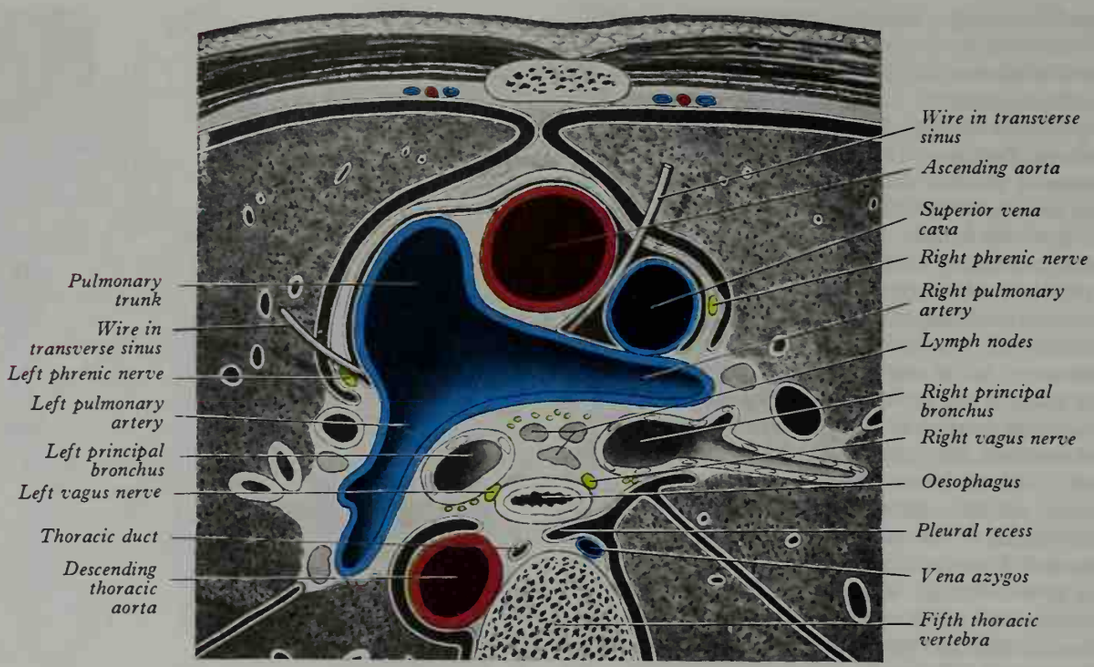
8.23B The relations of the pleurae and lungs to the chest wall. Right lateral aspect. Purple—lungs, covered with the pleural sacs. Blue—pleural sac, with no underlying lung.

part of its circumference is the line described above, along which it is continuous with the costal pleura. Medially it is continuous with the mediastinal pleura along the line of attachment of the pericardium to the diaphragm.



The *cervical pleura* or *dome of the pleura* is the continuation of the costal pleura over the apex of the lung (**8**.23B). It extends from the internal border of the first rib medially and upwards to the apex of the lung, its summit reaching as high as the lower edge of the neck of the first rib; it then descends along the side of the trachea to become continuous with the mediastinal pleura. Owing to the obliquity of the first rib, the cervical pleura extends 3 or 4 cm above the first costal cartilage, but does not rise above the level of the neck of the first rib. The cervical pleura is strengthened by a dome-like expansion of fascia, named the *suprapleural membrane*. It is attached in front to the internal border of the first rib and behind to the anterior border of the transverse process of the seventh cervical vertebra; it is covered and strengthened by a few spreading muscular fibres derived from the scaleni. A muscle, frequently present, which is called the *scalenus minimus*, arises from the anterior border of the transverse process of the seventh cervical vertebra and is inserted into the inner border of the first rib, behind the groove for the subclavian artery, and into the dome of the pleura, which, on contraction, it renders tense; some consider that the suprapleural membrane represents the spread-out tendon of this muscle. The cervical pleura (like the apex of the lung) reaches the level of the seventh cervical spine at a distance of 2·5 cm from the median plane. It can be represented by a curved line drawn from the sternoclavicular joint to the junction of the medial and middle thirds of the clavicle, the summit of the curve being 2·5 cm above the clavicle. The subclavian artery, directed upwards and laterally, occupies a furrow a little below the summit of the cervical pleura. the relations of the cervical pleura are similar to those of the apex of the lung (*see* p. 1253, and 8.24A).

The *mediastinal pleura* forms the lateral boundary of the interpleural space or mediastinum (see also p. 1251). Above the root of the lung it is a continuous sheet between the sternum and the vertebral column. That of the right side is in contact with the



8.23C The lower limits of the lung and pleura, posterior view. The lower portions of the lung and pleura are shown on the right side.

right brachiocephalic vein, the upper part of the superior vena cava, the terminal part of the azygos vein, the right phrenic and right vagus nerves, the trachea and the oesophagus. That of the left side is in relation with the arch of the aorta, the left phrenic and left vagus nerves, the left brachiocephalic and superior intercostal veins, the left common carotid and subclavian arteries, the thoracic duct and the oesophagus. At the root of the lung the

8.24A Structures in relation with the cervical pleura of the left side. Inferior aspect.

8.24B A transverse section of the mediastinum at the level of the lower part of the body of the fifth thoracic vertebra. Viewed from the superior aspect.

mediastinal pleura is carried laterally as a tube of serous membrane enclosing the structures of the lung root and passing into continuity with the visceral or pulmonary pleura. Below the lung root the mediastinal pleura extends as a double layer from the lateral surface of the oesophagus to the mediastinal surface of the lung, where it is continuous with the pulmonary pleura. This double layer is named the *pulmonary ligament* (**8**.27A, B). It is continuous above with the tube investing the lung root; below it ends in a free falciform border.

The inferior limit of the pleura is on a considerably lower level than the corresponding border of the lung (**8**.23A–C), but does not extend to the attachment of the diaphragm, so that below the line of reflexion of the pleura from the chest wall to the diaphragm, the latter is in direct contact with the rib cartilages and the muscles in the intercostal spaces. Moreover, in ordinary inspiration the thin inferior margin of the lung does not extend as low as the line of the pleural reflexion, with the result that the costal and diaphragmatic pleurae are here in contact, the intervening narrow slit being termed the *costodiaphragmatic recess*. In quiet respiration the lower limit of the lung is about 5 cm above the lower limit of the pleura. A similar condition exists behind the sternum and rib cartilages, where the anterior thin margin of the lung falls short of the line of pleural reflection, and where the slit-like cavity between the two layers of pleura forms the *costomediastinal recess*. It should be noted that the extent of the costomediastinal recess, the position of the anterior costomediastinal line of pleural reflexion, and the position of the thin anterior margin of the lung are subject to considerable variation in different individuals.

Structure. The free surface of the pleura is smooth, and moistened by serous fluid. Like many serous membranes, its surface is a single layer of flattened cells, which form a mesothelium, and rest on a basement membrane beneath which are networks of yellow elastic and white fibres embedded in ground substance, containing also fibroblasts, macrophages and

8.24C A transverse section of the mediastinum at the level of the body of the sixth thoracic vertebra. Viewed from the superior aspect.

the cell types which also characterize loose connective tissue (p. 414). The deeper layers of fibrous tissue in the pulmonary pleura are continuous with the connective tissue around and between the lobules of the lung. Blood vessels, lymph vessels and nerves are distributed in the substance of the pleura. In their ultrastructural details the pleural mesothelial cells are in many respects similar to those of peritoneum (p. 1333). Material studied from human biopsies (de Gasperis and Miani 1969) showed that the squamous cells rest upon a basal lamina 30–40 nm thick, but their highly infolded basal plasma membranes are separated from the lamina by an interval of 20–30 nm. Laterally the surfaces of adjacent cells interdigitate and are joined at intervals by desmosomes. Their free surfaces bear scattered microvilli and numerous cilia (*see* **8**.24D). Micropinocytotic vesicles are common in the cytoplasm. Several structural variants of the squamous cells have been recognized, one type probably being a stem cell.

Vessels and Nerves

The parietal and visceral layers of the pleura are respectively developed from the somatopleural and splanchnopleural layers of the lateral plate mesoderm (pp. 110, 209). Correlated with this origin, the parietal pleura derives its arterial supply from somatic (body wall) arteries (intercostal, internal thoracic and musculophrenic); its veins join the systemic veins in the neighbouring parts of the chest wall; its lymphatics also join those in the body wall and drain into the intercostal, parasternal, posterior mediastinal and diaphragmatic nodes, and its nerve supply is derived from the spinal nerves supplying the muscles and skin of the body wall (intercostal and phrenic nerves). The visceral pleura, which is an integral part of the lung itself, derives its vascular supply from the bronchial vessels, its lymphatics join those of the lung, and its nerve supply is derived from the autonomic nerves innervating the lung and accompanying the bronchial vessels. (For details of a special technique for demonstrating the lymphatics of the visceral pleura and of observations thus effected, consult Pennell 1966.) Whereas pain is elicited by the application of tactile or thermal stimuli to the parietal pleura, these do not form adequate stimuli when applied to the visceral pleura (*see* also the peritoneum, p. 1333). The costal pleura and the pleura on the peripheral part of the diaphragm are supplied by the intercostal nerves; the mediastinal pleura and the pleura on the central part of the diaphragm are supplied by the phrenic nerve. Irritation of the former parts of the pleura results in pain referred along the intercostal nerves to the thoracic or abdominal wall, whereas irritation of the latter parts results in pain referred to the lower part of the neck and over the shoulder (that is, to the area of skin supplied by the same segments of the spinal cord that give origin to the phrenic nerve, C. 3, 4, 5).

8.24D The surface of the pleura viewed by scanning electron microscopy, showing the numerous cilia of the mesothelial cells lining this structure (murine). (Magnification × 7,000.)

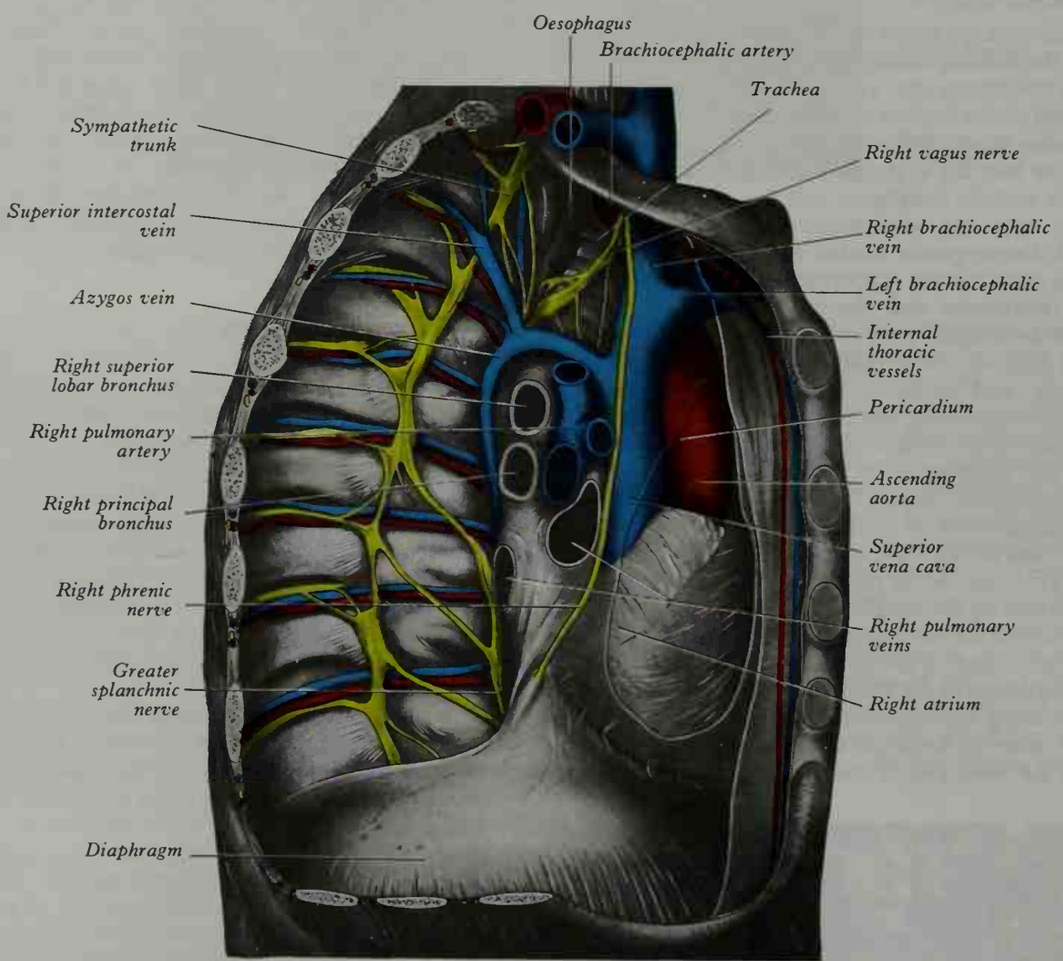
Applied Anatomy. Normally the visceral pleura slides smoothly on the parietal pleura during respiration and does not cause any sound appreciable on auscultation; if, however, the pleura is inflamed, characteristic friction sounds can be heard. If an effusion of fluid occurs into the pleural cavity, the sounds disappear, and as fluid accumulates the lung gradually collapses and the heart and mediastinum are hence displaced towards the opposite side. Entry of air into the pleural cavity (pneumothorax), whether caused accidentally by an external penetrating wound, by rupture of part of the lung, or produced as a therapeutic measure (e.g. to rest the lung in tuberculosis), also results in collapse of the lung, as its elastic tissue recoils. Normally this is prevented by the negative pressure in the pleural cavity and by the cohesion between the opposed parietal and visceral pleura. In operations on the kidney from the back, the relation of the costal pleura to the twelfth rib must be borne in mind. Usually the pleura crosses the rib at the lateral border of the erector spinae, so that its posterior part is superior to the reflexion of the pleura (**8**.23C). If the last rib is too short to project beyond the erector spinae, the eleventh rib may be mistaken for the last when palpated in this position, and an incision which is prolonged up to this level will wound the pleura. It is therefore important to determine whether the lowest palpable rib is the eleventh or twelfth by counting down from the second (at the junction of its costal cartilage with the sternal angle).

The Mediastinum

The mediastinum, strictly speaking, is the *partition* between the two lungs and therefore includes the mediastinal pleura of both sides, but it is generally defined as the *interval* between the two pleural sacs. It extends from the sternum in front to the vertebral column behind (**8**.24B, C), and from the thoracic inlet above to the diaphragm below. For purposes of description it is divided into two parts, an upper, which is named the *superior* mediastinum, and a lower, which is subdivided into the *anterior*, *middle* and *posterior* mediastina. The superior mediastinum is continuous with the lower part at the plane passing through the manubriosternal joint in front and the lower surface of the fourth thoracic vertebra behind.

The superior mediastinum (**8**.17, 18) lies between the manubrium sterni in front, and the upper four thoracic vertebrae behind. It is bounded below by the plane passing through the sternal angle in front, and the lower part of the body of the fourth thoracic vertebra behind; above, by the plane of the thoracic inlet, and laterally by the mediastinal pleurae. It contains the origins of the sternohyoid and sternothyroid and the lower ends of the longus colli muscles; the aortic arch; the brachiocephalic, left common carotid and left subclavian arteries; the brachiocephalic veins and the upper half of the superior vena cava; the left superior intercostal vein; the vagus, cardiac, phrenic and left recurrent laryngeal nerves, and superficial part of the cardiac plexus; the trachea, oesophagus and thoracic duct; the remains of the thymus, and the paratracheal, brachiocephalic and some of the tracheobronchial lymph nodes.

The anterior mediastinum lies between the body of the sternum in front and the pericardium behind (**8**.24B); above the level of the fourth costal cartilages, it is exceedingly narrow, owing to the close approximation of the two pleural sacs. It contains some loose areolar tissue, the sternopericardial ligaments, two or three lymph nodes and a few small mediastinal branches of the internal thoracic artery and sometimes also part of the thymus gland or its degenerated remains.



The middle mediastinum (**8**.24 C, 26) is the broadest part of the inferior mediastinum. It contains the heart, pericardium, ascending aorta, lower half of the superior vena cava, terminal part of the azygos vein, the bifurcation of the trachea, the two bronchi, the pulmonary trunk dividing into right and left pulmonary arteries, the right and left pulmonary veins, the phrenic nerves, the deep part of the cardiac plexus and some tracheobronchial lymph nodes.

The posterior mediastinum (**8**.24B, C; 25, 26) is bounded *in front* by the bifurcation of the trachea, the pulmonary vessels, the pericardium and by the posterior part of the upper surface of the diaphragm; *behind*, by the vertebral column from the lower border of the fourth to the twelfth thoracic vertebrae; *on each side* by the mediastinal pleura. It contains the descending thoracic aorta, the azygos and hemiazygos veins, the vagus and splanchnic nerves, the oesophagus, the thoracic duct, and the posterior mediastinal lymph nodes.

Radiology of the mediastinum (**6**.27, 28, 29). In anteroposterior radiographs of the chest (**6**.27), the heart and large blood vessels form an opacity called the mediastinal shadow. Forming the left border of this shadow can be recognized, from above downwards, the left subclavian artery, the arch of the aorta ('the aortic knuckle'), the left auricle and the left ventricle. Immediately below the aortic arch, the infundibulum of the right ventricle or and the aortic arch and large vessels in the superior mediastinum produce faint shadows.

The Lungs

The lungs are the essential organs of respiration; they are situated one on each side within the thorax, and separated from each other by the heart and the other contents of the mediastinum (**6**.14). Except for its attachment to the heart and trachea by the root (and the pulmonary ligament), each lung lies freely in the corresponding pleural cavity. The substance of the lung is of a light, porous, spongy texture; it floats in water, and crepitates when handled, owing to the presence of air in its alveoli; it is also highly elastic, hence the retracted state of the lungs when removed from the closed cavity of the thorax. The surface is smooth, shining, and

8.25A The mediastinum, right lateral aspect. A part of the pericardial sac has been removed to expose the lateral surface of the right atrium.

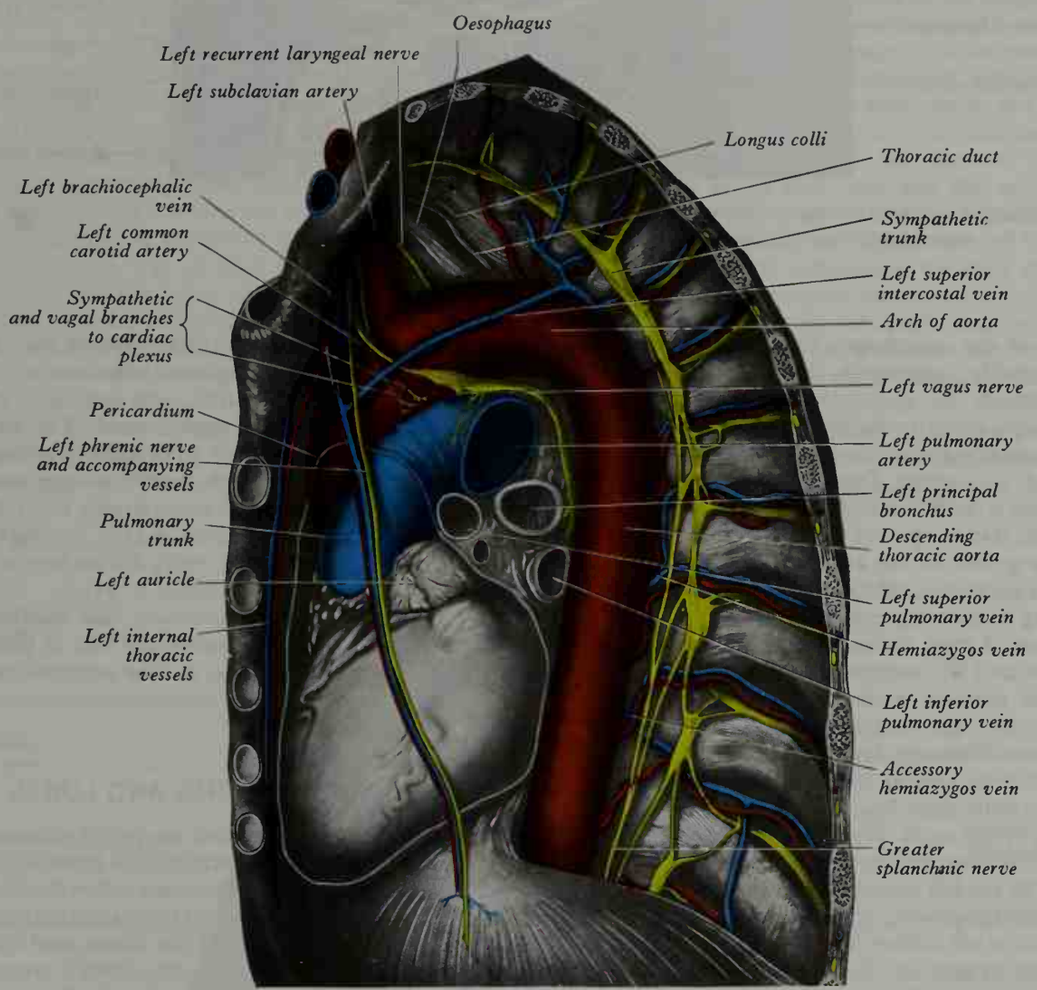
pulmonary trunk may be recognizable upon this border. On the right border of the shadow are seen the right brachiocephalic vein, the superior vena cava, the right atrium and the thoracic part of the inferior vena cava. Enlargements or lateral displacements of any of the above structures accentuate the normal 'bulges' on the borders of the mediastinal shadow. On both sides of the mediastinum, the opacities of the pulmonary vessels entering the lungs constitute the root or hilar shadows. In the upper part of the chest the less dense shadow of the trachea is seen in the median plane.

In lateral or oblique radiographs of the thorax the heart shadow lies above the anterior part of the diaphragm. In front of it is 'the retrosternal space' (the anterior mediastinum), while behind it is 'the retrocardiac space' (posterior mediastinum) containing the oesophagus, rendered visible during the passage of a barium meal (**8**.90), and the descending thoracic aorta. Above the heart shadow, the 'translucent' trachea and bronchi are recognizable, marked out by fine, dark, intersecting lines into numerous polyhedral areas, indicating the lobules of the lung; each of these areas is crossed by numerous lighter lines.

At birth the lungs are rose-pink in colour; in adult life the colour is a dark slaty-grey, mottled in patches, and as age advances, this maculation assumes a black colour. The colouring matter consists of granules of inhaled carbonaceous particles deposited in the areolar tissue near the surface of the lung; it increases in quantity as age advances, and is more abundant in men than in women. As a rule, the posterior border of the lung is darker than the anterior. On the upper, less movable parts of the lungs, the surface pigmentation tends to lie opposite the intercostal spaces. The lungs of the fetus, or of the stillborn child who has not respired, differ from those of the child who has done so, in that they are firm to the touch (like the liver), do not crepitate when handled, and, containing no air, sink in water.

The right lung usually weighs about 625 gm, the left 565 gm,

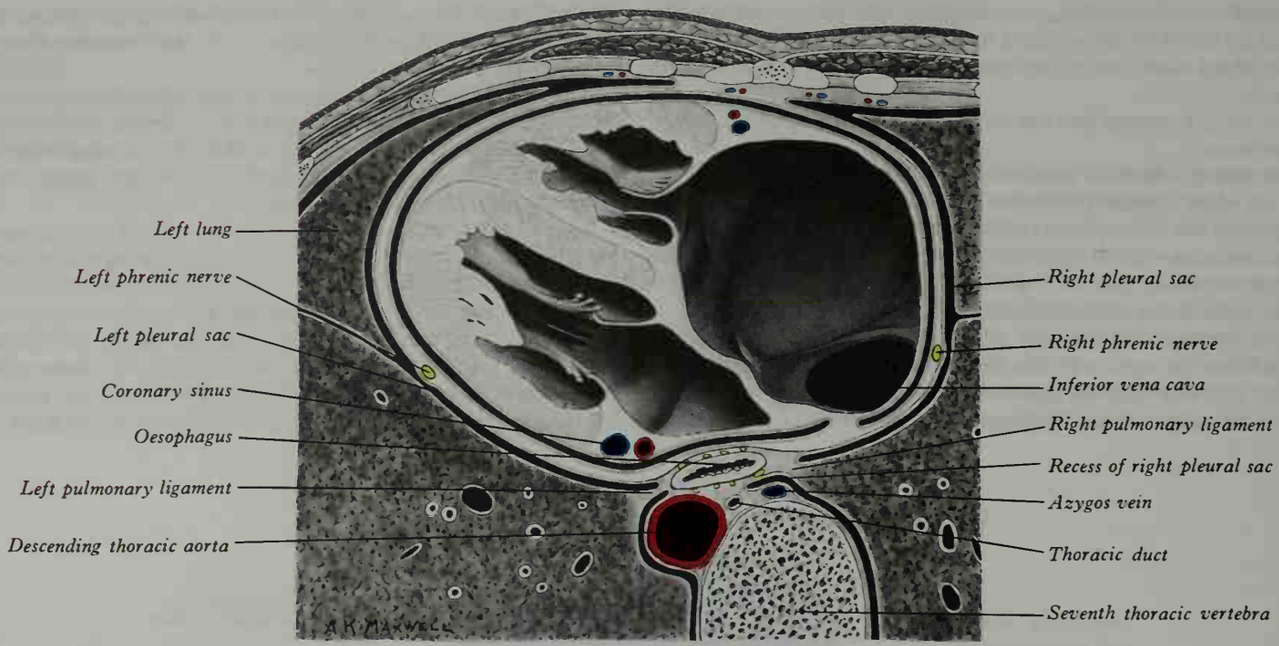
but much variation occurs; the weight is also dependent on the amount of blood or serous fluid that they contain. The lungs are heavier in the male than in the female, both absolutely and relative to stature.



Each lung is conical and has an apex, a base, three borders and two surfaces.

The apex, which is rounded, protrudes above the thoracic inlet, in close contact with the cervical pleura. Owing to the obliquity of the inlet (p. 291), this part of the lung reaches from 3 cm to 4 cm above the level of the first costal cartilage, although it does not rise above the level of the neck of the rib. Its summit lies about 2·5 cm above the medial third of the clavicle, and the apex is situated therefore in the root of the neck (**8**.23B). It has been asserted that the apex is in fact intrathoracic, close to the neck of the first rib, and that the anterior surface of this region ascends highest in inspiration (Andreassi 1967). This view requires confirmation. The cervical pleura intervenes between the apex of the lung and the suprapleural membrane (p. 1249), on which the subclavian artery arches upwards and laterally, producing a groove on the anterior surface of the apex just below its summit and separating it from the scalenus anterior. Posteriorly the apex is related to the cervicothoracic ganglion of the sympathetic trunk, the ventral ramus of the first thoracic nerve and the superior intercostal artery (**8**.24). Laterally, it is related to the scalenus medius; medially, to the brachiocephalic artery, right brachiocephalic vein and trachea on the right side, and to the left subclavian artery and left brachiocephalic vein on the left side.

The base is semilunar in shape, and concave; it rests upon the convex surface of the diaphragm, which separates the right lung from the right lobe of the liver, and the left lung from the left lobe of the liver, the fundus of the stomach and the spleen. Since the diaphragm extends higher on the right side than on the left, the concavity on the base of this is deeper than it is on the left. Laterally and behind, the base is bounded by a thin, sharp margin which projects for some distance into the costodiaphragmatic recess of the pleura (p. 1250).



The costal surface is smooth, convex, and corresponds to the form of the cavity of the chest, which is deeper behind than in front. It is in contact with the costal pleura, and exhibits, in specimens which have been hardened *in situ*, slight grooves corresponding with the overlying ribs.

The medial surface is divided into a posterior or *vertebral* part, and an anterior or *mediastinal* part. The vertebral part is in contact with the sides of the thoracic vertebrae and intervertebral discs, the posterior intercostal vessels and the splanchnic nerves. The mediastinal part exhibits a deep concavity, which accommodates the pericardium and is termed the *cardiac impression*; this concavity is larger and deeper on the left than on the right lung, because the heart projects more to the left than to the right side of the median plane. Above and behind this concavity there is a somewhat triangular depression named the *hilum*, where the structures which form the root of the lung (p. 1255) enter and leave the viscus. These structures are invested by pleura, which extends downwards, below the hilum and behind the cardiac impression, forming the pulmonary ligament.

8.25B The mediastinum, left lateral aspect.

Apart from these features, which are shared in common by both lungs, the markings on the mediastinal surface seen in specimens hardened *in situ* are different on the two sides (**8**.25A, B; 27A, B). On the *right lung*, the cardiac impression is contiguous with the anterior surface of the right auricle, anterolateral surface of the right atrium and a small part of the anterior surface of the right ventricle. The impression is continued upwards in front of the hilum as a wide groove which lodges the superior vena cava and the lower end of the right brachiocephalic vein (**8**.27A). Posteriorly this groove is joined by a deep, narrow sulcus which arches forwards above the hilum and is caused by the azygos vein.

8.26 A transverse section through the mediastinum at the level of the body of the seventh thoracic vertebra. Viewed from the superior aspect.

The right edge of the oesophagus produces a shallow groove which runs vertically downwards behind the hilum and the pulmonary ligament. As it approaches the diaphragm, the oesophagus inclines towards the left and passes away from the right lung. The oesophageal groove, therefore, does not extend to the lower limit of this surface. The postero-inferior corner of the cardiac impression is confluent with a short but wide notch which accommodates the thoracic part of the inferior vena cava. Between the apex and the groove for the azygos vein, the trachea and the right vagus nerve are in close relation to the lung, although there is no corresponding surface depression.

On the *left lung* (**8**.27B), the cardiac impression is in relation with the anterior and left surfaces of the left ventricle and left auricle, and the anterior surface of the infundibulum and adjoining part of the right ventricle. It is continued upwards in front of the hilum to accommodate the pulmonary trunk. A wide, deep groove arches backwards above the hilum and downwards behind it and the pulmonary ligament; it lodges the arch and the descending part of the aorta. Near the summit of its curve it is confluent with a narrower groove which ascends towards the apex and is occupied by the left subclavian artery. Behind this groove and above the aortic groove, the lung is in contact with the thoracic duct and the left surface of the oesophagus. In front of the upper part of the groove for the left subclavian artery a faint groove is produced by the left brachiocephalic vein. Inferiorly, the left surface of the oesophagus may make a slight impression in front of the lower end of the pulmonary ligament.

The *inferior border* is thin and sharp where it separates the base from the costal surface and extends into the costodiaphragmatic recess; medially, where it divides the base from the mediastinal surface, it is blunt and rounded. It is represented, during quiet respiration, by a line drawn from the lower end of the anterior border to reach the eighth rib in the mid-axillary line, where it lies nearly 10 cm above the costal margin; the line is then continued medially and slightly upwards across the back to a point 2 cm lateral to the tenth thoracic *spine* (**8**.23C). The *posterior border* separates the costal surface from the vertebral part of the medial surface, and corresponds to the medial margins of the heads of the ribs. It is not marked by any recognizable ridge or line. The thick, rounded posterior part of the lung (the so-called 'posterior border') comprises the adjoining parts of the costal and vertebral surfaces.

The *anterior border* is thin and sharp, and overlaps the front of the pericardium; that of the *right* lung is customarily described as corresponding quite closely to the costomediastinal line of pleural reflexion, being almost vertical; that of the *left* approaches the costomediastinal line of pleural reflexion in its upper part, but below the level of the fourth costal cartilage it presents a notch of variable size, named the *cardiac notch*. The margin of this notch passes laterally for some 3·5 cm before curving downwards and medially to reach the sixth costal cartilage about 4 cm from the median plane. It thus falls considerably short of the recessed part of the line of pleural reflexion (**8**.23A), leaving the pericardium in this situation covered only with a double layer of pleura. (See Area of Superficial Cardiac Dullness, p. 653.)

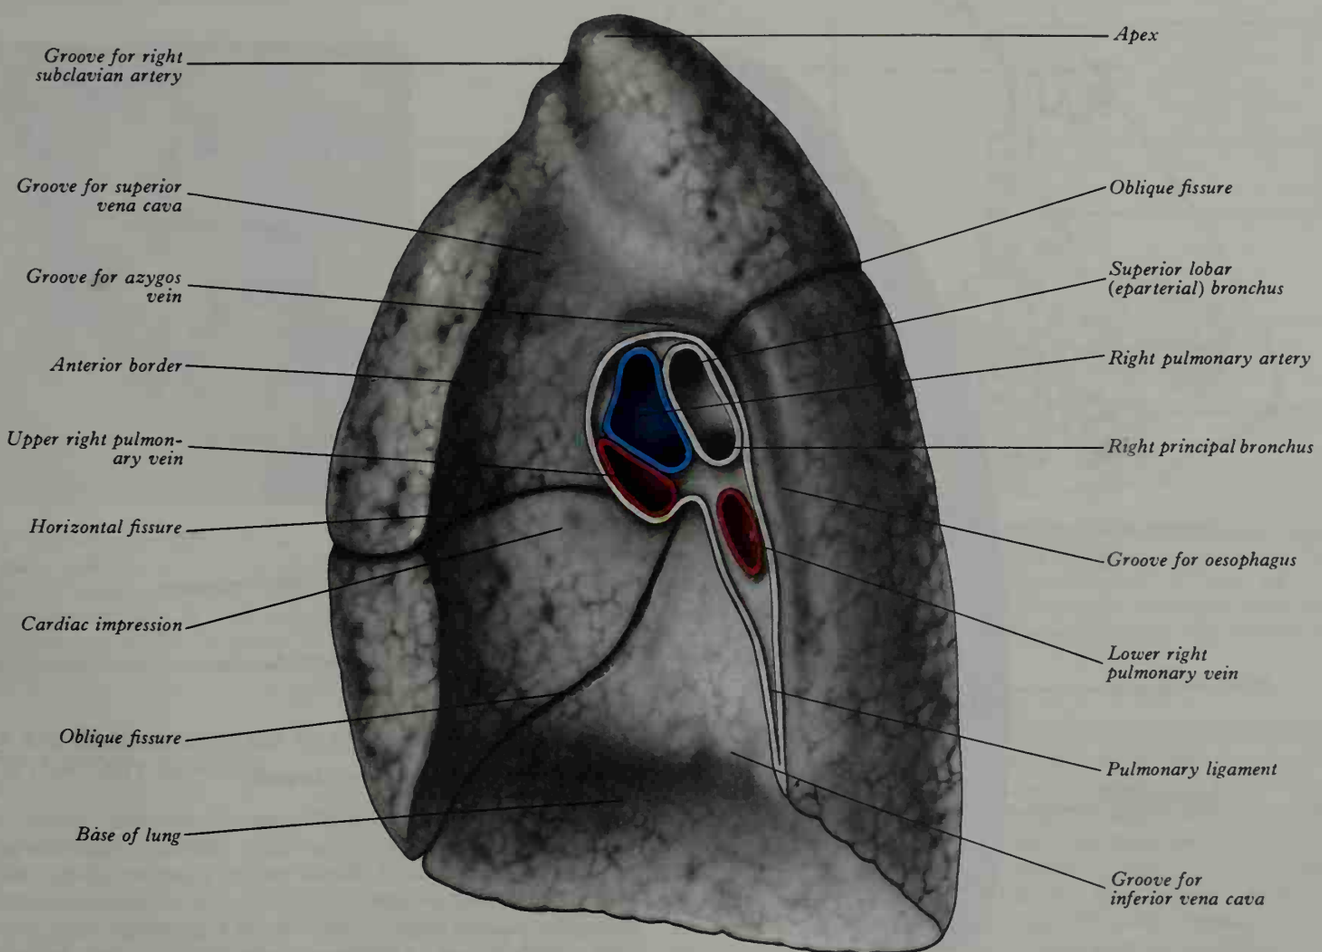
It should be noted, however, that cardiothoracic surgeons consider that the costomediastinal line of pleural reflexion, the anterior margin of the lung, and the extent of the costomediastinal pleural recess, show *great variability* between subjects.

PULMONARY FISSURES AND LOBES

The left lung is divided into a superior and an inferior lobe by an *oblique fissure* (**8**.27B), which extends from the costal to the medial surface of the lung both above and below the hilum. As seen on the surface, this fissure begins on the medial surface of the lung at the upper and posterior part of the hilum, and runs backwards and upwards to the posterior border, which it crosses at a point about 6 cm below the apex. It then extends downwards and forwards over the costal surface (**8**.23A), reaching the lower border a little behind its anterior extremity. Its further course can be followed upwards and backwards across the mediastinal surface as far as the lower part of the hilum. On the posterior border of the lung the oblique fissure lies opposite the interval between the spines of the third and fourth thoracic vertebrae (about 2 cm from the median plane), but it may be either above or below this level. Traced downwards and forwards across the costal surface of the lung, the fissure reaches the fifth intercostal space (in or near the mid-axillary line) and follows this until it intersects the inferior border of the lung close to, or just below the sixth costochondral junction (7·5 cm from the median plane). As a rule the oblique fissure of the left lung is more vertical than the corresponding fissure of the right lung. The fissure corresponds roughly with the medial border of the scapula when the arm is abducted above the level of the shoulder, as by placing the hand on the back of the head, the inferior angle of the bone moving outwards and forwards. The *superior lobe* lies above and in front of this fissure, and includes the apex, the anterior border, a considerable part of the costal surface and the greater part of the medial surface of the

lung. A small projection is usually present at the lower part of the cardiac notch and is termed the *lingula* of the lung. The *inferior lobe*, the larger of the two, is situated below and behind the fissure, and comprises almost the whole of the *base*, a large portion of the costal surface, and the greater part of the posterior border. (*See* pp. 1243–1246 for details of bronchopulmonary segmentation.)

The right lung is divided into three lobes, superior, middle and inferior, by two fissures (**8**.27A). One of these separates the inferior from the middle and superior lobes, and corresponds closely with the oblique fissure in the left lung. Its direction is, however, less vertical, and cuts the lower border about 7·5 cm behind its anterior end. On the posterior border it lies opposite the spine of the fourth thoracic vertebra or at a slightly lower level. As it descends it crosses the fifth intercostal space and then follows the general line of the sixth rib to the sixth costochondral junction. A short *horizontal fissure* separates the superior from the middle lobe. It begins in the oblique fissure near the mid-axillary line, and, running horizontally forwards, cuts the anterior border on a level with the sternal end of the fourth costal cartilage; on the mediastinal surface it may be traced backwards to the hilum. The *middle lobe* of the right lung is small and cuneiform, and includes a part of the costal surface, the lower part of the anterior border and the anterior part of the base of the lung. Sometimes the medial part of the upper lobe is partially separated from the rest by a fissure of variable depth which contains the terminal part of the azygos vein enclosed in the free margin of a mesentery derived from the mediastinal pleura. The portion of the right lung so defined is sometimes termed the *'lobe of the azygos vein'*. It varies in size and sometimes includes the apex of the lung. It is always supplied by one or more branches of the apical bronchus. Radiographically, a pleural effusion may be limited to the azygos fissure.



Attempts have been made to equate the lobation of the two lungs and in particular to equate the right middle lobe with the lingula. The primary pattern of the development of the lungs does not favour this view (p. 208). For a recent discussion and introduction to the literature consult Yokoh (1977).

Since the diaphragm rises higher on the right side in order to accommodate the liver, the right lung is shorter (by 2·5 cm) than the left, but, owing to the projection of the heart to the left side, it is broader and its total capacity and weight are greater than those of the left lung.

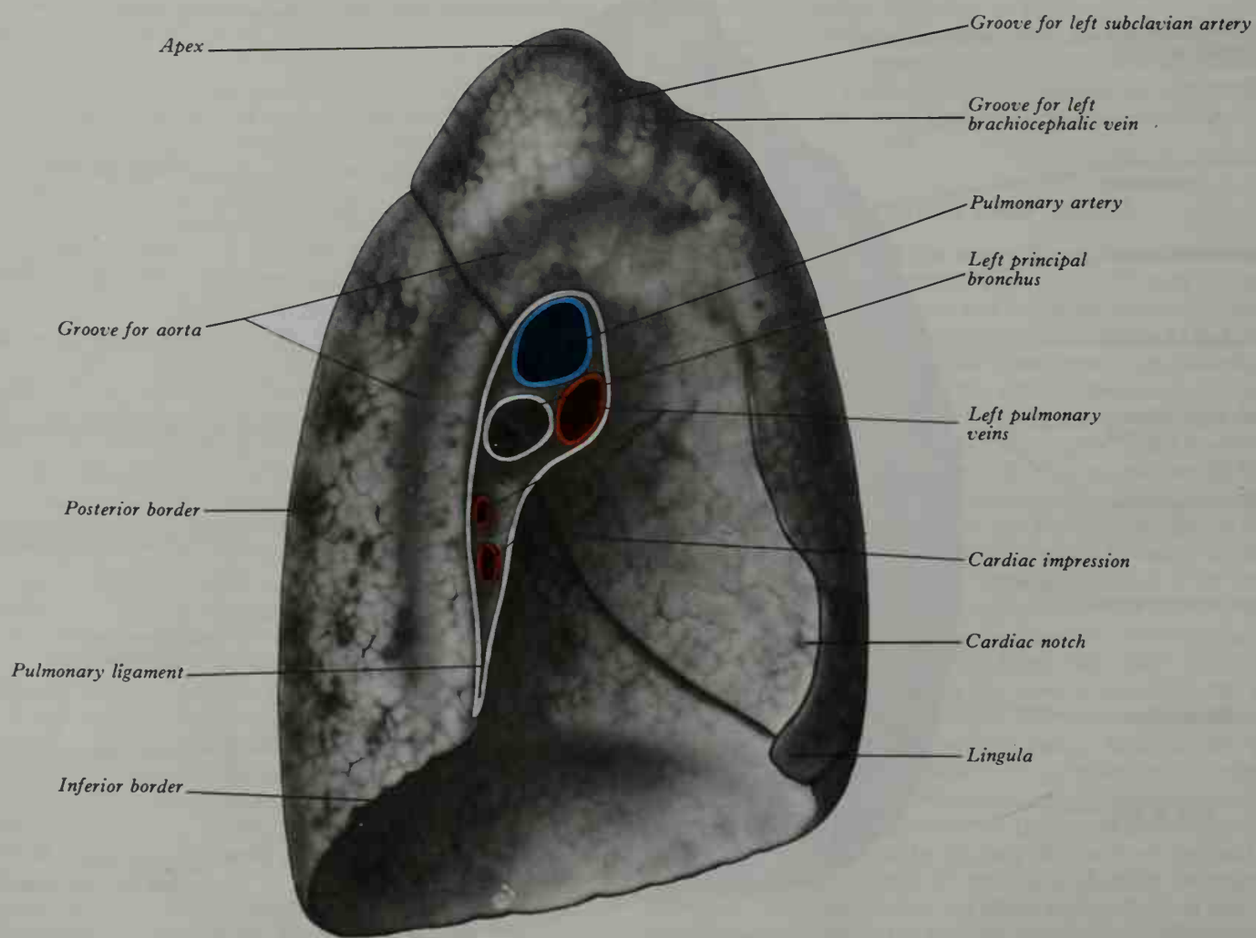
PULMONARY HILA AND ROOTS

The root of the lung (**8**.25) connects the medial surface to the heart and the trachea and is formed by the structures which enter or emerge at the hilum. It comprises the principal bronchus, the pulmonary artery, the two pulmonary veins, the bronchial arteries and veins, the pulmonary plexus of nerves, lymph vessels, bronchopulmonary lymph nodes and areolar tissue, all of which are enveloped by pleura. The roots of the lungs lie opposite the bodies of the fifth, sixth and seventh thoracic vertebrae. That of the right lung lies behind the superior vena cava and part of the right atrium, and below the terminal part of the azygos vein. That of the left lung is below the aortic arch and in front of the descending thoracic aorta. The following relations are common to the two lung roots—*anterior*, the phrenic nerve, the pericardiacophrenic artery and vein, and the anterior pulmonary plexus; *posterior*, the vagus nerve and posterior pulmonary plexus; *inferior*, the pulmonary ligament.

The chief structures composing the root of each lung are arranged in a similar manner from before backwards on both sides, viz.: the upper of the two pulmonary veins in front; the pulmonary artery, the principal bronchus behind, with the bronchial vessels on its posterior aspect. Their arrangement differs from above downwards on the two sides; on the right side their position is—superior lobar bronchus, pulmonary artery, right principal bronchus, lower pulmonary vein; but on the left side their position is—pulmonary artery, bronchus, lower

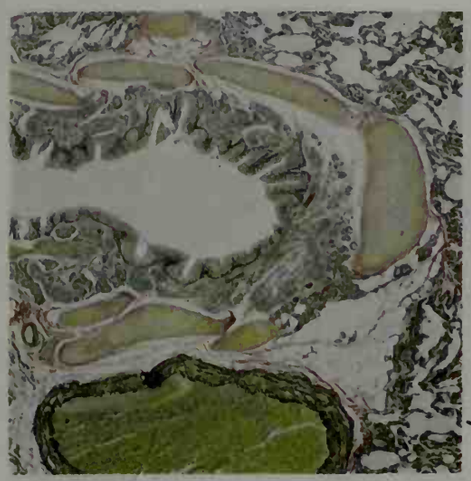
8.27A The medial surface of the right lung.

pulmonary vein. The lower left pulmonary vein is inferior to the principal bronchus, which is lowest in the hilum (**8**.27A, B).

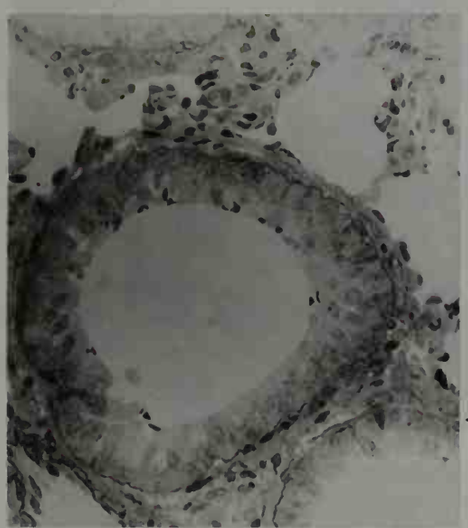


All parts of the lungs do not move equally in respiration. The region near the root hardly moves at all, while the middle region of the lungs moves very slightly in quiet respiration. The superficial parts of the lungs expand most, but the mediastinal surface, the posterior border and the apical region do not move to the same extent owing to the less movable structures related to them. The diaphragmatic and costomediastinal regions undergo most expansion of all. (*See* Movements of Respiration, p. 550.) Most of the volumetric change in the lungs during respiration occurs in the alveoli. The number of alveoli in the lung of a newborn infant may be over 20 million, increasing to 300 million or more during childhood. Each alveolus varies from 200 to 300 μm in diameter, and a very large number of capillary segments (1,800 is suggested) may make contact with a single alveolus. The area of gas-epithelium-blood interface is relatively enormous even in childhood. Figures of 70 to 100 m² have been estimated (Peters 1969; Fisherman and Pietra, 1974), while the more recent investigations of Gehr *et al.*, (1978) have yielded even higher values.

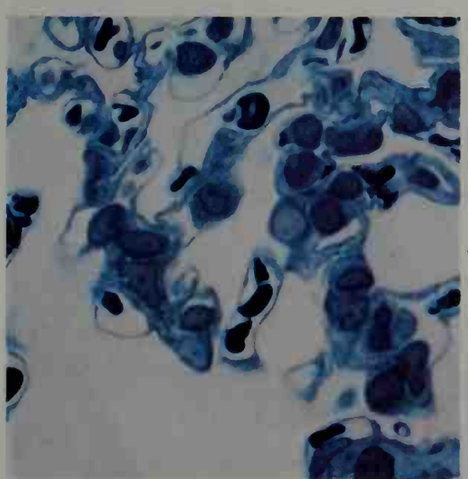
Structure of the Lung



The lungs arise during development (*see* pp. 199, 207) as epithelial outgrowths of the anterior foregut, forming a system of tubes which branch as they grow, and which become invested externally by mesenchymal tissue rich in blood vessels. This developing mass of tissue protrudes into the anterior coelomic cavity (later the pleural cavities) and becomes lined externally by coelomic epithelium (mesothelium) which eventually forms the lining of the serous coat of the pulmonary pleurae. Within the lung the proximal parts of the tubular system become the *conducting* airways of the bronchial tree and the more distal ones expand to form the cavities across the walls of which *respiratory exchange* takes place between the atmosphere and the closely applied capillaries. The individual components in this complex will now be considered in some detail.



THE SEROUS COAT AND ASSOCIATED CONNECTIVE TISSUE



The serous coat forms the visceral pleura, and is a thin transparent layer composed of a single layer of mesothelium situated on its underlying lamina propria, inseparably connected with the main mass of lung tissue, which it invests as far as the root. The subserous, loose connective tissue underlies the serous coat and covers the entire surface of the lung, extending inwards along the conducting tubes and blood vessels from the hilum, and delineating the *lung lobules*, which are important functional units of lung structure. Each lobule is a small polyhedral mass of lung tissue which receives a small air passage (a bronchiole) together with the terminal ramifications of the pulmonary arterioles and venules, lymphatics and nerves. Lobules vary in size, those on the surface being large and of a pyramidal form, with their bases turned towards the pleural surface, and are visible as polygonal areas about 5–15 mm across divided from adjacent areas by thin layers of connective tissue. The lobules in the interior are smaller and are of various forms. Because of this lobular structure, the lung is in some respects similar in general organization to a lobulated gland, consisting of terminal lobules and extralobular ducts which are the larger conducting passages of the lung (Miller 1947; von Hayek 1960; Engel 1962; Krahl 1964). The fairly gross pattern of lobulation just described is considered by some investigators to consist of *secondary lobules*; these are delineated on the lung surface by substantial connective tissue septa enclosing areas of 1–2 cm². Close inspection of the latter shows them to be subdivided by delicate septa into small polygonal areas about 1 mm²—the surfaces of the *primary lobules*. A widely accepted terminology for the different suborders of lobulation has yet to be devised.

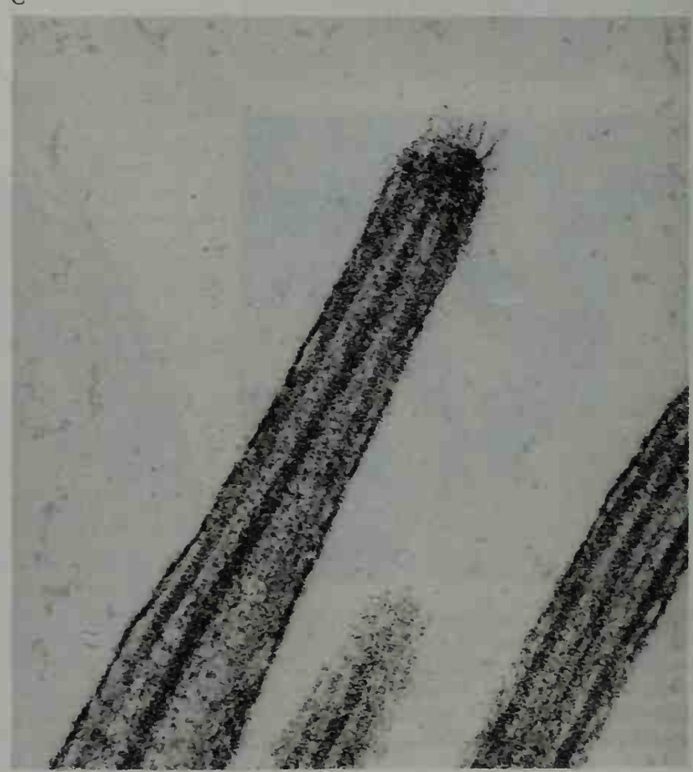
8.28A Bronchopulmonary structure. The diagram on the right shows the gross architecture of the conducting and respiratory parts of the trachea and lungs at segmental levels. On the left are three sections at the levels indicated. *Top:* A small bronchus lined by highly convoluted epithelium, surrounded by plates of hyaline cartilage. A pulmonary arteriole is visible below. *Middle:* A bronchiole. Note absence of cartilage, and conspicuous nonstriated muscle external to the epithelium. (Epoxy resin section prepared by Mrs. Susan Smith; photographed by Miss Marina Morris, Guy's Hospital Medical School.) *Bottom:* An interalveolar septum. Note capillaries containing erythrocytes (dark blue) separated from air spaces by thin alveolar epithelial cells. (Epoxy resin section stained by toluidine blue.)

THE AIR PASSAGES AND THEIR ASSOCIATED RESPIRATORY SPACES



The 'lower' respiratory tract includes larynx, trachea and extrapulmonary bronchi (*vide supra*) and various orders of smaller intrapulmonary tubes which branch repeatedly in a dichotomous manner. It is usual to distinguish between *secondary bronchi*, each supplying a whole lobe, *tertiary bronchi* supplying individual bronchopulmonary segments, and further subdivisions of bronchi which branch repeatedly within bronchopulmonary segments, becoming narrower towards their distal ends. All the intrapulmonary bronchi are supported by irregular cartilaginous plates which become smaller and more widely spaced distally (Reid 1976) until the cartilage is absent, at which point the air passages, now less than 1 mm in diameter, are termed *bronchioles*. After repeated branching, one of the smaller bronchioles enters a lung lobule; this *lobular bronchiole* immediately gives rise to about six *terminal bronchioles* which further subdivide into from one to three generations of *respiratory bronchioles* (Spencer 1977). The terminal bronchioles are the most

(Preparations B, C, D by Mr. Michael Crowder, Department of Anatomy, Guy's Hospital Medical School, London.)

distal air passages lined completely by simple columnar epithelium, while the respiratory bronchioles are characterized by the presence of alveoli which arise directly from their walls. The respiratory bronchioles open into two or three *alveolar ducts*, thin walled tubes which terminate in expanded passages, the *atria*, which in turn lead into *alveolar sacs* or *air sacs*. The thin walls of the alveolar ducts, atria and alveolar sacs are studded with small pouches, the *acini* or *alveoli*, separated from each other by thin *interalveolar septa* in which lie the connective tissue elements of the respiratory tissue and the capillary beds of the pulmonary blood supply. The above arrangement, shown diagrammatically in **8**.28A and **8**.29A, B, is normally found in the adult; variations in the pattern occur during periods of active growth during childhood and have been described in detail by Engel (1947).

It should be noted that the terminology for these various orders of branches which has been outlined here is not followed universally and considerable confusion exists in the terminology of all conducting passages beyond the level of the bronchi. Some authors, for example, define the terminal bronchiole as that duct which enters a lung lobule, and others adopt a simpler view of the various passages leading to the alveoli.

Air Passage Epithelium

The epithelial lining of the intrapulmonary bronchi and bronchioles is similar, in many respects, to that of the trachea and extrapulmonary bronchi (Collet *et al.* 1967). The epithelium of the larger intrapulmonary air passages is pseudostratified and, in the main, ciliated, while that of the terminal and respiratory bronchioles consists of a single layer of cells, many of which are non-ciliated.

Only in the rat has there been a systematic survey of the ultrastructure of the epithelial cell types present at different air passage levels (Jeffery and Reid 1975). There are ten distinct cell types within the epithelium: eight of epithelial origin and two mesenchymal (probably migratory). All the epithelial cells rest on a basal lamina, but in the larger, more proximal bronchi, not all reach as far as the lumen of the air passage. The epithelial cells proper are of the following types: *ciliated*, *serous*, *Clara*, *goblet*, *intermediate*, *brush*, *basal* and *Kulchitsky*. Of these, the serous type has not previously been described in air passage epithelium. The mesenchymal cells are either '*globule*' *leucocytes* or *lymphocytes*. The distinguishing ultrastructural features of these cells are listed

in the table below. In the rat, goblet cells occur at all air passage levels, but comprise less than 1 per cent of the cells; in some species they are absent from the smaller bronchioles. Basal cells decrease in number distally and are virtually absent from the smaller bronchioles, where the epithelium is simple in type. Clara cells are represented throughout the system. Even in the most proximal regions over 40 per cent of the cells are non-ciliated (Jeffery and Reid 1975).

The *ciliated cells*, which play an important role in maintaining the ciliary rejection current of the bronchial tree, have electron-lucent cytoplasm, a nucleus with a smooth outline, and cilia which bear apical, claw-like projections (**8**.28C, D) described by Jeffrey and Reid (1975). The cilia are surrounded by a low-viscosity liquid produced, in part, by the serous cells (*vide infra*). Above this periciliary liquid lie flakes and droplets of mucus (Van As and Webster 1972) produced by the goblet cells and by the exocrine cells of the bronchial mucous glands. According to Sleigh (1974) only the tips of the cilia are in contact with this mucus, which they 'claw' along in a disto-proximal direction. The finding of claw-like projections at the tips of the cilia supports this hypothesis. The mucus-secreting *goblet cells* are distended by supranuclear electron-lucent granules which often have electron-dense cores.

The *serous cells* each contain a nucleus of irregular outline, copious rough endoplasmic reticulum and supranuclear homogeneously electron-dense granules. Although most numerous in the trachea and extrapulmonary bronchi, serous cells are occasionally found in the intrapulmonary air passages. Similar cells have been observed in human bronchial submucosal glands (Meyrick and Reid 1970). The serous cells probably contribute to the low-viscosity periciliary fluid mentioned above.

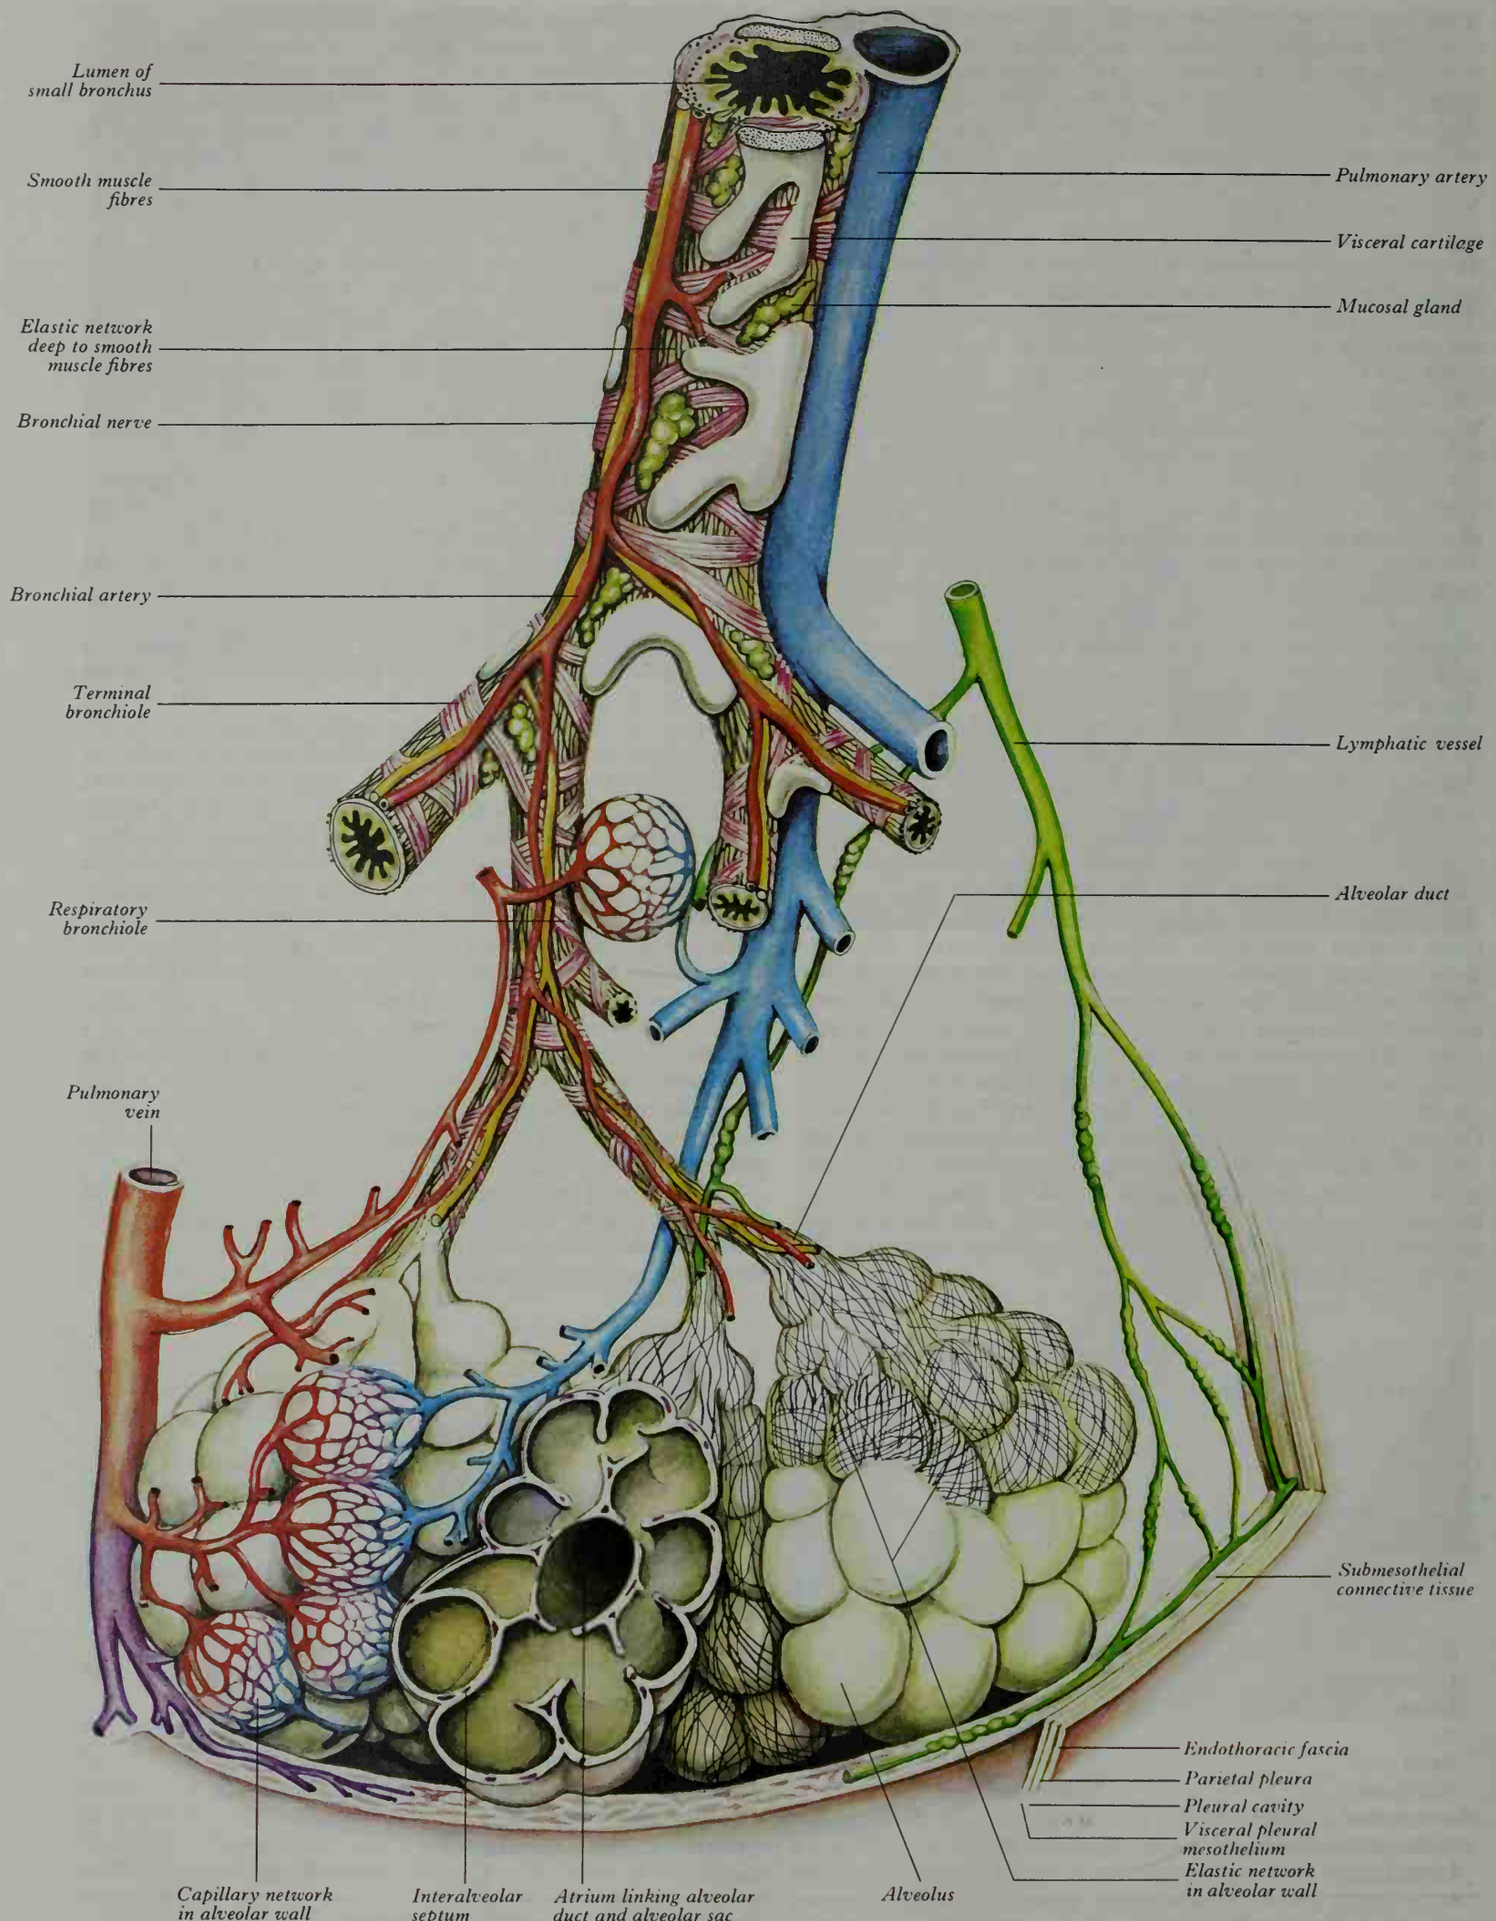
The *Clara cells*, originally thought to be characteristic of the terminal bronchioles (Clara 1937), are also present at more proximal levels of the bronchial tree, and even in the nasal mucosa (Matulionis and Parks 1973). They are non-ciliated cells with blunt luminal projections, irregular homogeneously electron-dense secretory granules, many lysosomes, osmiophilic lamellar bodies, and much smooth endoplasmic reticulum often concentrated in the apical region, which may be connected to the rest of the cell by a narrow 'waist' (Spencer 1977). Niden and Yamada (1966) were the first to suggest that the Clara cell might be a source of surfactant material, a view supported by Etherton and Conning (1971), whose autoradiographic localization of radioactively labelled dipalmitoyl lecithin (a constituent of alveolar surfactant) over the secretory granules of the Clara cells within five minutes of its intraperitoneal injection, cast doubt on the previously held view that type II alveolar cells (p. 1262) were the sole source of surfactant.

Epithelial cells described as '*intermediate*' have been observed in the bronchial epithelium of the rat (Rhodin and Dalhamn 1956; Jeffery and Reid 1975) and in the tracheal epithelium of man (Rhodin 1966). They have long, luminal filopodia, electron-dense cytoplasm but no secretory granules; they do, however, at times contain fibrogranular accumulations, suggestive of ciliogenesis (Sorokin 1968). They may be undifferentiated cells capable of developing into either ciliated or secretory cells (Rhodin 1966).

The *brush cells* are non-ciliated cells with a distinct brush border of microvilli on their luminal aspect. The presence of numerous pinocytotic vesicles near the bases of these microvilli suggests that the brush cells are specialized for absorption. They are most numerous in the tracheal epithelium, where in the rat they constitute about 1 per cent of the epithelial cells, but are also found scattered throughout the rest of the system of air passages (Jeffery and Reid 1975).

The rarest epithelial cell type is the *bronchial Kulchitsky (argentaffin) cell* (Bensch *et al.* 1965). This has electron-lucent cytoplasm containing dense-cored secretory granules which accumulate between the nucleus and the base of the cell, and discharge their contents in response to hypoxia (Moosavi *et al.* 1973; Lauweryns and Cokelaere 1973). Termed *Feyrter* cells by Moosavi *et al.* (1973), and P_a *cells* by Capella *et al.* (1978) in a recent report of the ultrastructure of these cells in the human lung, they resemble the D_1 cells (p. 1365) of the gastro-entero-pancreatic system, store and secrete amines (Ericson *et al.* 1972), and should thus be included in the diffuse endocrine system of APUD cells (Pearse and Polak 1971; Hage 1973). Innervated groups of related cells form neuro-epithelial bodies in the human bronchial and bronchiolar mucosa (Lauweryns and Peuskens 1972). Functions suggested for the Kulchitsky cells include an involvement in the regulation of lobular growth (Rosan and Lauweryns 1971) and chemoreception (Lauweryns *et al.* 1972).

The final group of epithelial cells proper are the undifferentiated *basal cells* found in those parts of the airways lined by pseudostratified epithelium. Division of these cells provides a pool of replacements for the other epithelial cell types, in a manner reminiscent of the activity of the germinal layer of the epidermis (Blenkinsopp 1967). In more distal regions of the bronchial tree, where the epithelium is of a simple type, undifferentiated cells scattered amongst the mature epithelial cells perform this function.



The remaining cells occurring in the normal airway epithelium are either 'globule' leucocytes or lymphocytes, both migratory cells, and not epithelial cells proper. The '*globule*' *leucocytes* have very electron-dense granules and numerous filopodia; they

DISTINGUISHING ULTRASTRUCTURAL FEATURES OF CELLS WITHIN THE EPITHELIUM LINING THE AIR PASSAGES

8.29A Diagram of the detailed structure of the respiratory tree and its blood supply and drainage, lymphatic drainage, and nerve supply. Vessels shown in blue contain de-oxygenated blood, those shown in red contain oxygenated blood.

resemble tissue mast cells, from which they may be derived (Murray *et al.* 1968). The *lymphocytes* have sparse electron-lucent cytoplasm and are most numerous in the extrapulmonary airways. Their ultrastructural appearance in human bronchi has been described by Meyrick and Reid (1970). Both cell types may have immunological functions.

The epithelial surface of the smaller bronchi and of the bronchioles is folded into conspicuous longitudinal ridges which allow for the changes in diameter of the passages (**8**.29A). The epithelium of the respiratory bronchioles is progressively less thick towards the alveolar termination, and is eventually composed of cuboidal, non-ciliated cells; the lateral pouches are lined with simple squamous cells, providing a small accessory respiratory surface.

MICROSCOPICAL STRUCTURE OF THE AIR PASSAGES (**8**.29A, B, C)

The epithelium of the bronchi and various bronchioles is situated on a basal lamina attached to a lamina propria in which broad, conspicuous, longitudinal bands of elastin follow the course of the bronchial tree, branching at the bifurcations of air passages and finally ramifying amongst the elastin network of the respiratory portions of the lung. The elastic framework which this system creates is an important mechanical element, responsible for much of the elastic recoil of the lung during expiration, although, in the respiratory portions, surface tensional forces may be more important (*vide infra*), and *see* Peters (1969). Nonstriated muscle fibres lie in the submucosal connective tissue, within the confines of the visceral cartilages where these are present, forming two helical tracts which run in opposite directions along the entire intrapulmonary bronchial tree, becoming thinner and finally absent at the bases of the alveoli. These muscle fibres are under nervous and hormonal control, and their contraction narrows the airways, whilst their relaxation permits bronchial dilatation. Normally there is a degree of tone in the muscular bands, which relax slightly during inspiration and contract a little during expiration, thus assisting the tidal flow of air. Abnormal contraction may result if stimulants to nonstriated muscle occur in the circulation or from the local release of such

8.29B Diagram showing the respiratory portion of the lung. The arrows indicate the possible routes taken by air during inspiration (blue) and expiration (magenta).

excitants as serotonin and histamine, to give bronchial spasm and impairment of respiration.

Prolongations of mucous membrane extend beyond the muscle layer in some bronchi and bronchioles. The deep mucosal crypts so formed may develop into canals which provide additional connexions between the peribronchiolar alveoli and the more proximal air passages (Lambert 1955).

Tubular glands are also present within the submucosa of the bronchi and upper parts of the bronchioles; these are *mucous* and *serous* in type, as in the extrapulmonary ducts.

STRUCTURE OF THE ALVEOLUS

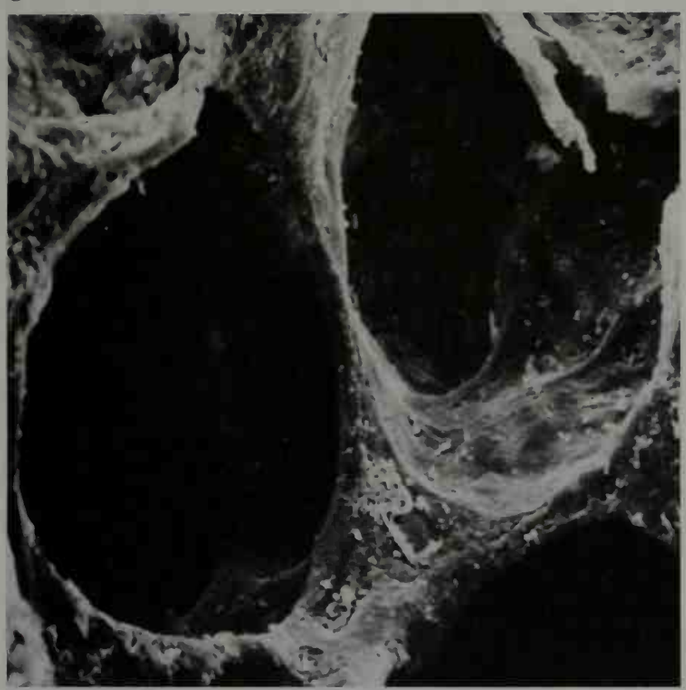
The alveoli, consisting of thin-walled pouches, provide collectively a respiratory surface with a total area which is high yet presents only a minimal barrier to the exchange of gases between the atmosphere and the blood of the capillaries lying in close association with the surface lining (Karrer 1956; Collet *et al.* 1967; Klika and Petřík 1965).

The walls of the alveoli are composed of a thin epithelial lining situated on a layer of connective tissue (**8.29B**, 30). Since the walls are thin and adjoin the walls of adjacent alveoli, the connective tissue and its contained blood vessels are frequently sandwiched as a thin irregular lamina between two layers of epithelium, forming together an *interalveolar septum*. Apertures have been demonstrated in such septa, allowing the passage of air between adjacent alveoli, and also between alveoli and respiratory bronchioles (Macklin 1936; Lambert 1955; Suarez 1979).

The epithelium lining each alveolus consists, in the main, of a single layer of attenuated squamous cells, termed *type I alveolar epithelial cells* or *type I pneumonocytes*, which form a continuous layer as little as 0·05 μm thick. Since the basement membrane of this epithelium and that of the underlying capillaries may be fused together and only about 0·1 μm thick, and the capillary endothelium about 0·05 μm thick, the total barrier to diffusion between the air of the alveolus and the blood may be as little as 0·2 μm (Collet *et al.* 1967). Despite this, the arithmetic mean thickness of the barrier is 2·2 μm in normal human lung (Gehr *et al.* 1978), a figure well beyond the range of 0·6 to 1·5 μm found in other mammals, and due mainly to the broader interstitial space rich in connective tissue fibres found in the interalveolar septa. Over approximately half the barrier surface, the space between the alveolar epithelium and the capillary endothelium is reduced to the two fused basement membranes, but over long distances there are much wider spaces in which free fluid, fixed and free cells, collagen and elastic fibres are very common (**8.29B**). Why the air-blood barrier is, over much of its area, thicker in human lung than in that of non-human mammals is unknown, although it has been suggested (Wang and Ying 1977) that the large human lung requires a stronger fibrous continuum to support the weight of the blood in its capillaries. This cannot be the full explanation, however, for the barrier is much thinner in the larger lungs of animals such as the cow and the horse (Gehr *et al.* 1978).

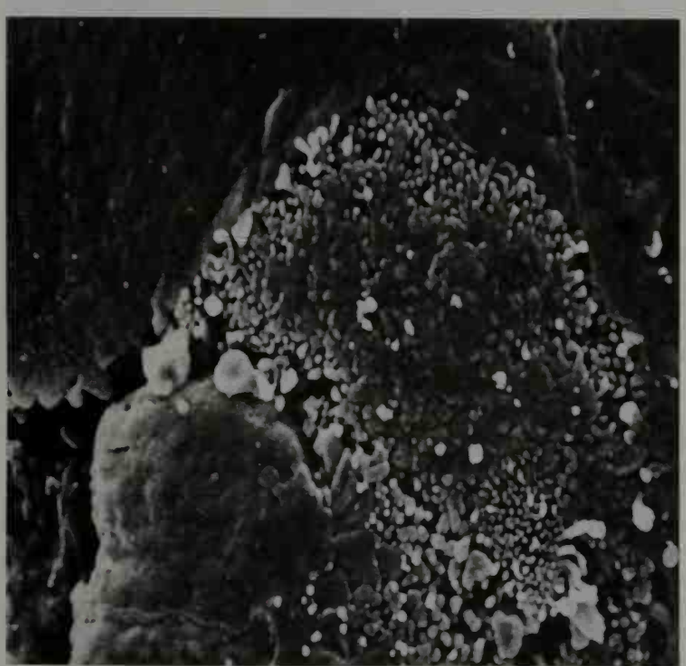
Morphometric evaluation, by stereological methods, of electron micrographs taken of random samples of normal human lungs, has led to a revised estimate of total alveolar surface area (Gehr *et al.* 1978). The mean alveolar area of eight pairs of normal human lungs was found to be 143 ± 12 m^2, a value 75 per cent higher than previous light microscopic estimates, and due mainly to the higher resolution of the electron microscope which results in a more precise definition of the alveolar surface. Capillary surface area and volume were found in this same investigation to be 126 ± 12 m^2 and 231 ± 31 ml respectively.

The alveolar surface is normally covered by a surface film of *pulmonary surfactant*, consisting of phospholipid (tubular 'myelin'). This material, secreted mainly by the type II alveolar epithelial cells (*vide infra*), although Clara cells of the bronchioles may also be involved (Etherton *et al.* 1973), has well-established surface tension reducing properties (Goerke 1974; King 1974; Tierney 1974). Likened to an emulsifying agent that stabilizes bubbles in an aqueous phase, it has been postulated to be essential for normal alveolar expansion (Macklin 1954) and to prevent total alveolar collapse during expiration (Pattle 1965). The introduction of polar solvents and water-containing embedding media in electron microscopy has improved the retention of lipids and carbohydrates in ultrathin sections and has led to a re-assessment of the ultrastructure of pulmonary surfactant (Stratton 1977; Stratton 1978) and of its precursors, the multilamellar bodies of the type II alveolar epithelial cells (Douglas *et al.* 1975; Stratton, 1976). Formerly described as a duplex layer consisting of a basal hypophase in contact with the alveolar epithelial cells and a superficial epiphase (Weibel and Gil 1968), the pulmonary surfactant now appears to be a five-layered material, each layer representing a different stage in the transformation of secreted multilamellar bodies. The layers characteristic of human pulmonary surfactant are as follows: (1) a layer of recently secreted multilamellar bodies lying nearest to the alveolar epithelial cells; (2) a layer of paired lamellae which expand and rearrange to form tubules; (3) a mature layer of tubular 'myelin' surfactant; (4) a surfactant-air interface layer, usually a single lipid bilayer; and (5) a layer of degraded surfactant, consisting of lipid bilayer spheres which are formed at the interface and degraded in the alveolar space (Stratton 1978). At isolated alveolar sites, degradation of surfactant proceeds until it has been removed completely, leaving the site empty until it can be repopulated by multilamellar bodies which transform into functional surfactant. Localized absence of pulmonary surfactant is part of the natural cycle of secretion and degradation in apparently normal human lung.



The cell population of the interalveolar septa can best be described with respect to the three principal tissue components: the alveolar epithelium, the capillary endothelium, and the interstitial space.

The *alveolar epithelium* is a mosaic of at least two cell types. The most numerous members of the mosaic are the squamous *type I alveolar epithelial cells*; these resemble endothelial cells, having thin cytoplasmic flaps from about 0·05 to 0·2 μm wide which extend from a thicker perinuclear region. The thinness of these flaps provides little barrier to gaseous diffusion between the alveolus and its capillaries. Weibel (1971) has found that deep cytoplasmic extensions of the type I cells pass through the interstitial space between the capillaries to reach and cover part of the opposite side of the interalveolar septum. This arrangement, whereby one cell extends on to two surfaces while its nucleus is situated only on one, makes it impossible for the cell to divide successfully and may in part explain why the type I cells do not undergo proliferative repair. If severely damaged, they are replaced by primitive type II cells which may later redifferentiate into type I (Spencer 1977). The attenuated cytoplasm of the type I cells contains pinocytotic vesicles, while the perinuclear cytoplasm contains a few mitochondria, a little smooth endoplasmic reticulum, and an occasional lysosome. The edges of adjacent type I cells overlap and are bound together by tight junctions.



The *type II alveolar epithelial cells*, first reported by Reinhardt in 1847, are rounded secretory cells mainly engaged in the production and secretion of pulmonary surfactant (Gil and Weibel 1969; King and Clements 1972; Gil and Reiss 1973). They project into the lumen of the alveolus, and their free surfaces are covered by microvilli which are particularly numerous at the periphery of the cells. Their cytoplasm contains many mitochondria, much rough endoplasmic reticulum, and many lysosomes. Their most characteristic feature is the presence of multilamellar bodies or secretory granules which contain mainly phosphatidylcholine, a precursor of pulmonary surfactant (Gil and Reiss 1973), arranged in regularly stacked lamellae, each of which represents a phospholipid bilayer. The ultrastructure of the multilamellar bodies has been described in detail by Stratton (1976) who found that, when lipid retention embedding medium and polar dehydrants were employed during tissue processing, the lamellar width (and hence the periodicity, since there was no interlamellar space) was either 5·5 nm or 6·6 nm, depending on the processing procedure, and that the lamellae tended to fracture at bends, to bifurcate, and to anastomose. Freeze-fracture preparations show that the lamellae are arranged in cup-shaped layers around a core region (Weibel *et al.* 1976). Experiments in mice have shown that radioactive palmitate, a component of surfactant, injected intraperitoneally, is rapidly incorporated into the multilamellar bodies or secretory granules of both type I

alveolar epithelial and Clara cells, suggesting that both are involved in pulmonary surfactant production (Niden 1967). Although primarily secretory cells, there is evidence that type II cells have phagocytic properties (Corrin 1970; Suzuki *et al.* 1972). In contrast to the type I cells, type II cells respond to injury by rapid proliferation and it has been suggested that they may replace damaged type I cells (Weibel 1974A).

A third alveolar cell type, the *brush cell* (Meyrick and Reid 1968), is a rare element of the alveolar surface in some species; also called the *type III cell*, it was not observed by Gehr *et al.* (1978) in their exhaustive study of the human lung ultrastructure, although, as they themselves point out, the presence of these rare cells in the human lung cannot be excluded.

In addition to their role in gaseous exchange, the *pulmonary endothelial cells* have many non-respiratory activities: they can clear emboli and thrombi from the blood (Heinemann and Fishman 1969), participate in the metabolism of chylomicrons (Schoefl and French 1968), produce thromboplastin (Zeldis *et al.* 1972), selectively process a variety of hormones and prohormones arriving via the systemic circulation (Vane 1969) and synthesize prostaglandins and related substances (Ryan and Ryan 1977). Their microanatomy and ultrastructure fit them to perform these diverse functions efficiently. The capillary endothelium is a simple layer of squamous cells and of the continuous type (Smith and Ryan 1973). The most remarkable features of its cells are their abundant pinocytotic vesicles (Smith and Ryan 1970), their extreme thinness (less than 0·1 μm in some areas), and their extensive meshwork of luminal projections (Ryan and Ryan 1977). They thus present an enormous surface area to the blood, an area which in man must be many times greater (Ryan and Ryan 1977) than the commonly quoted figure of 70 m^2 (Fishman and Pietra 1974). According to Ryan and Ryan (1977) the adult human lung may have of the order of 3×10^8 terminal airspaces (alveoli), each of which may have a thousand or more capillary segments in its walls; the capillary bed of the lungs may extend for 1,500 miles or more, with 1·0 ml of blood occupying 10 miles of capillaries. The capillaries lie in the alveolar walls or interalveolar septa. They cross the interstitital space of the septa, interlacing with the connective tissue fibres of this space, and bulge alternately into one or other of the adjacent alveoli which each interalveolar septum separates; thus, in general, on one side of each capillary connective tissue fibres are intercalated between the endothelium and the alveolar epithelium, while on the other the space contains only the fused basement membranes of these two cell layers, providing on approximately half of the capillary surface a minimal barrier to the exchange of gases and the non-volatile solutes of the blood.

The *interstitial spaces* of the interalveolar septa contain, in addition to free fluid, collagen and elastic fibres, a variety of cells of both fixed and free types. The most numerous of these are the fixed cells, which are represented by fibroblasts and pericytes, the latter being demonstrated in human lung by Weibel (1974a). Both fibroblasts and pericytes have contractile properties (Kapanci *et al.* 1974) and are structurally very similar (pp. 46 and 627). They can, however, be distinguished by their relative positions, the fibroblasts generally being associated with the connective tissue fibres whose components they manufacture, while the pericytes lie within the basement membranes of the capillaries. Those fibroblasts situated at the free edges of the interalveolar septa, that is, at the ring-shaped openings of the alveoli into the alveolar sacs resemble smooth muscle cells. Of the free cells of the

interstitial space, histiocytes, mast cells and lymphocytes are the most numerous; plasma cells are occasionally present.

Within the cavity of the alveoli another cell type is often seen, the *alveolar phagocyte* (*dust cell*), which is a typical macrophage similar to the connective tissue macrophages beneath the epithelial lining, and to circulatory monocytes. There is evidence that these cells enter the lung in the circulation and migrate out of the capillaries and through the epithelial lining to wander about on the alveolar surface (Collet and Normand-Reuet 1967). Such phagocytic cells are capable of clearing the respiratory portions of the lung of inhaled particles small enough to reach them, subsequently migrating back into the lymphatic drainage of the lung or moving to the base of the bronchial tree where they are taken up by the ciliary rejection current (*vide infra*) and eliminated from the lung by way of the glottis. Whenever extravasation of red blood corpuscles occurs from the lumina of the pulmonary capillaries, the phagocytes become brick-red in colour, by virtue of the erythrocytes which they engulf, and appear in the sputum; such cells are a characteristic feature of congestive heart failure and are often termed '*heart failure cells*' as a result. Other cells of the circulation may also invade the alveoli in pathological conditions, for example neutrophil leucocytes and lymphocytes in inflammatory disturbances, which also give the sputum a characteristic appearance. The presence of these various cell types in sputum is an important diagnostic feature.

PULMONARY DEFENSIVE MECHANISMS

The biological problems associated with the protection and maintenance of the respiratory tract are numerous, since such an exposed structure is subject to damage by desiccation, by microbial invasion, and by the mechanical and chemical action of inhaled particulate matter. Inhaled air is humidified chiefly in the upper respiratory tract where it passes over the mucous membranes of the nasal and bucco-pharyngeal cavities. However, the secretions of the various glands which line the bronchial tree are also of great importance in preventing the desiccation of the conducting passages and of the alveolar surfaces. The precise composition of these secretions is of some interest; the goblet cells secrete sulphated acid mucosubstances, whereas the cells of mucous glands beneath the epithelial surface contain mainly carboxylated mucosubstances, particularly those associated with sialic acid, although sulphated groups are also present (de Haller 1969). The cells of serous glands, in contrast, contain neutral mucosubstances. The goblet cells respond to local irritation and the tubular glands, both mucous and serous, to nervous and hormonal control. Excessive secretion, or an altered composition of the materials secreted, may have serious consequences in causing obstruction to the flow of air in the conducting passages.

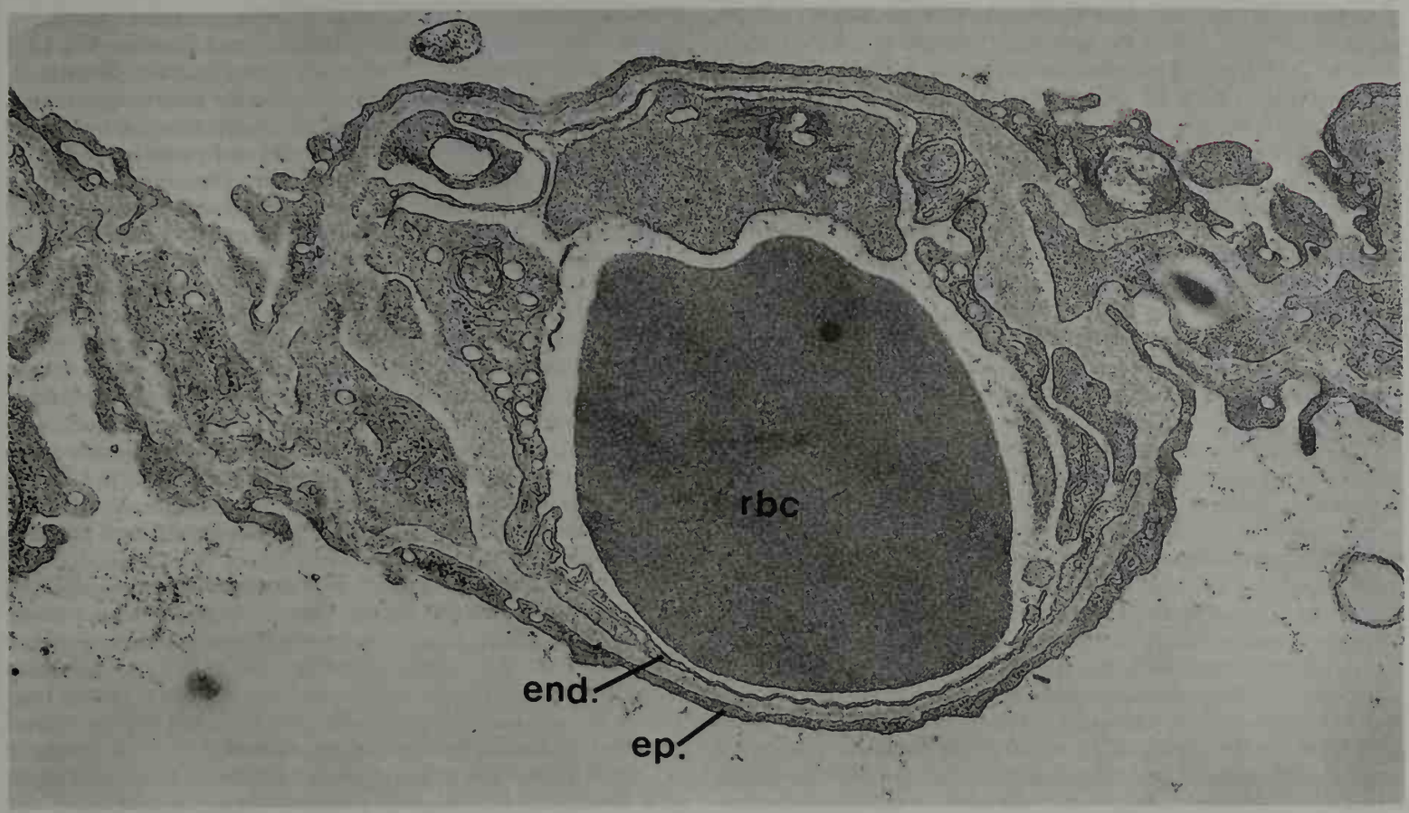
In addition to the mucosubstances secreted by the glands of the bronchial tree, antibacterial and antiviral substances are also present within the secreted fluid; these include the bactericidal enzyme lysozyme, antibodies of the IgA type, and also possibly the antiviral material interferon (Havez *et al.* 1966).

Another line of defence against the action of inhaled particles is the ciliary rejection current, already mentioned. The cilia beat the layer of fluid overlying the surface of the bronchioles, bronchi and trachea upwards at a rate of about 1 cm/minute, and those inhaled particles which are trapped in the viscous fluid may be removed from the lung by this route. However, particles smaller than the narrowest respiratory bronchioles may reach the alveoli, and may subsequently be removed by alveolar phagocytes (*vide supra*); if the particles are sufficiently abrasive they may nevertheless cause considerable damage to the respiratory surface, which may be subsequently replaced by fibrous scar tissue with a consequent reduction in respiratory efficiency. Many industrial diseases of the lung, such as pneumoconiosis, caused by inhaling coal dust, are of this pattern. Unless replaced by fibrous connective tissue as a consequence of chronic trauma, the epithelium of the alveoli has limited powers of regeneration and is under normal conditions continually being replaced. The life-span of an alveolar squamous cell is about three weeks; likewise there is a continuous and rapid turnover of alveolar phagocytes, which have a life averaging about four days (Bertalanffy 1966).

Finally, associated with the linings of the various conducting passages are numerous patches of lymphoid tissue which provide foci for the production of lymphocytes, giving local immunological protection against infection.

In addition to all of these cellular mechanisms for protection, the mechanical action of coughing in clearing pulmonary obstructions is, of course, of considerable importance. The initiation of such muscular responses to irritation involves stimulation of sensory endings in the epithelial surface; the identity of such sensory endings is open to argument, except at the laryngeal aditus, where epithelial receptors similar to taste buds are thought to be involved.

PERINATAL PULMONARY DEVELOPMENT



The histology of the lung undergoes considerable changes during development and can, for convenience of description, be divided into three main phases, the glandular, canalicular and alveolar periods (Engel 1947; de Reuck and Porter 1967; Emery 1969; Reid 1976). In the *glandular period*, lasting up to about sixteen weeks of embryonic development, the tubular epithelial outgrowths forming the ducts of the lung rudiments are lined with tall columnar epithelial cells rich in glycogen, which almost obliterate the lumina of the ducts; between these epithelial tubes lie closely packed mesenchymal cells and vascular tissue, so that the whole lung bud is composed of a concentrated mass of cells reminiscent of glandular tissue. At about sixteen weeks, the

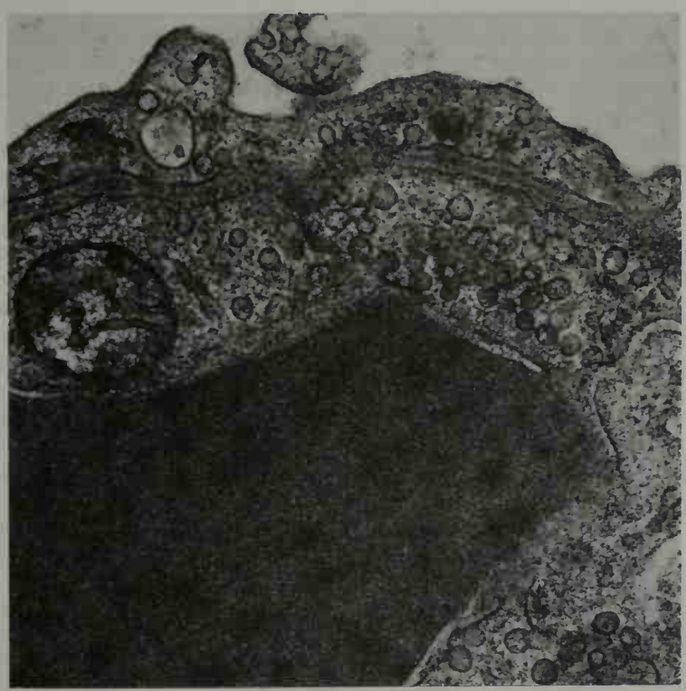
B Electron micrograph of a transverse section of a pulmonary capillary, situated in a murine interalveolar septum. A red blood cell (rbc) is present in the capillary



canalicular period commences, being marked by a rapid proliferation of the ducts which branch profusely and become more open as many of the cells transform to a cuboidal type, often ciliated. At this stage some of the cells also become squamous and begin to be associated closely with capillaries, a feature that predominates in the next phase, the *alveolar period*, from about twenty-four weeks and throughout post-natal life, when the alveoli and associated air spaces finally differentiate into their fully formed structure. The expansion of the future air spaces of the respiratory portions of the lung is associated with the passage

of fluid from the lung tissue into their lumina, although it is possible that incipient respiratory movements of the thoracic musculature, causing the inhaling of amniotic fluid, also play a part in the complete expansion of the cavities. By full term, and indeed some time before, the lung is therefore able to support normal respiration once its fluid contents are expelled by expiratory movements in air. After the time of birth, however, minor structural changes also occur, the alveolar surfaces becoming more complex and the alveoli more numerous with the increase in body size.

PULMONARY VASCULATURE AND INNERVATION

The *pulmonary artery* conveys the deoxygenated blood to the lungs; it divides into branches which accompany the segmental and subsegmental bronchi and lie for the main part on their dorsolateral aspects (**8**.20B). They end in a dense capillary mural network in the alveolar sacs and alveoli (**8**.29A). The arteries of neighbouring segments are independent of one another. Evidence has been recorded (Elliot and Reid 1965) to show that there is a fairly constant relationship between the luminal and mural

dimensions of branches of the pulmonary artery. Moreover, no regional differences can be detected (Simons and Reid 1969), despite evidence suggesting that there is a large difference between blood flow in the upper and lower regions of the lungs.

The *pulmonary capillaries* form plexuses which lie immediately beneath the lining epithelium, in the walls and septa of the alveoli and the alveolar sacs. In the septa between the alveoli the capillary network forms a single layer, the meshes of which are smaller than the vessels themselves; their walls are also exceedingly thin (*see* also above and Suarez 1979).

Arteriovenous shunts have been demonstrated in intact post-mortem human lungs in relation to terminal bronchioles. Experiments showed that such shunts may be capable of passing particles of 500 μm diameter. The functional implications of these findings are not clear (Tobin 1966).

The *pulmonary veins*, two from each lung, arise from the pulmonary capillaries, the radicles coalescing into larger branches which run through the substance of the lung, mostly independently of the pulmonary arteries and bronchi (*vide infra*). After communicating freely with other branches they form large vessels, which ultimately come into relation with the arteries and bronchial tubes, and accompany them to the hilum of the lung, the artery usually being situated dorsolateral, and the vein ventromedial, to the bronchus. Finally, they open into the left atrium of the heart, conveying oxygenated blood to be distributed to all parts of the body by the left ventricle.

Whereas in the region of the hilum of the lung the pulmonary arteries and veins closely accompany the main divisions of the bronchi, when traced peripherally the arteries and veins assume different relationships to the bronchopulmonary segments (pp. 1243–1246). In general, the centrally placed bronchus and its branches supplying a bronchopulmonary segment are accompanied by branches of the pulmonary arteries, whereas many tributaries of the pulmonary veins run between bronchopulmonary segments, so that each venous tributary drains adjacent segments and each segment is drained by more than one vein. Some of the veins also lie beneath the visceral pleura, including that in the interlobar fissures of the lung. Thus a bronchopulmonary segment of lung is not a bronchovascular unit in the sense of possessing its individual bronchus, artery and vein. In surgical removal of bronchopulmonary segments, it should be noted that the planes between adjacent segments are not avascular, but are crossed by pulmonary veins and sometimes by branches of pulmonary arteries. There is considerable variation in the above pattern of the bronchi, arteries and veins, the veins being more variable than the arteries, and the arteries more variable than the bronchi (Brock 1942, 1943, 1944, 1954; Boyden 1955; Cory and Valentine 1959; Bloomer *et al.* 1960; Volpe *et al.* 1969). What follows is a general account of pulmonary vasculature; for details of variations consult the references quoted.

Arteries of the right lung. Before it reaches the hilum of the lung, the right pulmonary artery (p. 667) gives off a large superior branch to the upper lobe, which lies at first in front of the superior lobe bronchus but soon comes to lie posterolateral to it. The main stem of the right pulmonary artery passes laterally between the superior lobar bronchus and the continuation of the principal bronchus and then lies posterolateral to the latter in the oblique fissure of the lung, supplying branches to the middle and lower lobes. The superior branch of the right pulmonary artery gives off the following branches to the bronchopulmonary segments of the upper lobe: apical, anterior descending, anterior ascending, posterior descending and posterior ascending. The branch to the middle lobe arises from the stem of the right pulmonary artery close to (or in common with) the origin of the superior branch to the lower lobe, and it divides into lateral and medial branches which supply the corresponding segments of the middle lobe. The stem of the artery supplies the following branches to the corresponding segments of the lower lobe: superior (apical), subsuperior (subapical), medial basal (cardiac), anterior basal, lateral basal and posterior basal.

Arteries of the left lung. The left pulmonary artery (p. 667), having crossed in front of the left principal bronchus to gain its posterolateral aspect in the hilum of the lung, gives off the following branches to the upper lobe segments: apical, posterior, anterior descending, anterior ascending and lingular (the last-named subdividing into superior and inferior branches). Thereafter the pulmonary artery supplies the following branches to the lower lobe: superior (apical), subsuperior (subapical), medial basal, anterior basal, lateral basal and posterior basal.

Although the right and left pulmonary arteries rarely depart from their mode of primary branching, the secondary (segmental) branches, which are listed above, display much variation in their precise sites of origin and in their numbers, reduplication being frequent. In a detailed study of the pulmonary hila at 521 partial pneumonectomies Cory and Valentine (1959) observed many variations. For example the right and left upper lobes, whose segmental arteries displayed the greatest range of variation, showed no less than 14 types of pattern in 152 right-sided operations and 29 types in 107 operations on the left. The remaining lobes displayed a lesser scale of variation, the types noted being in the right middle lobe 5, in the right lower lobe 6, and in the left lower lobe only 4. The details of all these observations cannot be given here, but the commonest patterns will be noted briefly.

Right upper lobe: Type 1: 3 segmental arteries, the apical and anterior from a common branch (91 of 152 cases = 60 per cent). Type 2: 3 segmental arteries from a single common branch (26 of 152 cases = 17 per cent). Type 3: like Type 1, but with reduplication of the posterior segmental artery (13 of 152 cases = 8·5 per cent). Type 4: like Type 2, but with a second posterior segmental branch arising separately (9 of 152 cases = 6 per cent). These common arrangements thus accounted for about 91·5 per cent of the observed patterns; the remainder (13 of 152 cases, classified as Types 5 to 14) were mostly represented by single cases. The number of direct branches from the right pulmonary artery varied from 1 to 4, and the actual number of segmental arteries (often arising by common trunks) varied from the classical 3 (118 cases = 77 per cent) to 6.

Right middle lobe: Type 1: 2 segmental arteries (25 of 51 cases = 49 per cent). Type 2: a single common stem for 2 segmental arteries (23 of 51 cases = 45 per cent). Types 3 to 5 (1 case each of 51) all showed multiplicity (3, 4 and 5) of middle lobe segmental branches.

Right lower lobe: Type 1: 3 segmental branches, 1 superior, 2 basal (31 of 43 cases = 72 per cent). Types 3 to 6 (8 of the 43 lobes) showed reduplication of the superior branch and its atypical origin from one of the basal branches. The number of segmental arteries was always either 3 or 4, the individual basal segments usually sharing common trunks.

Left upper lobe: Types 1 to 7 (78 of 107 cases = 70 per cent) showed 4 or 5 segmental branches, and most of these displayed early bifurcation, the resultant vessels being almost always distributed to two segments (with much variation in those supplied). The remaining types (8 to 29) occurred in single instances, showing variation in number (2 to 6 segmental branches) and in their sites of branching from the left pulmonary artery; bifurcation was slightly less common than in Types 1 to 7 and trifurcation occurred in 3 lobes. It appears impossible to define a 'usual' pattern for this lobe.

Left lower lobe: Type 1: showed 1 apical and 2 basal segmental arteries (44 of 57 cases = 77 per cent). Type 2: Type 1 but with 2 apical branches (9 of 57 cases) = 15 per cent). Type 3: like Type 1 but with 3 basal branches (3 of 57 cases). Type 4: showed 2 basal and 3 apical branches.

Veins of the right lung (see also p. 736). In the hilum of the lung the superior right pulmonary vein is formed by the union of three veins from the upper lobe—apical, anterior and posterior—and one vein from the middle lobe (middle lobar vein) which has two principal tributaries, a lateral and medial vein. The inferior right pulmonary vein is formed in the same site by the union of two veins from the lower lobe—superior (apical) and common basal. The common basal vein in its turn is formed by the union of a superior basal and an inferior basal vein.

Veins of the left lung (see also p. 736). In the hilum of the lung the superior left pulmonary vein, which drains the upper lobe, is formed by the union of three veins—apicoposterior (draining the apical and posterior segments), anterior and

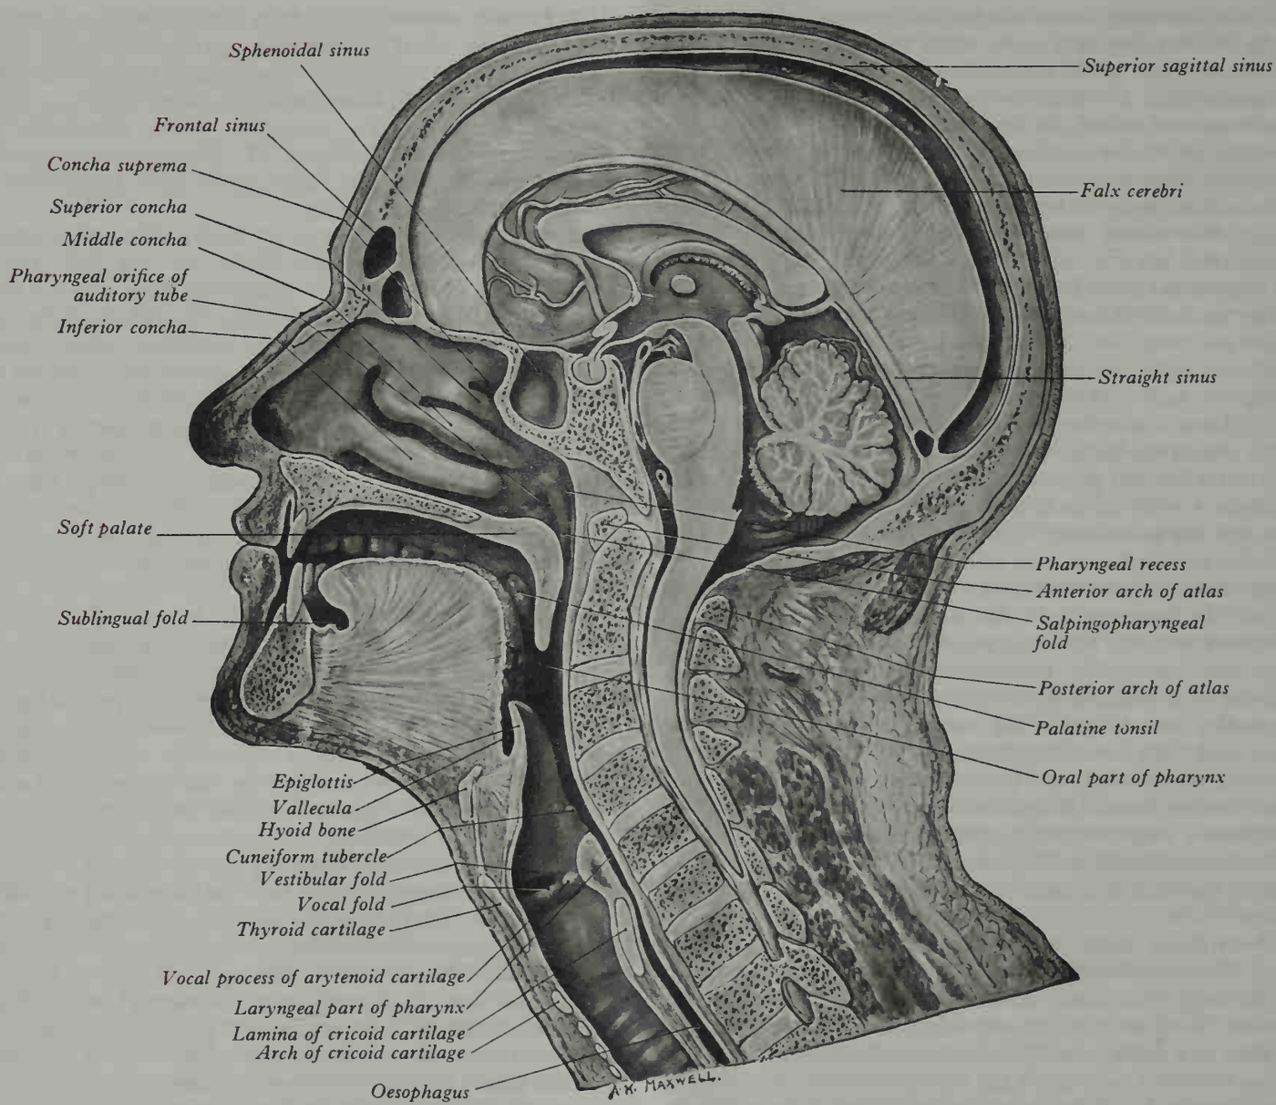
lingular, the last-named consisting of an upper and a lower part. The inferior left pulmonary vein, which drains the lower lobe, is formed in the hilum by the union of two veins—superior (apical) and common basal, the latter being formed by the junction of a superior basal and an inferior basal vein.

All of the above-named main tributaries of the right and left pulmonary veins receive in their turn smaller tributaries, some of which lie within the bronchopulmonary segments (intrasegmental veins), while others lie between and drain adjacent segments (intersegmental veins, p. 1266).

The bronchial arteries supply blood for the nutrition of the lung; they are derived from the descending thoracic aorta or from the upper posterior (aortic) intercostal arteries, and, accompanying the bronchial tubes, are distributed to the bronchial glands and upon the walls of the larger bronchial tubes and pulmonary vessels. Those supplying the bronchial tubes form, in the muscular coat, a capillary plexus from which branches are given off to form a second plexus in the mucous coat; this plexus communicates with branches of the pulmonary artery, and empties into the pulmonary veins. Others are distributed in the interlobular areolar tissue, and end partly in the deep, partly in the superficial, bronchial veins. Lastly, some ramify upon the surface of the lung, beneath the pleura, where they form a capillary network. The bronchial arteries supply the wall of the air passages only as far as the respiratory bronchioles. They anastomose with branches of the pulmonary arteries in the walls of the smaller bronchi and in the visceral pleura. There is some evidence that such bronchopulmonary anastomoses are more numerous in the newborn and they may later become obliterated to a considerable degree (Wagenvoort and Wagenvoort 1967). In addition to the main bronchial arteries, smaller branches arise from the descending thoracic aorta; one of these may pass in the pulmonary ligament and cause bleeding during surgical removal of the lower lobe.

The bronchial veins form two distinct systems (Marchand *et al.* 1950). *The deep bronchial veins* commence as a network in the intrapulmonary bronchioles and communicate freely with the pulmonary veins; they eventually join to form a single trunk which ends in a main pulmonary vein or in the left atrium. *The superficial bronchial veins* drain the extrapulmonary bronchi, the visceral pleura and the hilar lymph nodes; they also communicate with the pulmonary veins and end, on the right side in the azygos vein, and on the left in the left superior intercostal vein or the accessory hemiazygos vein. The bronchial veins do not receive all the blood conveyed to the lungs by the bronchial arteries, because some enters the pulmonary veins. The main bronchial arteries and veins lie on the dorsal surface of the extrapulmonary bronchi.

The lymph vessels of the lungs are described on p. 800. For reconstructions of the lymphatic networks around bronchi consult Bastianini (1967, 1968). The main ultrastructural features of the pulmonary lymphatics include a rather thin basal lamina, and many vesicles in the cytoplasm of the endothelial cells, together with other evidences of pinocytosis, suggesting a considerable passage of fluid across the lymphatic wall (Lauweryns and Boussaw 1967).



Nerves. The lungs are supplied from the anterior and posterior pulmonary plexuses, formed chiefly by branches from the sympathetic and vagus. The filaments from these plexuses accompany the bronchial tubes, supplying efferent fibres to the bronchial muscle and glands and afferent fibres from the bronchial mucous membrane and from the alveoli of the lung. Small ganglia are found upon these nerves. It is generally accepted that the bronchoconstrictors are supplied by the vagus (pp. 1081, 1123). The sympathetic supply is inhibitory; arrival of impulses along such nerve fibres causes relaxation of the non-striated bronchial musculature, as indeed does the withdrawal or reduction of parasympathetic (vagal) stimulation. In both the actual force which produces bronchodilatation is the pressure of inspired air.

Radiology (**3**.35, **6**.27). The trachea, because of its contained air, is more radio-translucent than the neighbouring tissues and is therefore seen in lateral and anteroposterior radiographs of the neck and upper thorax as a dark area in negatives (or as a light area in positive prints; **3**.35). For the same reason the lungs appear as dark areas in the thorax on both sides of the central mediastinal opacity; the lung areas are darker at the end of inspiration and in a diseased condition in which the alveoli are permanently distended (emphysema), but are more radio-opaque in conditions which reduce the amount of air in them (e.g. pneumonia). The dark lung areas are not homogeneous but have superimposed on them the white shadows of the pulmonary blood vessels extending from the hilum of the lung and branching into the lung areas (*see* **6**.27 and Lodge 1946). These white branching shadows are sometimes mistaken for bronchi, but the latter (because of their contained air) obviously appear as darker areas. Where a blood vessel is seen end-on, it appears as a homogeneous white circle (**6**.27); where a bronchus is seen end-on, it appears as a dark circle surrounded by a white line (the latter representing the wall of the bronchus). Lymph nodes at the hilum of the lungs, if enlarged or calcified, appear as mottled areas near the mediastinum. The shape of the lumen of the bronchi and bronchioles can be rendered plainly visible by injecting a suitable radio-opaque oil through the trachea. An effusion of fluid into the pleural cavity appears as an opacity in chest radiographs.

THE ALIMENTARY SYSTEM

Sometimes also described as the *digestive* or *gastro-intestinal* tract, the alimentary system is not merely concerned with the *digestion* of food, nor does it exclude the mouth, pharynx, and oesophagus. It is a muscular canal, lined by mucous membrane, which extends from lips to anal orifice and displays at successive levels a remarkably varied series of accessory structures, dental, glandular and muscular, adapted to the ingestion, mastication, transport, digestion and absorption of foodstuffs of every kind, and also the elimination of the unabsorbed or unabsorbable residues.

Throughout vertebrates, and indeed chordates, the alimentary and respiratory organs have shared a common entry channel from the exterior. In the primary, aquatic era of their evolution the two functions were intimately associated, as they continue to be in their extant representatives. Dissolved oxygen and suspended particulate matter are both absorbed or filtered off from the same stream of water, entering through a single opening, the mouth, and escaping via a branchial apparatus of some kind, as in *Amphioxus*. In this connexion it is pertinent to note that the largest aquatic vertebrates of today, for example, the basking-shark, *Cetorhinus*, and the baleen whales, the *Mysticeti*, still use a filtration technique for food-gathering, though the filter is palatal, rather than branchial, in the latter. In contrast, many fishes, including some teleosts, have developed an ability to gulp in air, either to fill a hydrostatic 'swim-bladder' or a respiratory 'air-bladder', both being pharyngeal diverticula. The teleostean 'swim-bladder' commonly loses its continuity with the pharynx and then derives its contained gas from the associated arterial supply (from the *dorsal* aorta). It is usually accepted that the respiratory system of the terrestrial vertebrates is a development of a ventral 'air-bladder', supplied by branches of the sixth branchial rami of the *ventral* aorta, such as exists in the extant *Dipnoi*, the lung fishes. From the same ancient stock the amphibians are derived, and in them the lungs and bronchial tree, typical of terrestrial vertebrates, have been established, even though many amphibians also depend upon transcutaneous respiration. (Some amphibia of urodelian type, such as the newt, *Necturus*, depend upon skin respiration to such an extent that the lungs are considered to have reverted to a flotation function!) Nevertheless, the buccal cavity and part of the pharynx retain their initially dual function, as they do even after division of the former into definitive buccal and nasal chambers by palatal

8.31 A median sagittal section through the head and neck. Where it divides the skull and the brain, the section passes slightly to the left of the median plane, but below the base of the skull, it passes slightly to the right of the median plane.

development in reptiles and all subsequent vertebrates. Only where there exist such specializations as that of the crocodilian larynx, which can be elevated into the nasopharynx during breathing, it is possible to achieve a complete separation of the respiratory and alimentary tracts in anatomical terms. In land vertebrates the functional separation is nevertheless complete—into a system which *alternately* inspires and expires air with a variable but relatively regular periodicity and another which is concerned with the unidirectional passage of a much more varied pabulum—solid, fluid, or any intermediate mixture—at intervals varying enormously in different species and often in the individual. The early anatomical association persists, however. Furthermore, the dorsal position of the *respiratory* nasal chamber, relative to the *alimentary* buccal cavity, and the reversal of this relationship, where the larynx diverges *ventrally* from the pharynx, inevitably entail a crossover between the two inlets, for air and food. Since both functions utilize the pharynx, except for its nasal part, mechanisms have evolved to shut off the nasopharynx (by the soft palate) and the respiratory tree (by the larynx) during the act of swallowing. Because of their respiratory function the nasal and oral parts of the pharynx, though possessing muscular walls, are able to preserve their patency. (These matters, which complicate the alimentary function of the pharynx, are considered elsewhere in greater detail. *See* pp. 1228, 1313.)

The alimentary tract, since its traffic is unidirectional, has a separate exit, caudal in position. This is essentially true even of the saccular urochordate *Ciona*, the sea-squirt, despite its sessile habit; its short gut, already showing distinct mouth, pharynx and intestine, opens into the atriopore, although this is, in fact, near to the mouth. In the cephalochordate *Amphioxus*, the differentiation of the gut has proceeded further, not only in the formation of a caudal anus separate from the atrial chamber into which the pharynx strains its aqueous intake, but also in the development of a diverticulum of the midgut; this has been regarded as 'hepatic' but is more probably a source of digestive enzymes. Both these chordates employ the pharynx, with its multitude of narrow branchial clefts, to strain off food particles from imbibed water, the concentrated solids being passed on into the intestine. Tracts of cilia and mucous glands form a part of this mechanism and of transport in the intestine, a functional cooperation also used in the mammalian respiratory system, though lost in the alimentary canal. These are but small examples of the ability of the lining ectoderm and endoderm (and also associated mesoderm) of the alimentary tract to develop a great variety of adaptations appropriate to the functions of its successive parts. Even in the Agnatha (e.g. *Petromyzon*, the lamprey) the buccal cavity has primitive teeth, a rasping tongue and salivary gland, the pharynx a branchial complex, and the gut is differentiated into oesophagus (foregut) and intestine (midgut), into which a liver delivers its secretion. There is no true stomach; but, while no pancreas is identifiable, some of the cells of the proximal part of the intestine

resemble those of the exocrine pancreas of later forms of vertebrate. (Moreover, follicles of intestinal cells have also been described at the same level which do not open into the midgut and may represent the endocrine element of the pancreas.) The lamprey's intestine also shows a surface-increasing specialization, the *typhlosole*, a helical fold of the mucosa like the spiral valve of the elasmobranch intestine. The elasmobranchs display, in addition, a well-defined stomach, pepsin-producing, which is already divisible into cardiac (glandular) and pyloric (muscular) parts. A distinguishable pancreas also appears, secreting into the midgut, together with the large liver. A distinct rectum is also recognized. In teleostean fishes the chief advance is a lengthening and spiralling of the intestine, the degree of this varying with feeding habits. In the amphibian alimentary tract the intestine is clearly separated into intestine proper and colon, a muscular valve intervening.

Except in the 'true', or *Eutherian* mammals, the vertebrate intestine terminates in a cavity, the *cloaca*, which also receives the urinary ducts and usually the genital ducts. Complete separation of the end of the alimentary tube at an anus, though foreshadowed in the Agnatha, was not achieved until the mammals appeared, though even here the monotremes must be excluded. Curiously, a similar peculiarity exists in regard to the *commencement* of the alimentary tract, for salivary glands, which are considered to be present in the Agnatha, are also characteristic of mammals, but are stated to be absent from intervening classes of vertebrate.

It is not possible in a short account to amplify this superficial delineation of the evolutionary history of the alimentary canal, even if restricted to the mammals; but a few further examples must be added to emphasize its apparently endless adaptations to feeding habits. As would be expected, birds display peculiar specializations: the teeth of their Jurassic ancestors (e.g. *Archaeopteryx*) have been lost, and a hard, horny beak of highly variable form provides an alternative feeding tool. The avian oesophagus is commonly dilated into a receptacle, the crop; and the stomach usually consists of a glandular proventriculus and, beyond this, a highly muscular gizzard, with a lining, often horny, and a content of swallowed stones to assist in grinding up hard foodstuffs. Amongst mammals the general pattern of the alimentary tract is alike, and similar to that of mankind; but there is great variation in the size and proportions of its different organs. There is, for example, much variation in the relative size of jaws and their musculature, and even more marked differentiation in the numbers, sizes, and structures of teeth. All such variation reflects the great plasticity of the epithelial tissues and their associated mesodermal derivatives. But it is especially in the mucous membrane lining the alimentary canal that such protean ability is manifest, in the production not only of varied epithelia (columnar, cuboidal, ciliated, stratified, keratinized, and enamel-generating), but also of a wide range of glandular structures, arranged either as single mucous cells or in vast complexes such as the liver and pancreas, capable of secreting a wide spectrum of digestive enzymes and hormones. Apart from exocrine secretion, a range of cells of endocrine function is produced, including not only the thyroid gland and the pancreatic islet tissue, as has long been recognized, but also the more recently identified system of enterochromaffin and other endocrine cells, scattered through the epithelia of much of the alimentary tract (p. 1364).

With the foregoing generalities in mind it is now necessary to consider the more detailed anatomy of the human alimentary tract, considered *seriatim* at its various levels, and including also its accessory organs, the teeth, tongue, salivary glands, liver and pancreas. The microscopic structure of all these is included at appropriate points. It is also convenient, as well as appropriate, to describe the peritoneum together with the subdiaphragmatic parts of the gut with which it is associated.

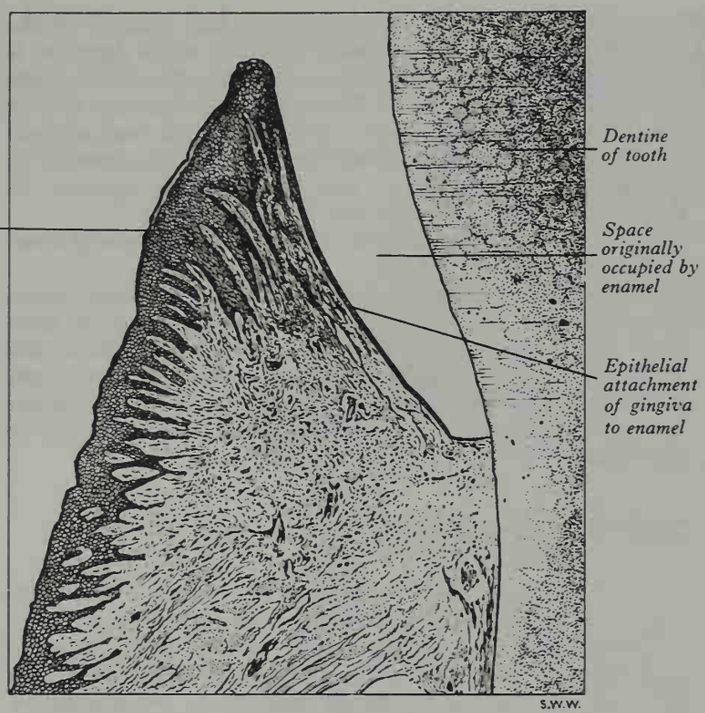
The alimentary canal, about 9 m long (*see* Underhill 1955, and p. 1342), extends from the mouth to the anus, and is lined almost throughout by mucous membrane. It consists of the following parts: it commences at the *mouth*, where provision is made for the mechanical division of food (*mastication*), and for its admixture with a fluid secreted by the salivary glands (*insalivation*); this is conveyed by the organs of deglutition, the *palate*, the *pharynx* and the *oesophagus*, into the *stomach*, where the first stages of the digestive processes take place; from the stomach it is passed into the *small intestine*, where digestion is continued and many of the resulting products are absorbed into the blood and lymph vessels. Finally the small intestine ends in the *large intestine*, which reaches the surface of the body again at the *anus*. At all levels the alimentary tube is characterized by sphincteric muscles, which will be described *seriatim*. In this connexion consult DiDio and Anderson (1968).

For an account of the general organization of the postpharyngeal alimentary tract *see* p. 1315.

The accessory digestive organs are the *teeth*, which break up and triturate the food in the process of mastication; the three pairs of main *salivary glands*—the *parotid*, *submandibular* and *sublingual*—the secretion from which mixes with the food in the mouth; the *liver* and the *pancreas*, two large glands in the abdomen, the secretions of which take part in the process of digestion.

The Oral Cavity

The oral cavity, the 'mouth', consists of an outer, smaller part, the vestibule, and an inner, larger part, the oral cavity proper.



The *vestibule* of the mouth is a slit-like space, bounded externally by the lips and cheeks, internally by the gums and teeth (**8**.31). It communicates with the exterior by the *oral fissure*. Above and below, it is limited by the reflexion of the mucous membrane from the lips and cheeks to the gums. When the teeth are apposed it communicates with the oral cavity proper by an aperture behind the third molar teeth on each side, and by narrow clefts between contiguous teeth. On the inner surface of the cheek, opposite the crown of the second upper molar tooth, a small papilla marks the opening of the duct of the parotid salivary gland.

The *oral cavity proper* (**8**.74, 75) is bounded laterally and in front by the alveolar arches, the teeth and the gums; behind, it communicates with the pharynx by the *oropharyngeal isthmus*, between the palatoglossal folds. The roof of the oral cavity consists of the hard palate and soft palate, while the greater part of the floor is formed by the anterior region of the tongue and the remainder by the reflexion of the mucous membrane from the sides and under surface of the tongue to the gum on the inner surface of the mandible. In the median plane a crescentic fold of mucous membrane, the *frenulum linguae*, connects the inferior surface of the anterior part of the tongue to the floor of the mouth. On each side of the lower end of the frenulum there is a small elevation, the *sublingual papilla*, on the surface of which is the orifice of the duct of the submandibular salivary gland. From this papilla a ridge extends laterally and backwards in the mucous membrane of the floor of the mouth; it is produced by the underlying sublingual salivary gland and is hence termed the *sublingual fold*. The minute multiple openings of the ducts of this gland are on the edge of the fold.

The *mucous membrane* of the mouth is continuous with the skin at the free margins of the lips, and with the mucous lining of the pharynx at the oropharyngeal isthmus; it is of a roseate tinge during life, and is very thick where it overlies the hard parts bounding the cavity. It is covered with stratified squamous epithelium, the superficial layers of which, unlike those of the skin, do not become cornified under normal conditions.

The *lymph vessels* of the mouth are described on p. 788.

The lips are two fleshy folds which surround the oral orifice. They are formed externally of skin and internally of mucous membrane, and these two layers enclose the orbicularis oris, the labial vessels and nerves, areolar tissue, and numerous small labial salivary glands. The line of contact between the closed lips (*the oral fissure*) lies opposite the cutting edges of the upper incisor teeth and forms, on each side, the *labial commissure*, which bounds the *angle of the mouth*; the latter usually lies just in front of the first premolar tooth. In the middle of the external surface of the upper lip is a shallow vertical groove named the *philtrum*; it ends below in a slight prominence (the *tubercle*) and is limited on each side by a ridge. The inner surface of each lip is connected in the median plane to the corresponding gum by a fold of mucous membrane, termed the *labial frenulum*—that of the upper lip being the larger.

8.32 A section across a tooth and the adjoining part of the gum. The enamel has been decalcified and removed, leaving a space between the dentine and the thin layer of stratified epithelium of the covering gum.

The *labial glands* are situated between the mucous membrane and the orbicularis oris, round the orifice of the mouth. They are about the size of small peas and in structure they resemble the mucous salivary glands (*see* p. 1275). Their ducts open into the vestibule.

The cheeks form a large part of the sides of the face, and are continuous in front with the lips, the junction being indicated externally on each side by a groove, termed *the nasolabial sulcus*, which runs downwards and laterally from the side of the nose to the angle of the mouth. The cheeks are composed of a muscular stratum, and a variable but usually considerable amount of adipose tissue, together with areolar tissue, vessels, nerves and buccal glands, covered with skin externally and with mucous membrane internally.

The *mucous membrane* lining the cheek is reflected above and below on to the outer surfaces of the maxilla and mandible, whence it is continued on to the gums; it is continuous behind with the mucous membrane of the soft palate. Opposite the crown of the second upper molar tooth there is a small papilla, on the summit of which the parotid duct opens. The principal muscle of the cheek is the buccinator; but others enter into its formation, e.g. the zygomaticus major, risorius and platysma.

The *buccal glands* are small mucous glands placed between the mucous membrane and the buccinator. Four or five, larger than the rest, and placed outside the buccinator around the terminal part of the parotid duct, are called *molar glands*; their ducts open in the mouth opposite the last molar tooth by piercing the buccinator.

The *lymph vessels* of the cheeks and lips are described on p. 786.

The gums (*gingivae*) (**8**.32) are composed of dense, vascular fibrous tissue covered with stratified, thinly keratinized squamous epithelium. They consist of two parts: the free part, which surrounds the neck of the tooth like a collar, and the attached part, which is firmly anchored to the alveolar processes of the mandible and maxillae. The fibrous tissue of the gum is continuous with the periosteum lining the alveoli. In young people the stratified squamous epithelium is attached to the surface of the enamel of the teeth (the epithelial attachment), but as age advances the gums recede from the enamel and become attached to the cement. Near the teeth, the mucous membrane on the buccal surface of the gums is thrown into tall papillae, but it becomes smooth where it is related to the enamel (**8**.32). *The nerves* supplying the upper gum are derived from the maxillary nerve through its anterior palatine, nasopalatine and anterior, middle and posterior superior alveolar branches. The mandibular nerve innervates the lower gum by its inferior alveolar, lingual and buccal branches, the last two supplying the corresponding surfaces of the gum. The buccal nerve supplies the lower gum as far forwards as the mental foramen of the mandible. The vessels for the main part accompany the nerves. (For a highly detailed study of the buccal cavity, including the tongue, consult Combelles 1972.) The lymphatics of the upper gum pass to the submandibular nodes; those from the anterior part of the lower gum pass to the submental nodes, while those from its posterior part enter the submandibular nodes.

The stratified squamous epithelium of the gums, like that of the skin, contains melanocytes, which are obvious in pigmented races. The occurrence of dendritic cells, which are DOPA negative, but probably capable of melanin production, has also been reported. Actual estimates of the incidence of these two types of cells have also been made (Barker 1967). The dendritic cells are located more superficially than the melanocytes, and they are more frequent in the crevices between adjoining teeth, than are melanocytes.

THE PALATE

The palate forms the roof of the mouth: it consists of two regions—the *hard* palate in front, the *soft* palate behind.

The hard palate (**8**.47) is formed by the palatine processes of the maxillae and the horizontal plates of the palatine bones; it is bounded in front and at the sides by the alveolar arches and gums; behind, it is continuous with the soft palate. It is covered with a dense tissue, formed by the periosteum and mucous membrane, which are intimately connected. It presents a median, linear raphe, which ends anteriorly in a small papilla overlying the incisive fossa. On each side of the raphe the mucous membrane of the front part is thick, pale in colour, and corrugated; behind, it is thin, smooth, and of a redder colour: it is covered with keratinized stratified squamous epithelium, and furnished in its posterior half with numerous palatine mucous glands, which lie between the mucous membrane and the periosteum. The upper surface of the hard palate forms part of the floor of the nasal cavity and is largely lined by ciliated epithelium.

The soft palate (**8**.31) is a movable fold, suspended from the posterior border of the hard palate, and extending downwards and backwards between the oral and nasal parts of the pharynx. It consists of a fold of mucous membrane enclosing an aponeurosis, muscular fibres, vessels, nerves, lymphoid tissue and mucous glands. When occupying its usual position (i.e. relaxed and pendant) its anterior (oral) surface is concave, and marked by a median raphe. Its posterior surface is convex, and continuous with the floor of the nasal cavity. Its superior border is attached to the posterior margin of the hard palate, and its sides are blended with the pharynx. Its inferior border is free. The lower region of the soft palate hangs like a curtain between the mouth and the pharynx.

A small conical process, termed the *uvula*, hangs from the middle of its lower border; and two curved folds of mucous membrane, containing muscular fibres, extend laterally and downwards from each side of the base of the uvula (**8**.75). The anterior of the two contains the palatoglossus and is named the *palatoglossal arch*. Below, it reaches the side of the tongue at the junction of the oral and pharyngeal portions and it forms the lateral boundary of the oropharyngeal isthmus. The posterior fold, which is termed the *palatopharyngeal arch*, descends on the lateral wall of the oral part of the pharynx and is described on p. 1309. (The term *isthmus of the fauces* includes both the palatal arches.)

Flanking the median palatine raphe, and near the junction of the hard and soft parts of the palate, there are often to be seen a pair of bilateral depressions, separated by a few millimetres. These *palatine foveae* may extend into pits, a few millimetres deep, and their openings may be anteroposteriorly elongated. It is probable that they are the common superficial orifices of a number of converging ducts from the palatine glands referred to above.

The *mucous membrane* of the soft palate is thin, and consists of

stratified squamous epithelium excepting the upper part of its posterior surface and near the pharyngeal orifice of the auditory tube, where it is columnar and ciliated ('respiratory epithelium'), like that of the nasal cavities with which it is continuous. Beneath the mucous membrane on both surfaces there are numerous palatine mucous glands; they are most abundant on the oral surface and round the uvula. Taste buds are present in the epithelium of its oral surface.

Vessels and Nerves

The *arteries* supplying the palate are the greater palatine branch of the maxillary artery, the ascending palatine branch of the facial artery, and the palatine branch of the ascending pharyngeal artery. The *veins* end chiefly in the pterygoid and tonsillar plexuses. The *lymph vessels* pass to the deep cervical lymph nodes. The *sensory nerves* are derived from the greater and lesser palatine, the nasopalatine and the glossopharyngeal nerves. The lesser palatine nerves contain taste fibres from the oral surface of the soft palate.

The Palatine Aponeurosis

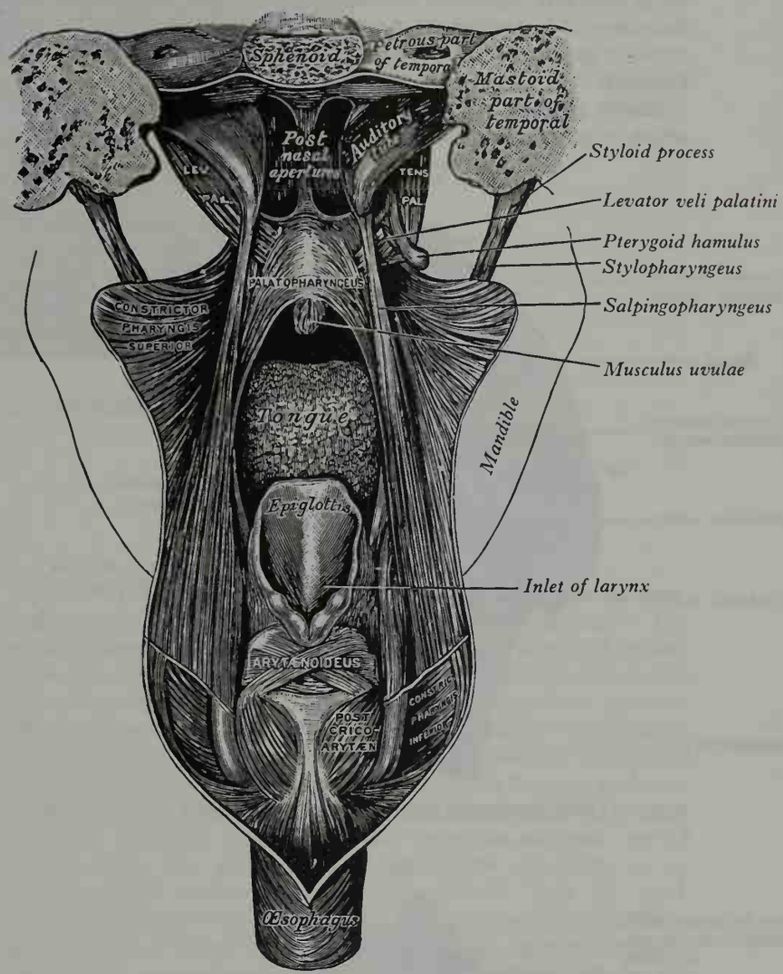
A thin, firm, fibrous lamella, termed the *palatine aponeurosis*, which supports the muscles and gives strength to the soft palate, is attached to the posterior border of the hard palate and to the inferior surface of the hard palate behind the palatine crest. It is thick in the anterior two-thirds of the soft palate, but very thin further back. The aponeurosis is actually the expanded tendon of the tensor veli palatini and, near the middle line, it splits to enclose the musculus uvulae. To it, all the other muscles of the soft palate are attached. The anterior (juxta-osseous) part of the soft palate contains little muscle and consists mainly of the palatine aponeurosis, inferior to which are numerous mucous glands; it is less movable and more horizontal than the posterior part and it is upon this part that the tensor veli palatini principally acts.

THE PALATINE MUSCULATURE

The muscles of the palate (**8**.33) include a levator and a tensor of the palate, the muscles underlying the palatoglossal and palatopharyngeal folds and extending into the palate itself, and the muscle of the uvula. For details of their activities in swallowing and speech, see p. 1313.

The levator veli palatini (**8**.33, 84, 85) is a cylindrical muscle situated on the lateral side of the posterior nasal aperture. According to Rohan and Turner (1956) it arises (*a*) by a small tendon from a rough area on the inferior surface of the petrous temporal bone, immediately in front of the lower opening of the carotid canal; (*b*) by fleshy fibres from a sheet of fascia which descends from the vaginal process of the tympanic part of the temporal bone to form the upper part of the carotid sheath; (*c*) by a few fleshy fibres from the inferior surface of the cartilaginous part of the auditory tube. At its origin, the muscle lies inferior rather than medial to the auditory tube and only crosses to the medial side of the tube at the level of the medial pterygoid lamina. After passing within the upper concave margin of the superior constrictor and in front of the salpingopharyngeus, it spreads out in the soft palate between the two strands of the palatopharyngeus, its fibres being inserted into the upper surface of the palatine aponeurosis as far as the median plane, where they blend with those of the opposite muscle.

Action. The levator veli palatini elevates the soft palate.



The tensor veli palatini (**8**.33, 79, 85) is a thin, triangular muscle, which lies lateral to the medial pterygoid plate, the auditory tube and the levator veli palatini. Its lateral surface is in contact with the upper and anterior part of the medial pterygoid, the mandibular, auriculo-temporal, and chorda tympani nerves, the otic ganglion and the middle meningeal artery. It arises from the scaphoid fossa of the pterygoid process, the lateral lamina of the cartilage of the auditory tube and the medial aspect of the spine of the sphenoid bone. As it descends, its fibres converge to form a delicate tendon which turns medially round the pterygoid hamulus, passes through the origin of the buccinator, and is inserted into the palatine aponeurosis and into the surface behind the palatine crest on the horizontal plate of the palatine bone. Between the tendon and the pterygoid hamulus there is a small bursa.

Actions. Acting singly the tensor veli palatini pulls the soft palate to one side; acting together the two muscles tighten the soft palate (principally its anterior part) and depress it by flattening out its arch.

The musculus uvulae, a bilateral structure, arises from the posterior nasal spine of the palatine bones and from the palatine aponeurosis, between the two laminae of which the two uvular muscles lie; it descends to be inserted into the mucous membrane of the uvula.

Action. The musculus uvulae pulls up and contracts the uvula on its own side.

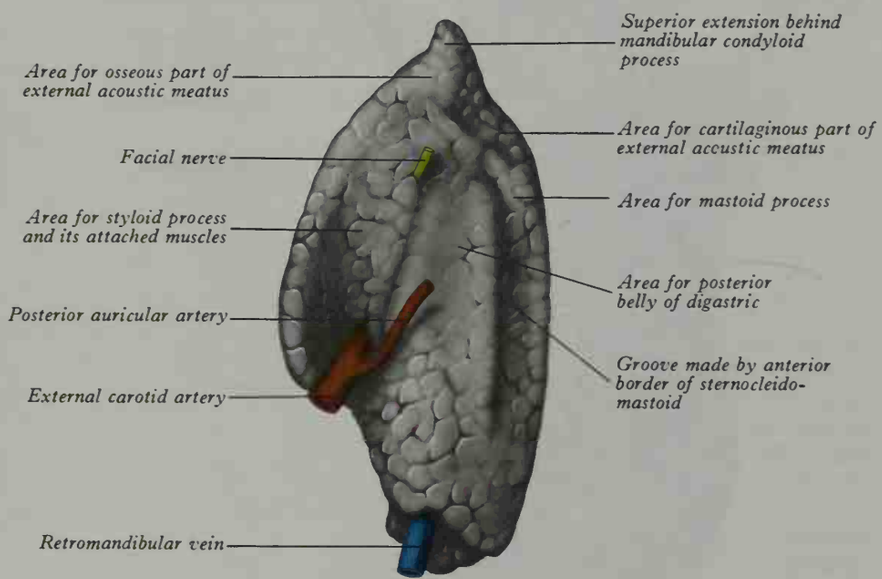
The palatoglossus is a small, fleshy fasciculus, narrower in the middle than at the ends, forming, with the mucous membrane covering its surface, the palatoglossal arch. It arises from the oral

8.33 The muscles of the palate. Exposed from the posterior aspect.

surface of the palatine aponeurosis, where it is continuous with the muscle of the opposite side, and passing antero-inferiorly and laterally in front of the tonsil, is inserted into the side of the tongue, some of its fibres spreading over the dorsum of the tongue, and others passing deeply into its substance to intermingle and blend with the transversus linguae.

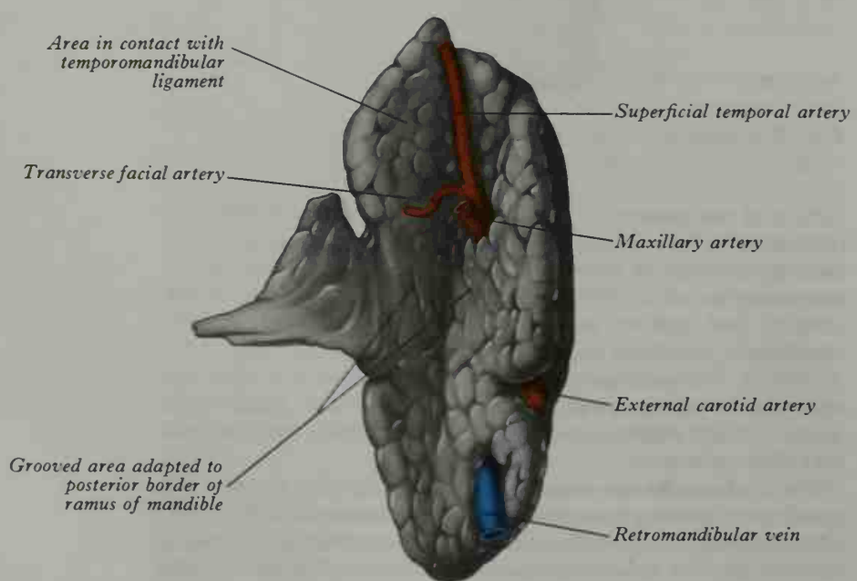
Actions. The palatoglossus pulls up the root of the tongue and approximates the palatoglossal arch to the median plane. Both muscles acting together close off the mouth cavity from the oral part of the pharynx.

The palatopharyngeus (**8**.33, 85) forms, with the mucous membrane covering its surface, the palatopharyngeal arch. In the palate it consists of two fasciculi, which are separated by levator veli palatini. The *posterior* fasciculus is in contact with the mucous membrane covering the pharyngeal surface of the palate; it joins with the posterior band of the opposite muscle in the median



plane. The *anterior* fasciculus, the thicker, passes between the levator and the tensor veli palatini. It arises from the posterior border of the hard palate and from the palatine aponeurosis, while some of its fibres join in the median plane with the corresponding strand of the opposite muscle. Both fasciculi are attached to the upper surface of the palatine aponeurosis and lie in the same plane in the soft palate. At the posterolateral border of the palate the two layers of the muscle unite and are joined by the fibres of the salpingopharyngeus (p. 1308). Passing laterally and downwards behind the tonsil, the palatopharyngeus descends posteromedial to, and in close contact with, the stylopharyngeus, and is inserted with it into the posterior border of the thyroid cartilage, some of its fibres ending on the side of the pharynx by being attached to the pharyngeal fibrous coat, and others passing across the median plane posteriorly, to decussate with those of the opposite muscle. The palatopharyngeus really forms an internal longitudinal muscular coat for the pharynx.

Actions. The palatopharyngeus pulls the walls of the pharynx, on its own side, upwards, forwards and medially, and so shortens the pharynx during the act of swallowing. Acting together the two muscles approximate the palatopharyngeal arches and draw them forwards.



Nerve supply. With the exception of the tensor veli palatini, which is innervated by the mandibular nerve (p. 1066), all the muscles of the soft palate are supplied by nerve fibres which leave the medulla in the cranial part of the accessory nerve and which reach the pharyngeal plexus via the vagus nerve.

The muscles in the soft palate lie in the following relation to each other: the palatine aponeurosis (tendon of tensor veli palatini) is an intermediate sheet, enclosing the uvular muscles near the median plane; the levator veli palatini and palatopharyngeus are inserted into its upper surface, the two fasciculi of the latter muscle lying in the same plane, respectively in front of and behind the levator veli palatini; the palatoglossus is inserted into the oral surface of the aponeurosis. (For description of *the palatopharyngeal sphincter, see* p. 1309.)

Applied Anatomy. The occurrence of a congenital cleft in the palate has been referred to already as a defect in development p. 149). Paralysis of the soft palate may occur after diphtheria due to the action of the toxin on the nerve cells in the medulla oblongata. It gives rise to a change in the voice, which becomes nasal, and to the regurgitation of fluids into the nose when swallowing is attempted. On inspection, the palate is seen to hang flaccid and motionless when phonation or deglutition is attempted; it is also anaesthetic. Similar results ensue from other pathological processes involving the glossopharyngeal, vagus and accessory nerves, or the nuclei in the medulla oblongata.

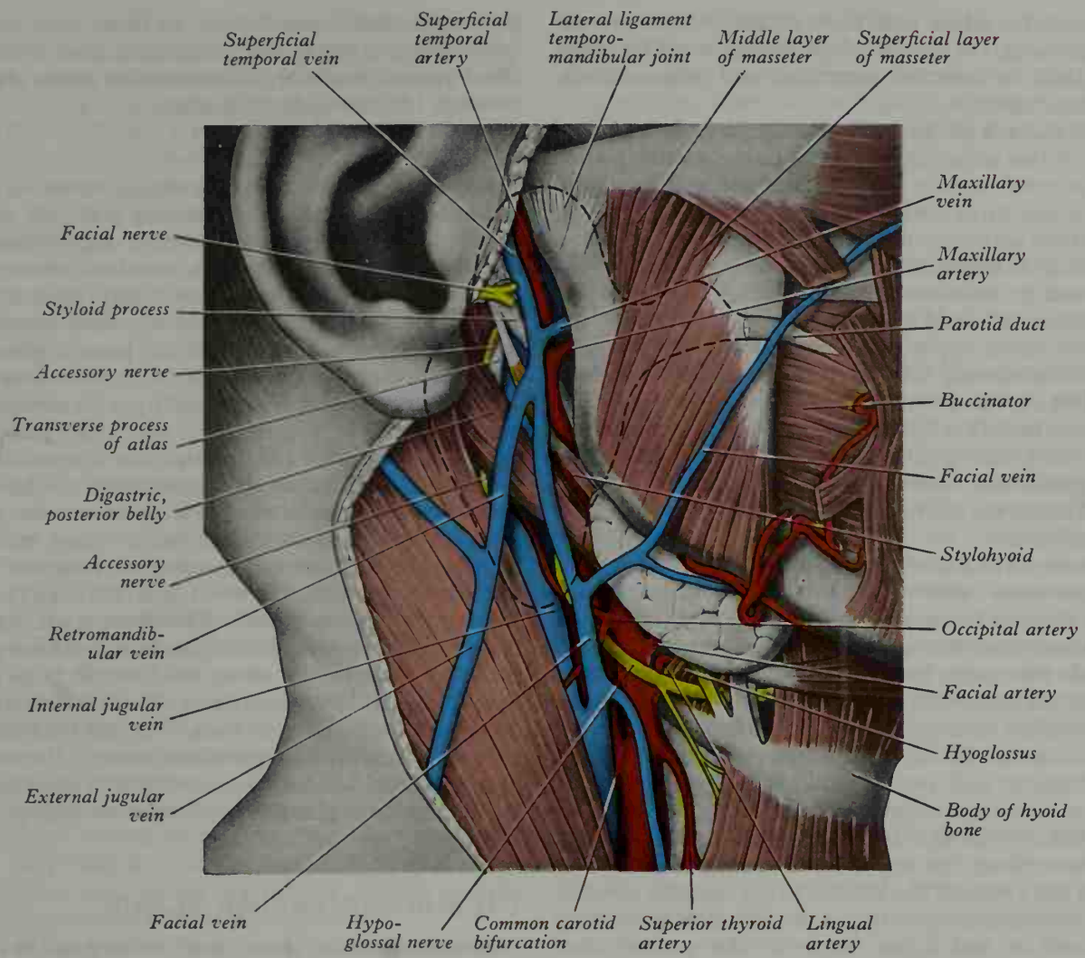
8.34B The right parotid gland. Anteromedial aspect.

The Salivary Glands



In the broadest sense, a salivary gland may be defined as any cell or organ which discharges a secretion into the oral cavity. Conventionally, a distinction is made between the *major salivary glands*, which lie at some distance from the oral mucosa, with which they communicate through one or more extraglandular ducts, and the *minor salivary glands*, which lie in the mucosa or submucosa and open directly or indirectly via many short excretory (collecting) ducts, on to the epithelial surface of the mucosa. In man the major salivary glands comprise three large paired masses—the parotid, submandibular and sublingual glands—while the minor salivary glands comprise the anterior lingual glands, numerous small glands (including von Ebner's glands, p. 1269) in the mucous membrane of the tongue, and small labial, buccal and palatal glands (p. 1281) in relation to the mucous membranes of the lips, cheek and roof of the mouth respectively. Their functions include: the lubrication of food, assisting swallowing; moistening of the buccal mucosa, essential for speech; provision of an aqueous solvent, necessary for taste; provision of a fluid seal, necessary for sucking (including suckling); secretion of digestive enzymes such as salivary amylase; secretion of hormones and others pharmacologically active compounds such as a glucagon-like protein (Lawrence *et al.* 1977) and possibly serotonin (Feyrter 1961).

THE PAROTID GLAND

The parotid gland (8.34A, B) is the largest and has an average weight of about 25 gm. It forms an irregular, lobulated, yellowish mass, lying below the external acoustic meatus, between the mandible and the sternocleidomastoid; it projects forwards on to the surface of the masseter, where a small part of it, usually more or less detached, lies between the zygomatic arch above and the parotid duct below; this detached portion is named the *accessory part* of the gland.

The gland is enclosed within a capsule derived from the deep cervical fascia; the part covering its superficial surface is dense, closely adherent to the gland, and attached to the zygomatic arch; the deep part of the capsule is attached to the styloid process, mandible and tympanic plate, and blends with the fibrous sheaths of the muscles related to the gland; a portion of the fascia attached to the styloid process and the angle of the mandible is thickened to form the stylomandibular ligament, which intervenes between the parotid and submandibular glands.

The parotid gland is like an inverted, flattened, three-sided pyramid; it presents a small superior surface, and superficial,

8.35 A drawing of a dissection to show the principal immediate deep relations of the parotid gland. The outline of the parotid gland is indicated by the interrupted black line.

anteromedial and posteromedial surfaces. The lower part of the gland tapers to a blunt apex.

The *superior surface* is concave and is related to the cartilaginous part of the external acoustic meatus, and to the posterior surface of the temporomandibular joint; here the auriculotemporal nerve winds round the neck of the mandible, embedded in the gland or in the capsule around it.

The *apex* of the gland overlaps the posterior belly of the digastric and the carotid triangle to a variable extent.

The *superficial surface* is covered with the skin and the superficial fascia, which contains the facial branches of the great auricular nerve, the superficial parotid lymph nodes (p. 786) and the posterior border of the platysma. It extends upwards to the zygomatic arch, backwards to overlap slightly the anterior border of the sternocleidomastoid, downwards to its apex behind and below the angle of the mandible and forwards across the superficial surfaces of the masseter below the parotid duct (**8**.35).

The *anteromedial surface* is grooved by the posterior border of the ramus of the mandible. It covers the postero-inferior part of the masseter, the lateral aspect of the temporomandibular joint and the adjoining part of the mandibular ramus, and passes forwards on the deep aspect of the ramus to reach the medial pterygoid. The branches of the facial nerve emerge on the face from under cover of the anterior margin of this surface.

The *posteromedial surface* is moulded to the mastoid process and the sternocleidomastoid, and to the posterior belly of the digastric, the styloid process and the styloid group of muscles. The external carotid artery grooves this surface before it enters the substance of the gland. The internal carotid artery and internal jugular vein are separated from the gland by the styloid process and the styloid muscles (**8**.35). The anteromedial and posteromedial surfaces meet along a medial margin which may project so deeply as to be in contact with the side wall of the pharynx.

Within the gland are a number of non-glandular structures, most of which traverse it or even branch within its substance. The external carotid artery enters through the posteromedial surface of the parotid gland, and divides into its terminal branches within its substance. One of these branches—the maxillary artery—emerges from the anteromedial surface, and runs forwards medial to the neck of the mandible, while the other—the superficial temporal artery—gives off its transverse facial branch, and then ascends to exit from the upper limit of the gland (**8**.34B). The posterior auricular artery may start from the external carotid artery within the gland, and it then leaves the latter on its posteromedial surface. The retromandibular vein (p. 740), formed in the upper part of the gland by the union of the maxillary and superficial temporal veins, which enter the gland at the point of exit of the corresponding arteries, is superficial to the intraglandular part of the external carotid artery. It emerges from the gland behind its inferior extremity and joins the posterior auricular vein to form the external jugular vein; before it makes its exit it gives off a communicating branch which leaves the gland in front of its lower extremity and joins the facial vein. On a still more superficial plane the facial nerve traverses the gland. It enters the upper part of the posteromedial surface (**8**.34A), and passes forwards and downwards behind the posterior border of the ramus of the mandible in two main divisions from which its terminal branches arise (**7**.186). These leave the anteromedial surface of the gland above, in front, and below, and pass to their destinations at first deep to its anterior margin.

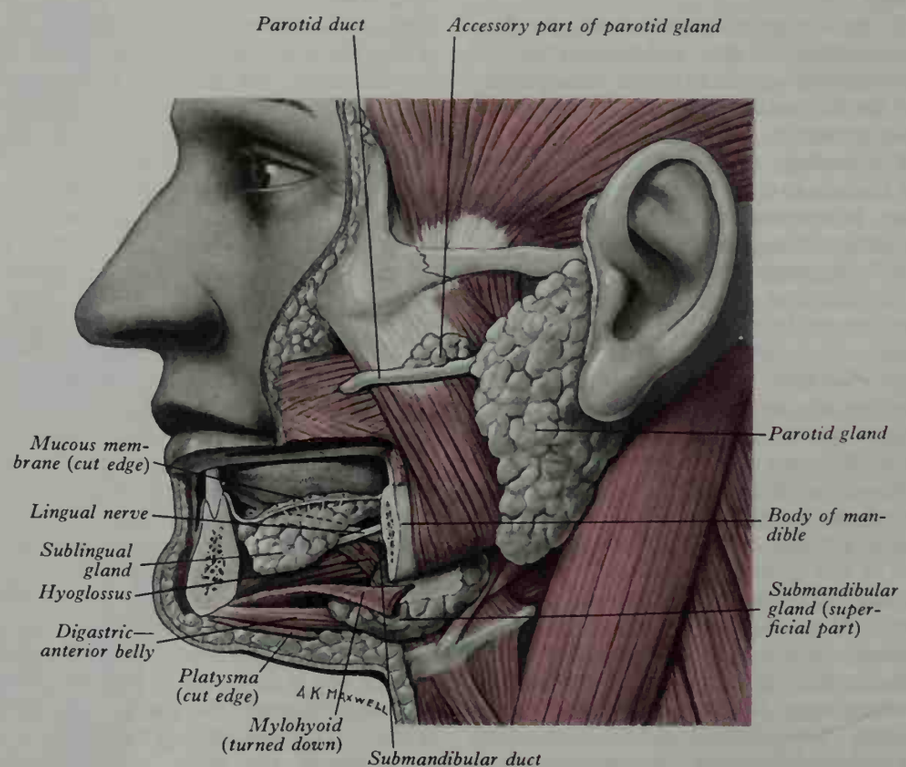
Developmentally the gland is an outgrowth from the buccal cavity (p. 197) and extends backwards towards the ear. As it does so it covers the facial nerve, but from its deep surface prolongations of the gland penetrate between the branches of the nerve in an irregular manner and constitute its deep portion. The largest of these is found between its main temporal and cervical divisions (Bailey 1947; McKenzie 1948). These outgrowths wrap

themselves round the nerve and its branches, which become buried in its substance. On account of this arrangement the gland may be considered to comprise superficial and deep sections, sometimes termed lobes.

The parotid duct (**8**.36, 40) is about 5 cm long. It begins by the confluence of two main branches within the anterior part of the gland (*see* p. 1281), crosses the masseter, and at the anterior border of this muscle turns inwards nearly at a right angle, passes through the corpus adiposum of the cheek (suctorial pad in the infant) and pierces the buccinator; it then runs for a short distance obliquely forwards between the buccinator and mucous membrane of the mouth, and opens upon a small papilla on the oral surface of the cheek opposite the crown of the second upper molar tooth. While crossing the masseter it receives the duct of the accessory lobe; in this position it lies between the upper and lower buccal branches of the facial nerve; the accessory part of the gland and the transverse facial artery are above it. The buccal branch of the mandibular nerve, as it emerges from beneath the temporalis and masseter, lies just below the duct at the anterior border of the masseter.

Surface Anatomy. The parotid duct can be felt in the living (on the face, or more easily in the vestibule of the mouth), as it dips inwards at the anterior border of the masseter, by pressing the index finger *backwards* on this border of the muscle (with the teeth clenched to make the muscle tense) and moving the finger up and down across the line of the duct. The anterior border of the gland is represented by a line passing downwards and forwards from the upper border of the mandibular condyle to a point just above the middle of the masseter and then downwards and backwards to a point about 2 cm below and behind the angle of the mandible. Its upper border, concave upwards and backwards, corresponds to a curved line drawn from the upper border of the mandibular condyle, across the lobule of the auricle, to the mastoid process. The posterior border corresponds to a straight line joining the ends of the anterior and upper borders. The parotid duct corresponds to about the middle third of a line drawn from the lower border of the tragus to a point midway between the ala of the nose and the red margin of the upper lip.

The wall of the parotid duct is thick, and consists of an external fibrous coat which contains nonstriated muscular fibres, and an internal mucous coat which is lined with short columnar epithelium (see below for further structural details). Its canal is about 3 mm in diameter, but at its orifice on the oral surface of the cheek its lumen is reduced in size.



Vessels and Nerves

The *arteries* supplying the parotid gland are derived from the external carotid artery, and from the branches given off by that vessel in or near the gland. The *veins* empty themselves into the external jugular vein, through some of its tributaries. The *lymph vessels* end in the superficial and deep cervical lymph nodes, interrupted in their course by two or three lymph nodes on the surface and in the substance of the parotid gland. The *efferent innervation* consists of sympathetic and parasympathetic nerves. The sympathetic supply is derived from the plexus on the external carotid artery. It is generally stated that the parasympathetic secretomotor nerves run through the tympanic branch of the glossopharyngeal nerve, are relayed in the otic ganglion, and then travel via the auriculotemporal nerve to the gland. Clinical investigations, however, have led to the conclusion that the human parotid gland also receives secretomotor fibres through the chorda tympani (Reichert and Poth 1933; Diamant and Wiberg 1965). More recently, Holmberg (1972) has shown that in the dog, secretomotor fibres pass to the parotid gland from the surface of the maxillary artery and from the facial nerve as well as from the auriculotemporal nerve. There are no reports, as yet, of these additional routes in man. The exact termination of these nerve supplies is still a topic of controversy. Experimental studies in cats suggest that both parasympathetic and sympathetic fibres end in relation to glandular cells (Genvis-Galvey *et al.* 1966, and *vide infra*).

THE SUBMANDIBULAR GLAND

The submandibular gland (**8**.36) is irregular in form and about the size of a walnut. It consists of a larger superficial part and a smaller deep part, which are continuous with each other around the posterior border of the mylohyoid.

The *superficial part* of the submandibular gland is situated in the digastric triangle, reaching forwards to the anterior belly of

8.36 A dissection showing the salivary glands of the left side. The cranial region of the superficial part of the submandibular gland has been excised and the cut mylohyoid has been turned down to expose a portion of the deep part of the gland.

the digastric and backwards to the stylomandibular ligament, which intervenes between the submandibular and parotid glands. Above, it extends under the cover of the body of the mandible; below, it usually overlaps the intermediate tendon of the digastric and insertion of the stylohyoid. It has three surfaces, an inferior, a lateral and a medial, and is partially enclosed between two layers of the deep cervical fascia which extend from the greater cornu of the hyoid bone, one layer passing to the lower border of the mandible and covering the inferior surface of the gland, the other passing to the mylohyoid line on the medial surface of the mandible and covering the medial surface of the gland.

The *inferior surface* of the gland is covered by the skin, platysma and deep fascia. It is crossed by the facial vein, and by the cervical branch of the facial nerve; near the mandible the submandibular lymph nodes are in contact with it and a few may actually be embedded in it (p. 787).

The *lateral surface* is in relation with the submandibular fossa on the medial surface of the body of the mandible, and with the insertion of the medial pterygoid. The facial artery is embedded in a groove in the posterosuperior part of the submandibular gland, lying at first deep to it and then emerging between the lateral surface of the gland and the insertion of the medial pterygoid to reach the lower border of the mandible.

The *medial surface* is related, in front, to the mylohyoid, separated from it by the mylohyoid nerve and vessels and by branches of the submental vessels; more posteriorly, the medial surface is related to the styloglossus, stylohyoid ligament and the glossopharyngeal nerve, which separate it from the wall of the pharynx in this region; in its intermediate part the medial surface is related to the hyoglossus, separated from it by the styloglossus, the lingual nerve, the submandibular ganglion, the hypoglossal nerve and the deep lingual vein (in that order from above downwards). Below, the medial surface is related to the stylohyoid and the posterior belly of the digastric.

The *deep part* of the submandibular gland extends forwards as far as the posterior end of the sublingual gland, and lies in the intermuscular interval between the mylohyoid below and laterally, and the hyoglossus and styloglossus medially; above, it is related to the lingual nerve, and below, to the hypoglossal nerve and the deep lingual vein.

In the living, the gland is palpable between the index finger placed on the floor of the mouth and the thumb placed medial to, and just in front of the angle of the mandible, below the floor.

The submandibular duct is about 5 cm long, and its wall is much thinner than that of the parotid duct. It begins as numerous branches in the superficial region of the gland and, emerging from the middle of the deep surface of that part of the gland a little behind the posterior border of the mylohyoid, it runs through the deep part of the gland passing at first upwards and slightly backwards for 4 or 5 mm and then turns forwards to run between the mylohyoid and the hyoglossus; it then passes between the sublingual gland and the genioglossus, and opens by a narrow orifice in the floor of the mouth, on the summit of the sublingual papilla at the side of the frenulum of the tongue (**8**.74). On the hyoglossus it lies between the lingual and hypoglossal nerves, but at the anterior border of the muscle it is crossed laterally by the lingual nerve; the terminal branches of the lingual nerve ascend on its medial side (**7**.177). As it passes through the deep part of the gland it receives the small ducts draining this part of the gland. Salivary calculi may occasionally appear in the submandibular duct and are readily detected radiologically.

Vessels and Nerves

The *arteries* supplying the submandibular gland are branches of the facial and lingual arteries. Its *veins* follow the course of the arteries. The *nerves* are derived from the submandibular ganglion, through which it receives fibres from the chorda tympani of the facial nerve, the lingual branch of the mandibular nerve and the sympathetic trunk.

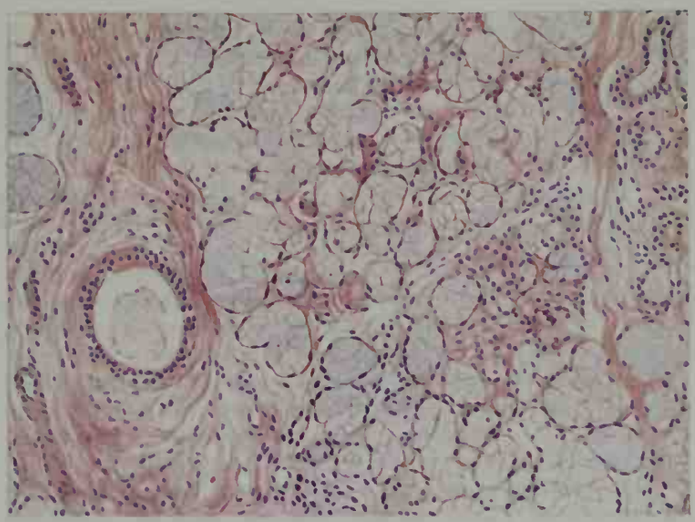
In the dog and cat the submandibular gland receives its nerve supply through a separate, subsidiary ganglion, known as Langley's ganglion (p. 1123), but in the human the cell stations on the parasympathetic nerve supply of the gland (chorda tympani) are mainly in the submandibular ganglion; some sub-ganglia may occur in the hilum of the gland, and in the branches of the submandibular ganglion passing to it. Garrett and Kemplay (1977), using catecholamine fluorescence and also electron micrography, have re-investigated arrangements in the cat, finding that all adrenergic fibres are derived from the superior cervical sympathetic ganglion.

THE SUBLINGUAL GLAND

The sublingual gland (**8**.36) is the smallest of the three main salivary glands. It is situated beneath the mucous membrane of the floor of the mouth, in contact with the sublingual fossa on the lingual surface of the mandible, close to the symphysis. It is narrow, flattened, shaped somewhat like an almond, and weighs between 3 and 4 gm. It is in relation, *above*, with the mucous membrane of the mouth, which it raises in the form of the sublingual fold; *below*, with the mylohyoid; *in front*, with its fellow of the opposite side; *behind*, with the deep part of the submandibular gland; *laterally*, with the mandible above the anterior part of the mylohyoid line and *medially*, with the genioglossus, from which it is separated by the lingual nerve and the submandibular duct. Its excretory ducts are from eight to twenty in number. Of the *smaller sublingual ducts*, most open separately into the floor of the mouth on the summit of the sublingual fold; occasionally a few open into the duct of the submandibular gland. From the anterior part of the gland some of the ducts sometimes join to form a *major sublingual duct*, which opens with, or near to, the submandibular duct.

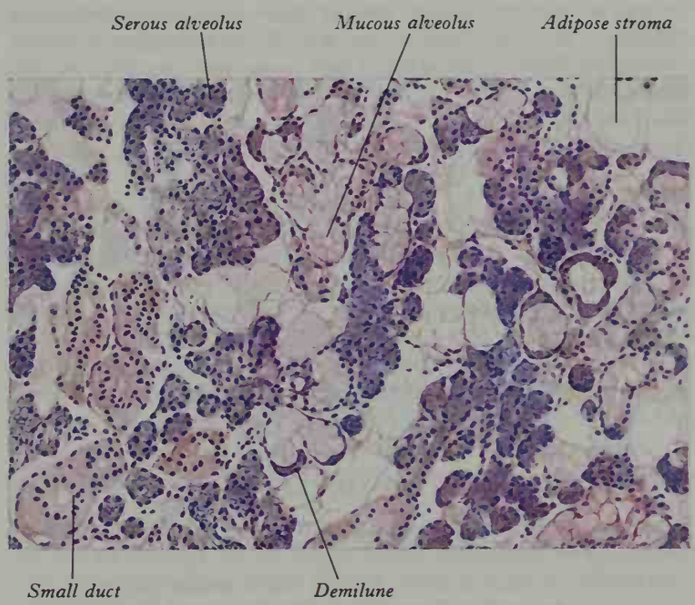
Vessels and Nerves

The sublingual gland is supplied with blood by the sublingual and submental arteries. Its nerves are derived from the lingual and chorda tympani nerves, and from the sympathetic. The parasympathetic cell station is in the submandibular ganglion; occasionally some nerve cells are found on the fibres passing distally from the submandibular ganglion to the lingual nerve and they constitute a sublingual ganglion. The precise terminations of these nerve supplies are not fully established (*vide infra*).



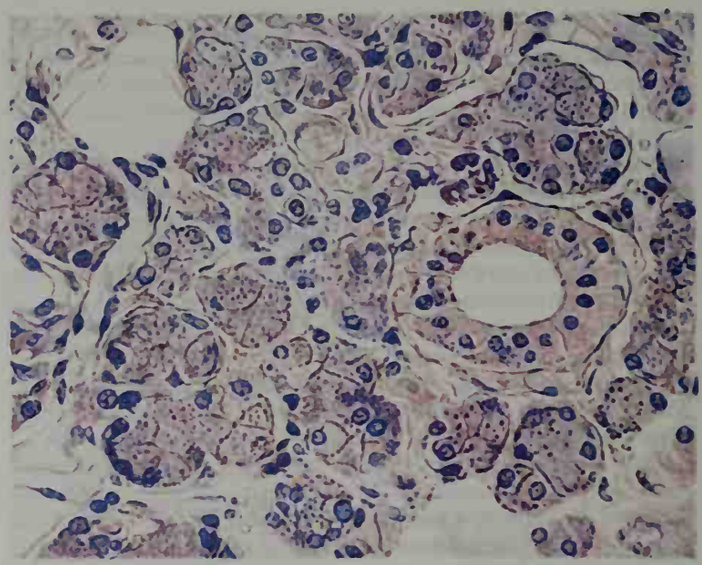
STRUCTURE OF THE MAJOR SALIVARY GLANDS

These are compound racemose glands (**8**.37A, B; 38A, B, C; 39A, B) consisting of numerous lobes made up of lobules linked by interlobular stroma, a dense areolar tissue containing excretory (collecting) ducts, blood vessels, nerve fibres and small ganglia. Each lobule consists of the ramifications of a single duct, the branches of which end as dilated secretory 'endpieces' which produce the primary secretion. This is secondarily modified as it passes sequentially through the intercalated (intercalary), striated and excretory ducts, the last of which open into one or more main ducts which direct the saliva into the oral cavity.

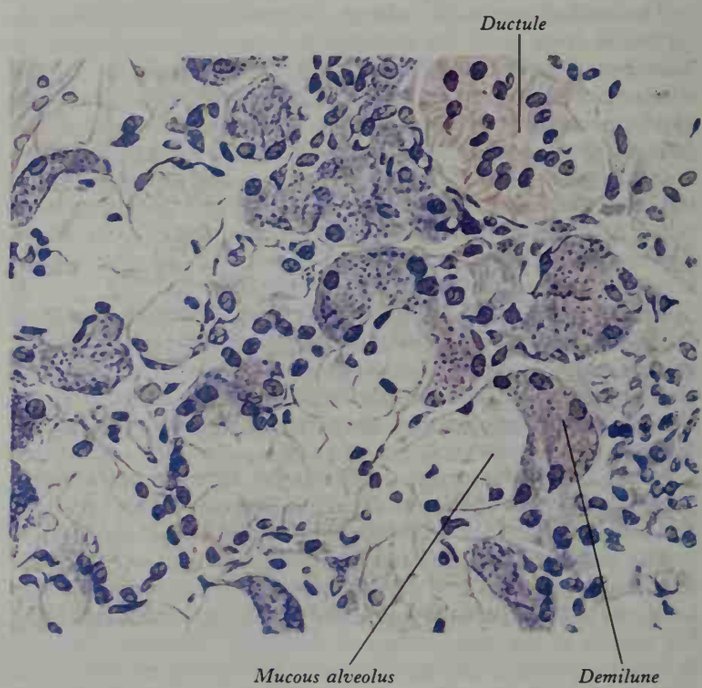


Secretory 'Endpieces' of Salivary Glands

Variation in the terms used to describe the form and cytology of the secretory endpieces has resulted in considerable confusion. The publications of Garrett (1976) and of Young and van Lennep (1978) include critical appraisals of the problems involved.

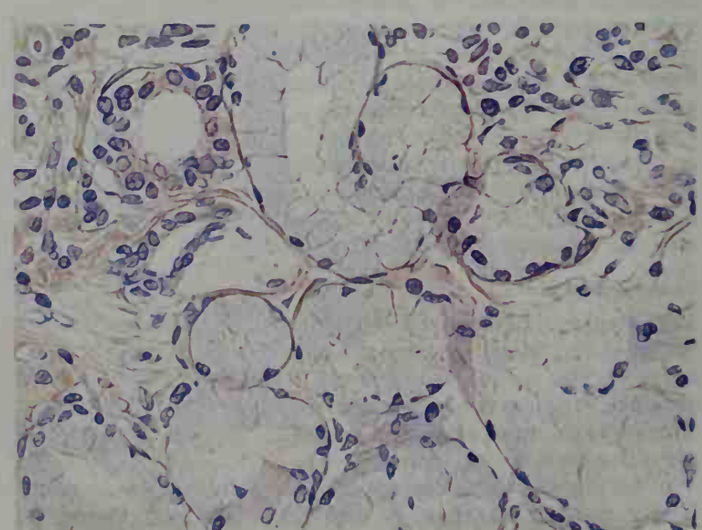


In the following description a secretory endpiece is termed an *acinus* if it is approximately spheroidal, and a *tubule* if its long axis is several times greater than its diameter; *tubulo-acini* are intermediate in shape. The glandular cells of acini are pyramidal, having a narrow luminal apex and a broad base, while those of tubules are more cylindrical. These cells, which are the main producers of salivary protein and glycoprotein, are customarily described as *serous*, *seromucous* or *mucous*; unfortunately there is no unanimity in the use of these terms. The observation that some cells produced a serous secretion of low viscosity while others produced a highly viscous mucus was correlated initially with the distinctive appearance of their cells after simple staining procedures; thus serous and mucous cells came to be distinguished. The application of improved histological techniques led to the recognition of a third group of glandular cells, the seromucous variety. It has now been shown that the substances secreted by the glandular cells can be arranged

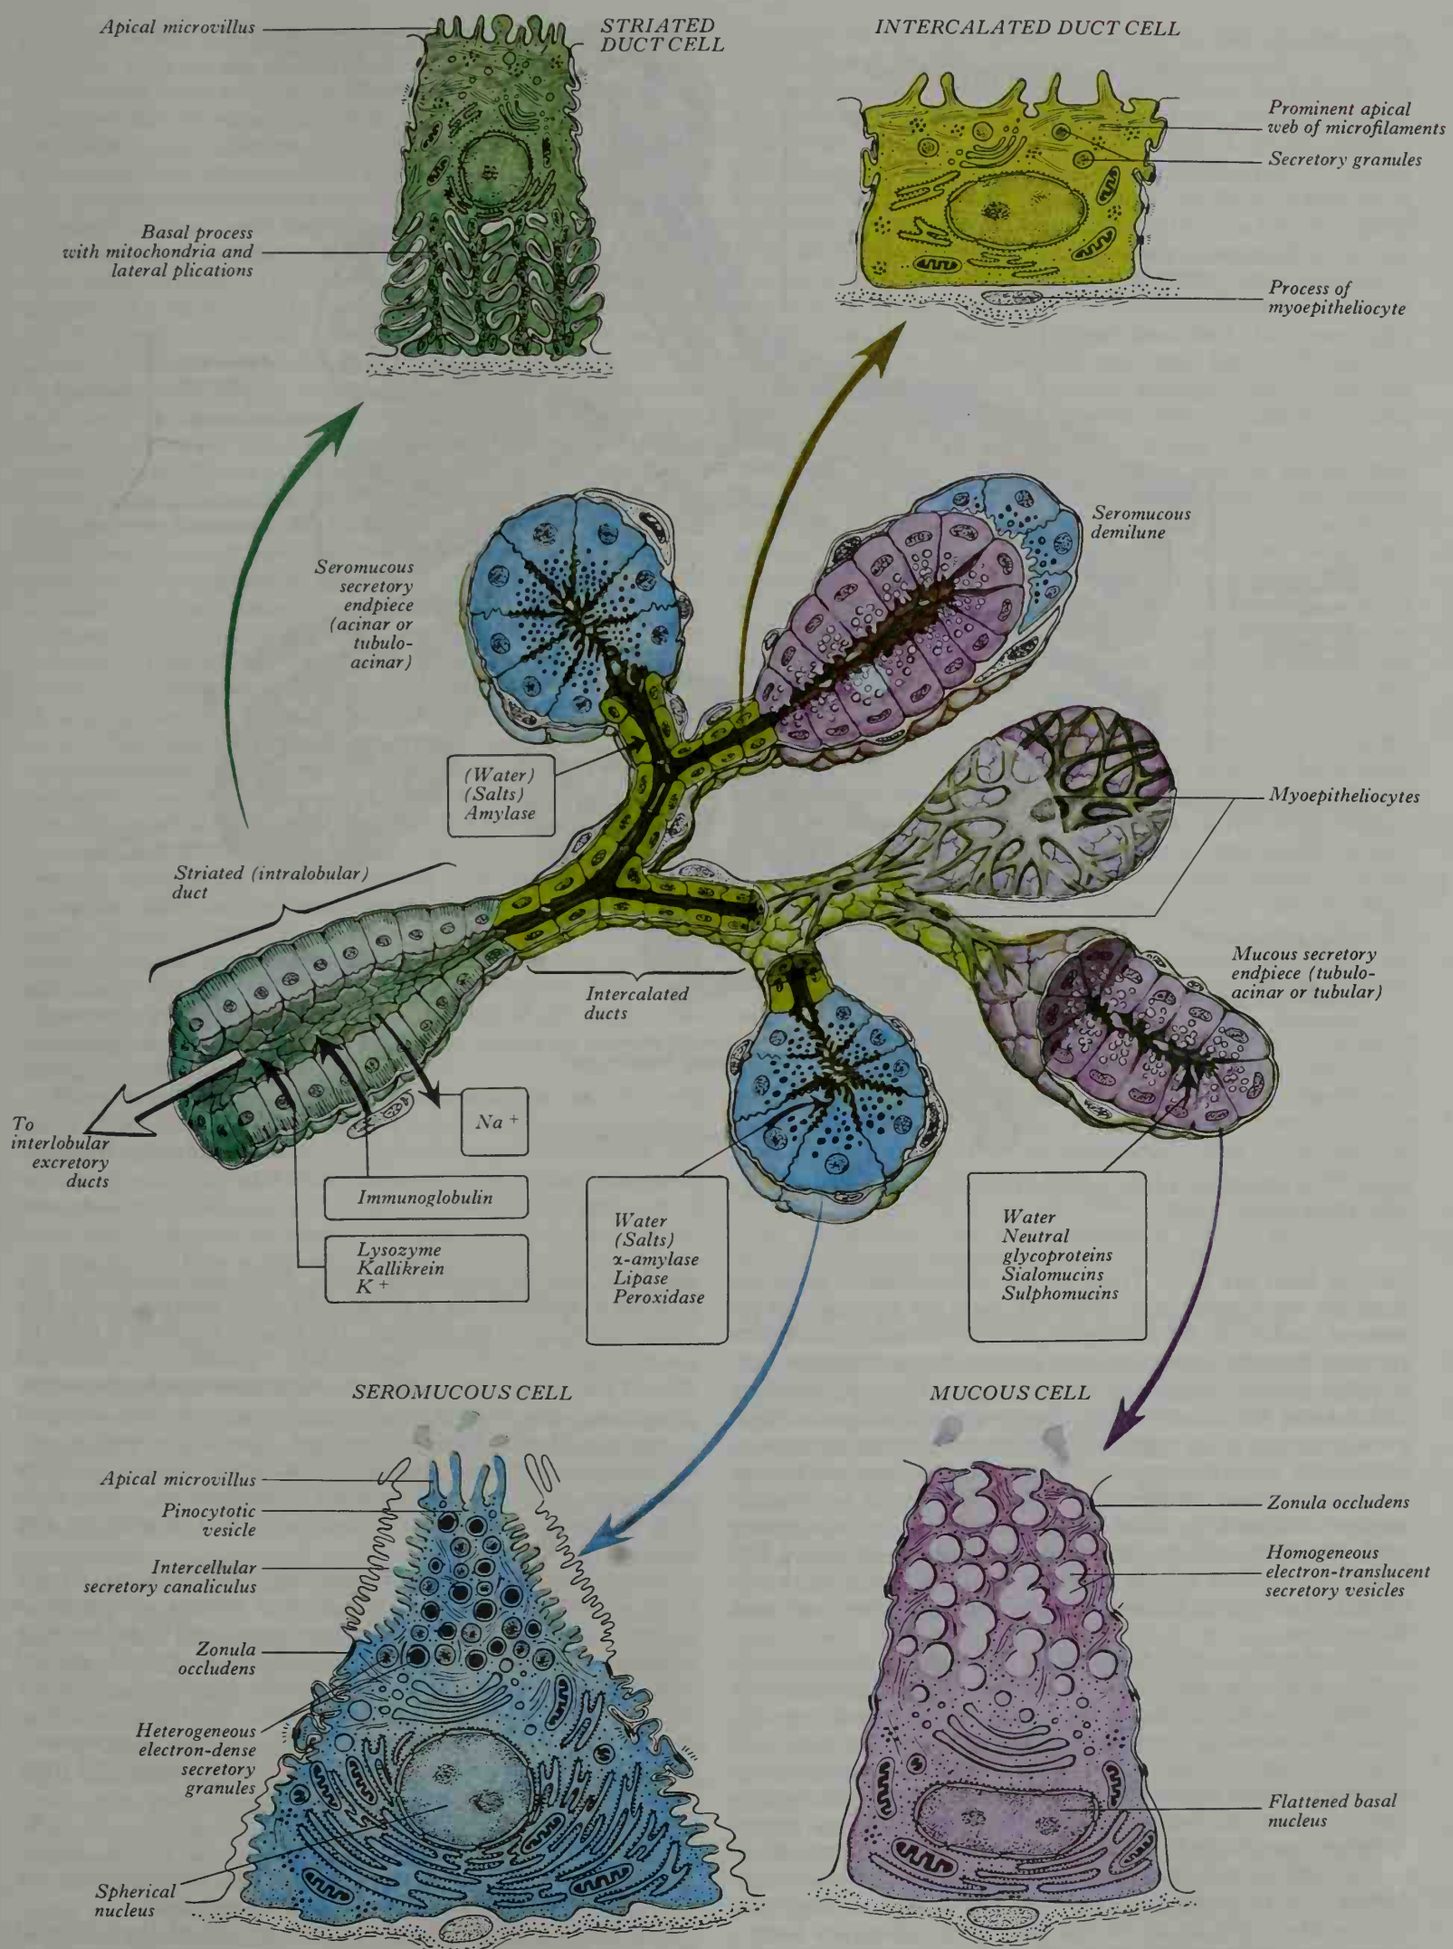


8.37A A section through the sublingual gland, stained with haematoxylin and eosin. Magnification about × 140. Compare with 8.38C.

8.37B A section of the submandibular gland, stained with haematoxylin and eosin. Magnification about × 140. Compare with 8.38B.

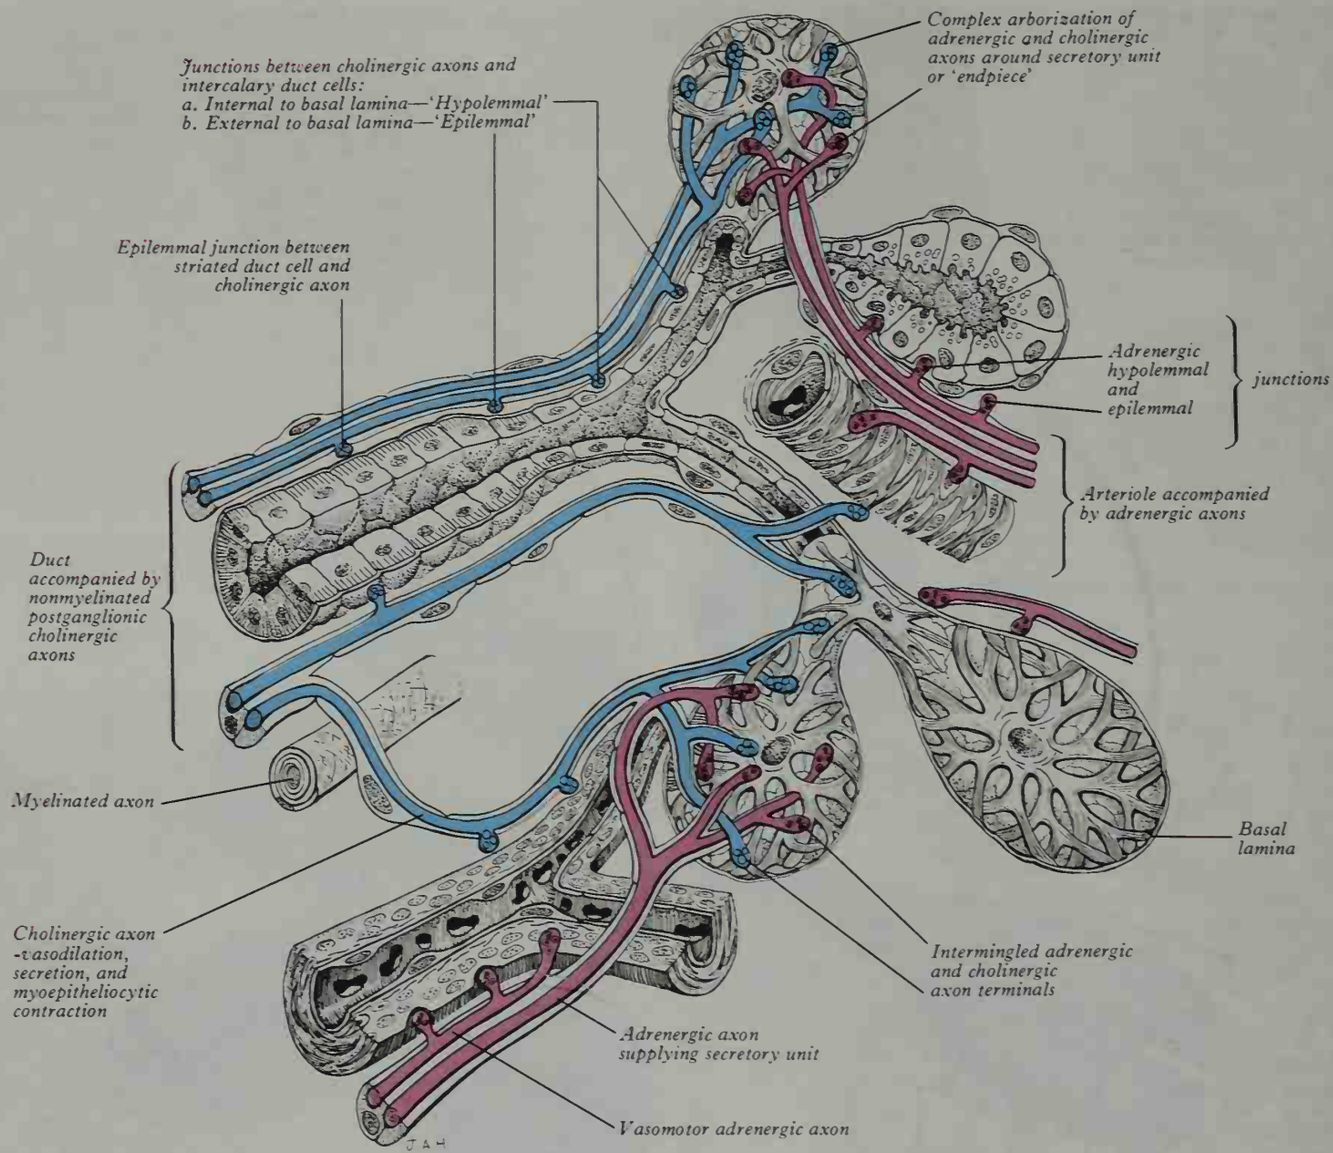


8.38A A section through the parotid gland, stained with haematoxylin and eosin. Magnification about × 350.



8.38B a section through the submandibular gland, stained with haematoxylin and eosin. Magnification about × 350.

in an almost continuous series extending from serous secretions containing only a negligible amount of protein-associated acidic carbohydrate to mucous secretions rich in these substances. Attempts have been made to define the descriptive terms serous, seromucous and mucous in strictly histochemical terms (Leblond 1950; Munger 1964; Shackleford and Wilborn 1968) but without general agreement. While recognizing the desirability of a histochemically based definition, it is practically more convenient to make use of readily observable cytological characteristics, such as the appearance of the secretory granules of the cells. Applying the criteria suggested by Young and van Lennep (1978) the glandular cells are here described as *serous* if their granules are small, discrete, homogeneous, generally eosinophilic and electron dense; *mucous* if their granules are larger, closely-packed and ill-defined, with a low affinity for eosin and with a homogeneous, fairly electron-translucent matrix; and *seromucous* if they are intermediate between the serous and mucous types in appearance, having granules which are either closely-packed, eosinophilic and homogeneous, or more discrete, larger than typical serous granules and heterogeneous. A gland or a secretory endpiece containing only one type of glandular cell is termed *homocrine*, while one containing more than one type of such cell is termed *heterocrine*.



The secretory endpieces of the human *parotid gland* consist mainly of seromucous (frequently described as serous) acini;

8.38C A section through the sublingual gland, stained with haematoxylin and eosin. Magnification about × 350.

8.39A Diagram of the architecture of a generalized salivary gland including ultrastructural details. Solid and outlined black arrows indicate direction of transport.

8.39B The innervation of the ducts, secretory units, and arterioles in a generalized salivary gland.

mucous acini are rare. Those of the *submandibular gland* are generally seromucous acini, although there are also some of the mucous variety. In the *sublingual gland* the secretory endpieces typically have the form of mucous tubules, but seromucous cells are also present, frequently arranged as acini or as *demilunes* (Young and van Lennep 1978). Seromucous demilunes, which are also present in the submandibular glands of many mammalian species, are crescentic groups of glandular cells found at the base of some mucous secretory endpieces (**8.39A**); they lie between the mucous cells and the basal lamina, apparently communicating with the lumen of the secretory endpiece by means of fine canaliculi which pass between the mucous cells. Using the criteria described above, all the major human salivary glands are thus heterocrine.

The ultrastructure of the glandular cells is shown diagrammatically in **8.39A**. Seromucous (and serous) cells are approximately pyramidal in shape. The basal plasmalemma is usually smooth, while the lateral plasmalemma is plicated, interdigitating with that of adjacent cells. The apical (luminal) plasmalemma commonly forms microvilli, between which pinocytotic vesicles may be seen. A number of discrete, short tubules, termed secretory canaliculi, lie between adjacent cells; they are limited basally and laterally by junctional complexes and open into the lumen of the secretory endpiece. Although it is often assumed that the zonulae occludentes of the junctional complexes form a continuous impermeable seal around each cell, recently published freeze-fracture micrographs of the tight junctions of the secretory endpieces of the rat parotid (de Camilli *et al.* 1976) suggest that the 'seal' may be incomplete. The shape and position of the nucleus is variable, but it tends to be more spheroidal and less basal than that of a mucous cell. The apical cytoplasm is filled by secretory granules of very variable form (Tandler 1972; Riva and Riva-Testa 1973), while a conspicuous feature of the infranuclear cytoplasm is the copious rough endoplasmic reticulum arranged in stacks of parallel, flattened cisternae. The Golgi complexes are supranuclear and have small coated vesicles and smooth vesicles associated with them. Elongated mitochondria, lysosomes, microfilaments and the occasional large lipid droplet are also present.

In contrast with serous and seromucous cells, mucous cells are more cylindrical in shape. The luminal plasma membrane is smoother, and only rarely are secretory canaliculi found between adjacent cells. The supranuclear cytoplasm is typically packed with large, electron-translucent, frequently fused, secretory droplets. The rough endoplasmic reticulum and Golgi complexes resemble those of the serous and seromucous cells in appearance and position, but the nucleus differs in being flatter and more basal.

Ducts of the Salivary Glands

Leading from the secretory endpieces are, consecutively, the *intercalated*, *striated*, and *excretory* (collecting) *ducts*.

The cells lining the intercalated ducts are cuboidal or somewhat flattened. Their cytoplasm contains elongated mitochondria, a few scattered cisternae of granular endoplasmic reticulum, juxtanuclear Golgi complexes, and some lysosomes and secretory

granules. While this unspecialized ultrastructure suggests that they play little part in protein synthesis, it does not preclude an involvement in the addition of water and electrolytes to the saliva. The problem of which cell type of the secretory endpiece-intercalated-duct complex is the main secretor of water and electrolytes is as yet unresolved, and although it is often assumed that the glandular cells have this function, the lining cells of the intercalated ducts could also be responsible for it.

The characteristic feature of the cells lining the striated ducts is their basal striation. This was described by Pflüger (1866) as resembling a thick lawn. In 1909 Regaud and Mawas concluded that the striated appearance was caused by columns of packed, elongated mitochondria, an interpretation confirmed by the ultrastructural studies of Pease (1956). Between the columns of mitochondria the cytoplasm is divided into a small number of basal processes by infolding of the basal plasmalemma. The lateral aspects of these processes may be extensively plicated and interdigitate with neighbouring processes. Desmosomes often link adjacent plications. This folding of the plasmalemma and the local abundance of mitochondria is characteristic of many epithelial cells engaged in electrolyte transport, as these cells certainly are; they transport potassium into the saliva, and by reabsorbing sodium ions in excess of water they render the saliva hypotonic (Thaysen *et al.* 1954). The lateral plasmalemmae of the lining cells of the striated ducts are linked to those of adjacent cells by slightly pervious junctional complexes (Garrett and Parsons 1974). The luminal plasmalemma forms microvilli, and the cytoplasm often extends into the lumen as apical blebs which are thought to enter the saliva by an apocrine process (Garrett 1976). The supranuclear cytoplasm contains a few scattered cisternae of granular endoplasmic reticulum, mitochondria, lysosomes, vesicles, microtubules and numerous microfilaments, the last being especially noticeable in the terminal web or 'separating zone' (Takano 1969). As well as modifying the electrolyte composition of saliva, the striated ducts also secrete immunoglobulin A (Klaus and Mestecky 1971), lysozyme (Kraus and Mestecky 1971) and kallikrein (Garrett and Kidd 1975). The immunoglobulin A is produced by plasma cells lying deep to the lining epithelium.

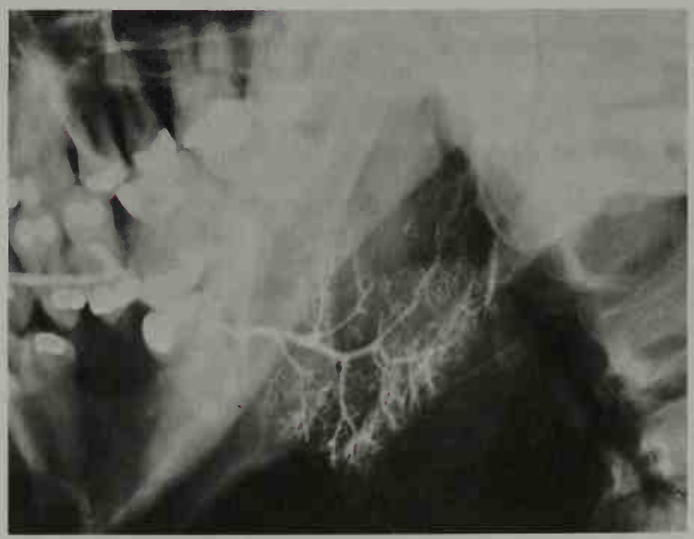
There have been few ultrastructural studies of the excretory ducts. They are lined in the rat by a simple columnar or pseudostratified epithelium, which consists mainly of tall columnar cells with perpendicular basal striations containing packed, elongated, mitochondria (Tamarin and Sreebny 1965). The presence of these striations, and the finding of more closely opposed blood capillaries here than in any other part of the duct system, suggests that the excretory ducts are more than merely passive conduits along which saliva is conducted. An involvement in electrolyte transport is suspected (Young and van Lennep 1978).

Myoepitheliocytes of Salivary Glands

These contractile cells are associated with the intercalated ducts, and usually also with the secretory endpieces, lying between the basal lamina and the epithelial cells proper. In a comprehensive review by Garrett and Emmelin (1979) of the activities of salivary myoepitheliocytes (myoepithelial cells) the effects of their contraction are summarized as follows: it speeds up the outflow of saliva, reduces the luminal volume of the intercalated ducts and secretory endpieces, contributes to the secretory pressure, supports the underlying parenchyma, helps salivary flow to overcome increases in peripheral resistance, and may, in certain circumstances, help to expel the contents of the associated secretory cells.

The shape of the salivary myoepitheliocytes depends upon their location: those of the endpieces are stellate, having long, branching, overlapping processes which, sometimes together with those of one or two other such cells, form an encircling basket-shaped network around each endpiece; in contrast, those of the ducts are more fusiform, have fewer branches, and extend along the intercalated ducts in a longitudinal direction. Each endpiece myoepitheliocyte has a central perikaryon from which radiate between four and eight processes, each of which gives rise to two or more generations of branches which cross but do not fuse, and which do not extend on to the ducts. In contrast, the processes of the myoepitheliocytes of the intercalated ducts seldom branch and often overlap on to the endpieces.

The cytoplasm of each myoepitheliocyte can be divided into two compartments, one filamentous and one non-filamentous. The latter contains the nucleus, juxtanuclear Golgi complexes, a few cisternae of granular endoplasmic reticulum, free ribosomes, lysosome-like bodies, and mitochondria. Globules of neutral fat have been described in human myoepitheliocytes (Garrett 1963). The filaments, which are particularly conspicuous in the processes and their branches, resemble the myofilaments of nonstriated myocytes (p. 518). Both thin (4nm diameter) and thick (10 nm diameter) filaments have been described, the former lying longitudinally in the processes and branches, with the less numerous thick filaments scattered amongst them., Filaments often pass to attachment plaques on the plasmalemma of the basal laminal (stromal) aspect of the cells, causing indentations there. The basal lamina opposite the plaques appears thicker than elsewhere, and is thought to be linked to the cells at these points. Bannerjee *et al.* (1977) have shown that the basal lamina affords strength to the underlying salivary epithelium. When the myoepitheliocytes contract the basal lamina is probably pulled on at the attachment plaques (Garrett and Emmelin, 1979). Numerous caveolae are commonly associated with the stromal plasmalemma, while that lying adjacent to the epithelial cells has fewer. The myoepitheliocytes are linked to the secretory and ductual cells by desmosomes, and occasionally cilia are found extending from the myoepitheliocytes into indentations on the adjacent epithelial cells. The cilia were first observed by Tandler (1965) in the myoepitheliocytes of the human submandibular gland, and have since been described in other human salivary glands (Tandler *et al.* 1970), and in glands of other species (Cutler and Chaudhry 1973; Kidd 1978). Garrett and Emmelin (1979) suggest that there may be a cilium on each salivary myoepitheliocyte, as has been proposed by Stirling and Chandler (1976) for the myoepitheliocytes of the human breast (p. 1436). The cilia may have a chemoreceptive and/or a mechanoreceptive role, but as yet their function is obscure.



Salivary myoepitheliocytes appear to have both a sympathetic and a parasympathetic innervation (Garrett 1972; 1976), with several axons of either the same or dissimilar type supplying a single myoepitheliocyte. This is not invariable, however, for in some situations, such as the sublingual gland of the rat, the myoepitheliocytes appear to have only a cholinergic innervation (Templeton and Thulin 1978). Where present, impulses from both sympathetic and parasympathetic nerves can result in myoepitheliocyte contraction (Garrett and Emmelin 1979).

CONTROL OF SALIVARY GLAND ACTIVITY

The wide and rapid variation in the composition of saliva, and in the quantity and rate at which it is produced, in response to environmental stimuli, suggests the existence of an elaborate control mechanism (Emmelin 1972). In some glands saliva is secreted spontaneously, apparently even in the absence of extraneous stimuli; in others secretion can be elicited by the stimulation of a wide variety of extraglandular receptors: gustatory, nociceptive, olfactory and tactile. Secretion may proceed at a continuous but low resting level, partly spontaneously, but mainly as a reflex response to drying of the oral and pharyngeal mucosae. A rapid increase in activity can be superimposed upon the resting level, for example during mastication, in response to the influence of autonomic secretory nerves. Controlled variation in the activity of the many different types of effector cells of the salivary glands—the serous, seromucous and mucous cells of the secretory endpieces, the myoepitheliocytes of the endpieces and intercalary ducts, the lining epithelial cells of all the ductual elements, and the nonstriated myocytes of the blood vessels—affects salivary production quantitatively and qualitatively. Variation in effector cell activity is under hormonal and nervous control.

Hormonal control

The effects of circulating hormones on the secretory activity of the salivary glands have been reviewed by Blair-West *et al.* (1967).

A

B

8.40A and B A Parotid sialogram; B Submandibular sialogram. In each case the shadow of the cannula used to introduce the radio-opaque medium into the duct of the gland is visible. See text for description.

There is no unequivocal evidence that they can evoke the secretion of saliva directly at physiological levels, although they may alter the response of the glandular cells to neural stimuli. Local hormones, however, have a profound effect on salivary gland activity; it has been shown in the cat submandibular gland, for example, that although vasodilatation is initiated by neural influences, it is maintained by the action of plasma-kinins which are formed locally when kallikrein is released from the secretory cells after stimulation by sympathetic amines (Gautvik *et al.* 1972). Vasodilatation and secretion are functionally related (Hilton and Lewis 1956).

Neural control

Most salivary glands, except those which secrete spontaneously, depend on autonomic nerves to evoke secretion, and in all the greater part of salivary flow is under nervous control. The nerves involved are cholinergic (parasympathetic) and adrenergic (sympathetic); there is no evidence for the involvement of non-cholinergic non-adrenergic nerves in salivary gland control (Garrett 1976).

The general pattern of innervation is shown in Fig. **8.39B**. It should be appreciated that there is considerable variation in different glands and in different species (Garrett 1972), and that the pattern of innervation may vary within a gland with age (Yohro 1971). Only the more constant features are illustrated and described below. The cholinergic nerves tend to accompany the ducts and form complex arborizations around the secretory endpieces. In contrast, the adrenergic nerves generally enter the glands with the arteries and are distributed with their branches. The main nerve trunks of the glands contain non-myelinated axons predominantly, although a few myelinated axons (presumed to be either those of preganglionic efferent or of afferent neurons) are present. The postganglionic efferent axons, like those of autonomic axons elsewhere (Norberg 1967), have periodic dilatations which contain mitochondria and vesicles, the latter appearing electron-lucent in cholinergic axons and electron-dense in adrenergic axons. Within the glands the nerve fibres intermingle, cholinergic and adrenergic axons commonly lying in adjacent invaginations of the same Schwann cell (Eneroth *et al.* 1969; Garrett 1972, 1976).

At *neuro-effector junctions* (**8.39B**) dilated, vesicle-containing regions of the axons and the effector cells they supply are functionally related. The axonal surface closest to the effector cell is free from Schwann cell cytoplasm. Where the effector cells are epithelial, the neuro-effector junctions may be either *epilemmal* or *hypolemmal* (Garrett 1975), terms introduced by Arnstein (1889, 1895). At epilemmal sites the free surface of the axon and the effector cell are separated by a distance of approximately 100 nm, with the basement membrane intervening. At hypolemmal sites the axon penetrates beneath the basement membrane and is separated from the effector cell by a distance of only 20 nm. A single axon may supply several effector cells directly, and many more indirectly through electrical coupling of adjacent cells (Lowenstein and Kanno 1964); group activity is thus possible. Furthermore, a single effector cell may be supplied by several axons, cholinergic and/or adrenergic. A single axon may act on several different types of effector cell; although there are separate sympathetic axons for secretion and vasoconstriction (Emmelin and Engström 1960), those causing secretion may also induce myoepitheliocyte contraction, and a single parasympathetic axon may, through sequential neuro-effector junctions of the en-passant type (p. 826), induce vasodilatation, secretory cell activity and myoepitheliocyte contraction (Emmelin 1972).

The secretory endpieces generally have the most copious innervation. Cholinergic and adrenergic axons may supply them, with individual secretory cells often having a dual innervation. It has long been accepted that the cholinergic axons are secretomotor, but it was not until 1974 that evidence was published showing unequivocally that, in the rat parotid gland at least, the sympathetic nerves were also secretomotor (Harrop and Garrett 1974; Hodgson and Spiers 1974). Adrenergically evoked saliva differs from that produced after parasympathetic stimulation both in quantity and in composition. How these differences are brought about is a matter for speculation. In heterocrine glands (p. 1276), adrenergic and cholinergic nerves could activate different types of secretory cell, but in homocrine glands (p. 1276), where all the secretory cells appear to be similar, adrenergic and cholinergic axons presumably evoke different responses from the same cells (Garrett 1972). In some situations sympathetic nerve activity may result in the secondary modification of the saliva produced in response to parasympathetic stimulation, rather than in the induction of salivary flow directly.

The ductual elements of the salivary glands can produce marked changes in the saliva (p. 1278) and, although they are less well innervated than the secretory endpieces, it appears that their activity is controlled, at least in part, by neural influences. In 1958, Lundberg showed that cells, assumed to be ductual cells, of the submaxillary gland of the cat, responded electrically to both parasympathetic and sympathetic stimulation. Cholinergic (parasympathetic) fibres lie adjacent to the striated ducts of most species, occasionally in a hypolemmal position, although this is more common in the intercalary ducts. In a number of species, including man, adrenergic nerves have also been shown to be associated with the striated ducts (Garrett 1967). The main (excretory) ducts were thought to have only cholinergic nerves associated with them but recently Schneyer (1976) has reported that sympathetic stimulation can alter electrolyte transport across the main duct epithelium in the submaxillary gland of the rat,

suggesting that here, at least, there is an adrenergic supply.

The innervation of the myoepitheliocytes which overlie the secretory endpieces and the intercalary ducts has proved difficult to resolve from a physiological standpoint. However, electron microscope observations suggest that both sympathetic and parasympathetic hypolemmal fibres may supply them (Kagayama and Nishiyama 1972). Myoepitheliocytes are stimulated to contract by adrenergic axons; they can respond to a single impulse, suggesting that they have a high sensitivity. The role of cholinergic axons is less certain, but there is experimental evidence that they also may cause contraction (Garrett 1975) and thus assist salivary discharge.

There is considerable morphological evidence that the arterioles of the salivary glands are innervated by both adrenergic and cholinergic axons (*see* Young and van Lennep 1978). The more numerous adrenergic axons are involved in maintaining a state of vasocontrictor tone. The cholinergic axons may induce vasodilatation, but this is maintained by locally-produced plasma-kinins (*vide supra*).

There is surprisingly little published information on the afferent innervation of the salivary glands. The pain associated with obstruction of the salivary ducts and even with sialography suggests that nociceptive endings are present, but these await morphological investigation. Sensory endings associated with the main ducts have been described, and presumably such endings are present elsewhere in the glands. Afferent axons are thought to be present in the main parasympathetic and sympathetic nerve trunks of the glands. It has been reported (*see* Garrett 1975) that increasing the pressure in the submandibular duct of the dog enhances afferent fibre activity in the chorda tympani; intraglandular baroceptors are presumed to be involved in this response. Detailed cytological studies of the sensory innervation of the salivary glands are clearly necessary.

Accessory glands. Besides the main salivary glands, numerous others occur in the buccal cavity. Some of these occur in the tongue (p. 1306); others lie around and in the tonsil between its crypts, and large numbers are present in the soft palate, the posterior part of the hard palate, the lips and cheeks. These glands are of the same structure as the larger salivary glands and are mainly of the mucous type (*see* also p. 1272).

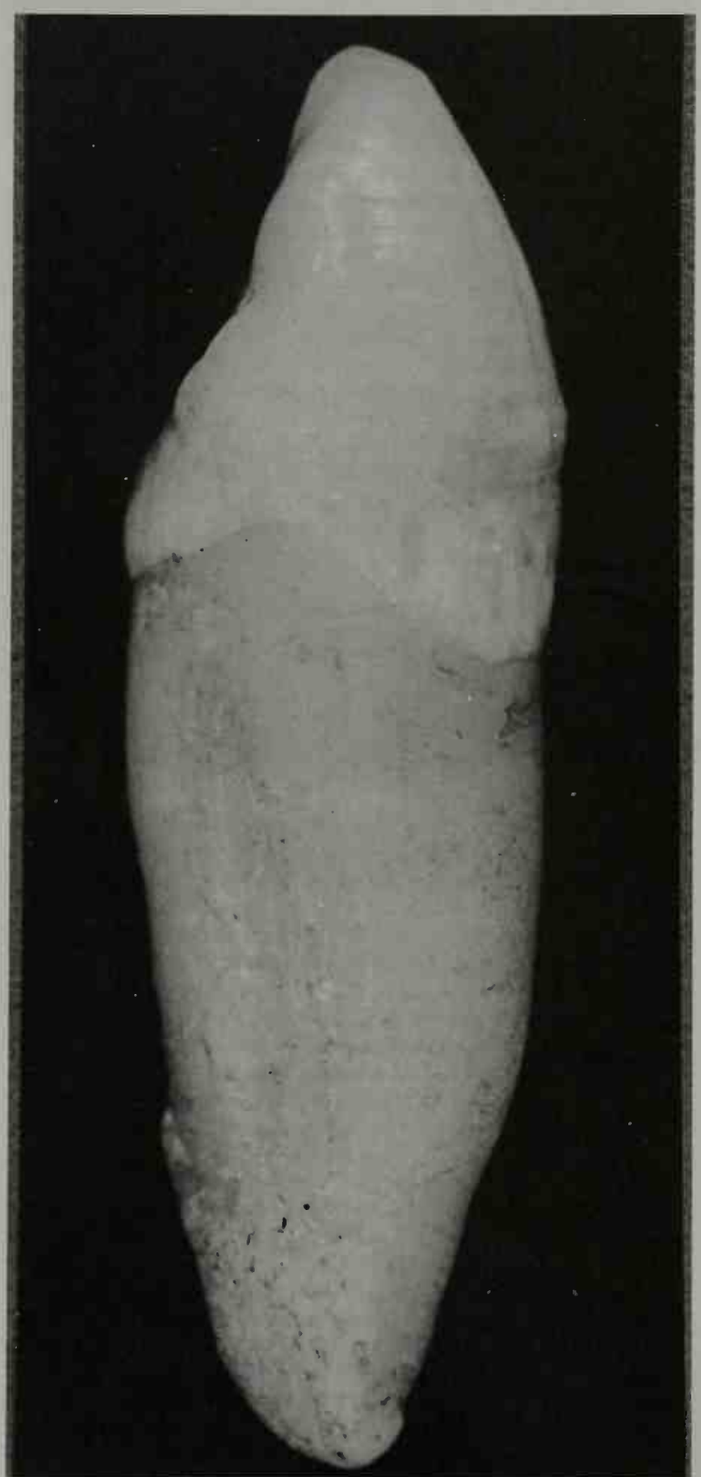
Sialography. A cannula can be introduced into the openings of the parotid and submandibular ducts and a substance opaque to X-rays (such as lipiodol) injected into the duct systems of these glands. The normal pattern and calibre of these systems, or their obliteration or dilatation by disease, can then be revealed by radiography. The *parotid duct*, as seen in sialograms (lateral view), is formed about the middle of the posterior border of the ramus of the mandible by the union of two ducts, of slightly smaller calibre, which pass upwards and downwards, respectively, to join the main parotid duct at right angles to its course (**8.**40A). As it runs across the face, the parotid duct receives from above five or six very small ductules from the accessory parotid gland, and as it bends inwards at the anterior border of the masseter, it is often compressed by that muscle so that the shadow of the lipiodol is considerably attenuated here. The intraglandular part of the main duct receives an alternating series of descending and ascending tributaries. Each of the main tributaries of the duct is formed in turn from an arborization of fine ductules, which are the terminal ducts and acini. The latter normally show no dilatation but are represented in sialograms by the tiny endings of the smallest ducts. The *duct of the submandibular gland* commences from the lowest part of the gland (below the lower border of the body of the mandible as seen in lateral views), passes vertically upwards to just above the lower border of the body of the mandible, and here turns sharply forwards and gradually ascends to its opening. The vertical part of the duct receives tributaries on both its anterior and posterior aspects and, as it turns sharply forwards, it receives a large tributary from the posterior part of the gland (**8.**40A). Each tributary is formed from an arborization of ductules (with their terminal acini) which have the same appearance as that described in the case of the parotid. Sometimes when a contrast medium for radiography, such as lipiodol, is injected into the submandibular duct, it passes also into the major sublingual duct, and the ductules of the anterior part of the sublingual gland are then revealed in the sialogram.

THE TEETH

Introduction

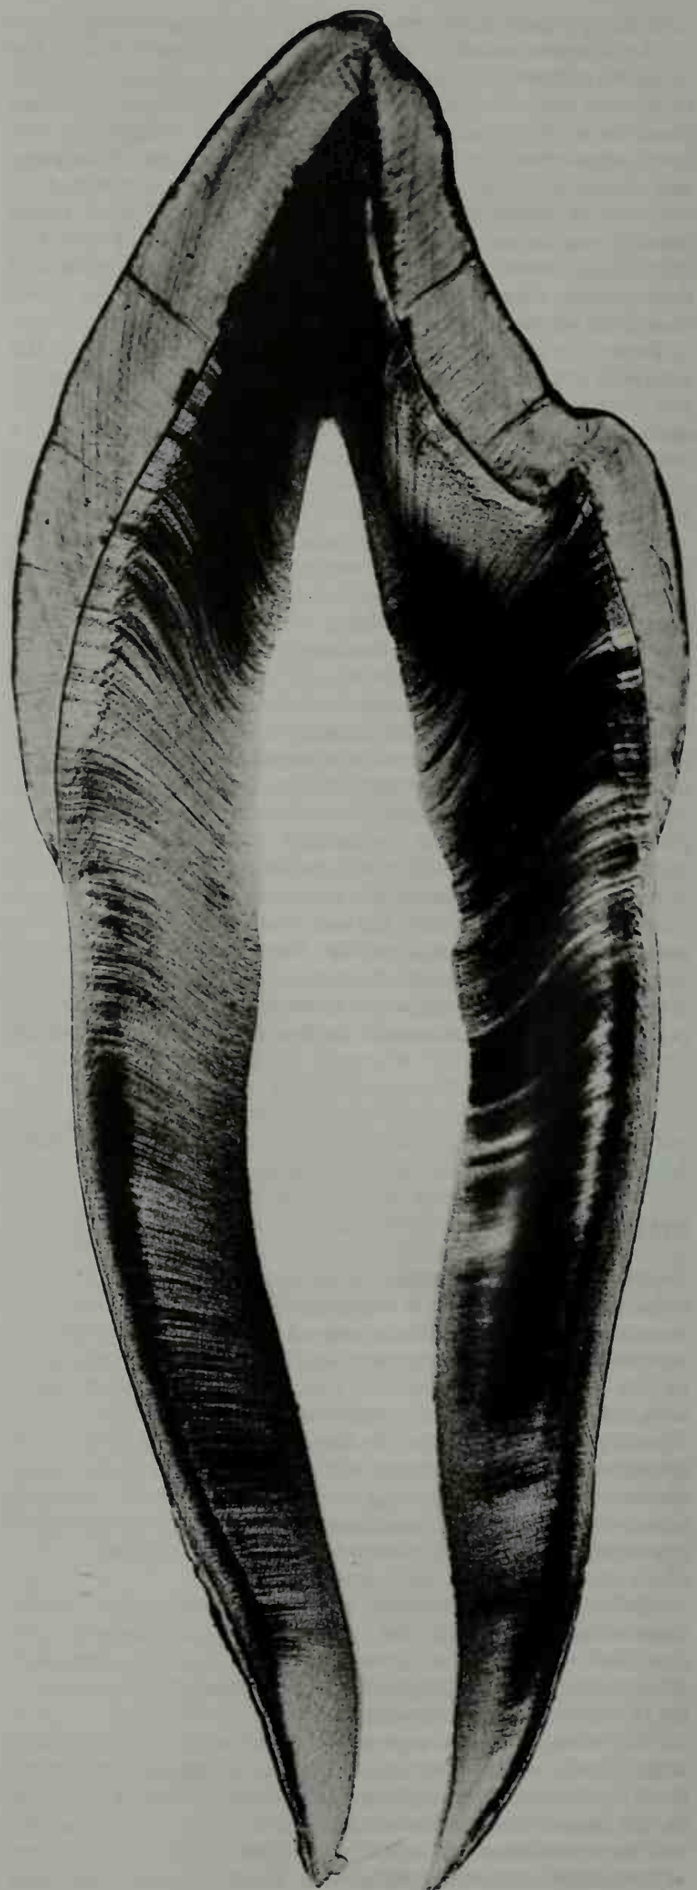
Teeth are of vital importance to nearly all animals except man. Indeed, the loss of them is incompatible with life, and in many mammals longevity is directly related to the time for which the dentition can withstand the very abrasive process of mastication. In non-mammalian vertebrates the teeth are constantly being replaced throughout life, a condition known as *polyphyodonty*. This is probably related to the fact that many such forms grow throughout life, and larger replacement teeth, more commensurate with the increasing size of the animal, are constantly required. Thus, tooth replacement may be primarily a reflexion of a growth process, and only secondarily related to the maintenance of the dentition against wear and tear.

Limitation of the number of replacement teeth is rare in non-mammalian dentitions; the condition of *diphyodonty* (two dentitions—a *deciduous*, so-called 'milk', and a *permanent* dentition) – is almost diagnostic of a mammal. Some mammals, for example the rat, are *monophyodont*.



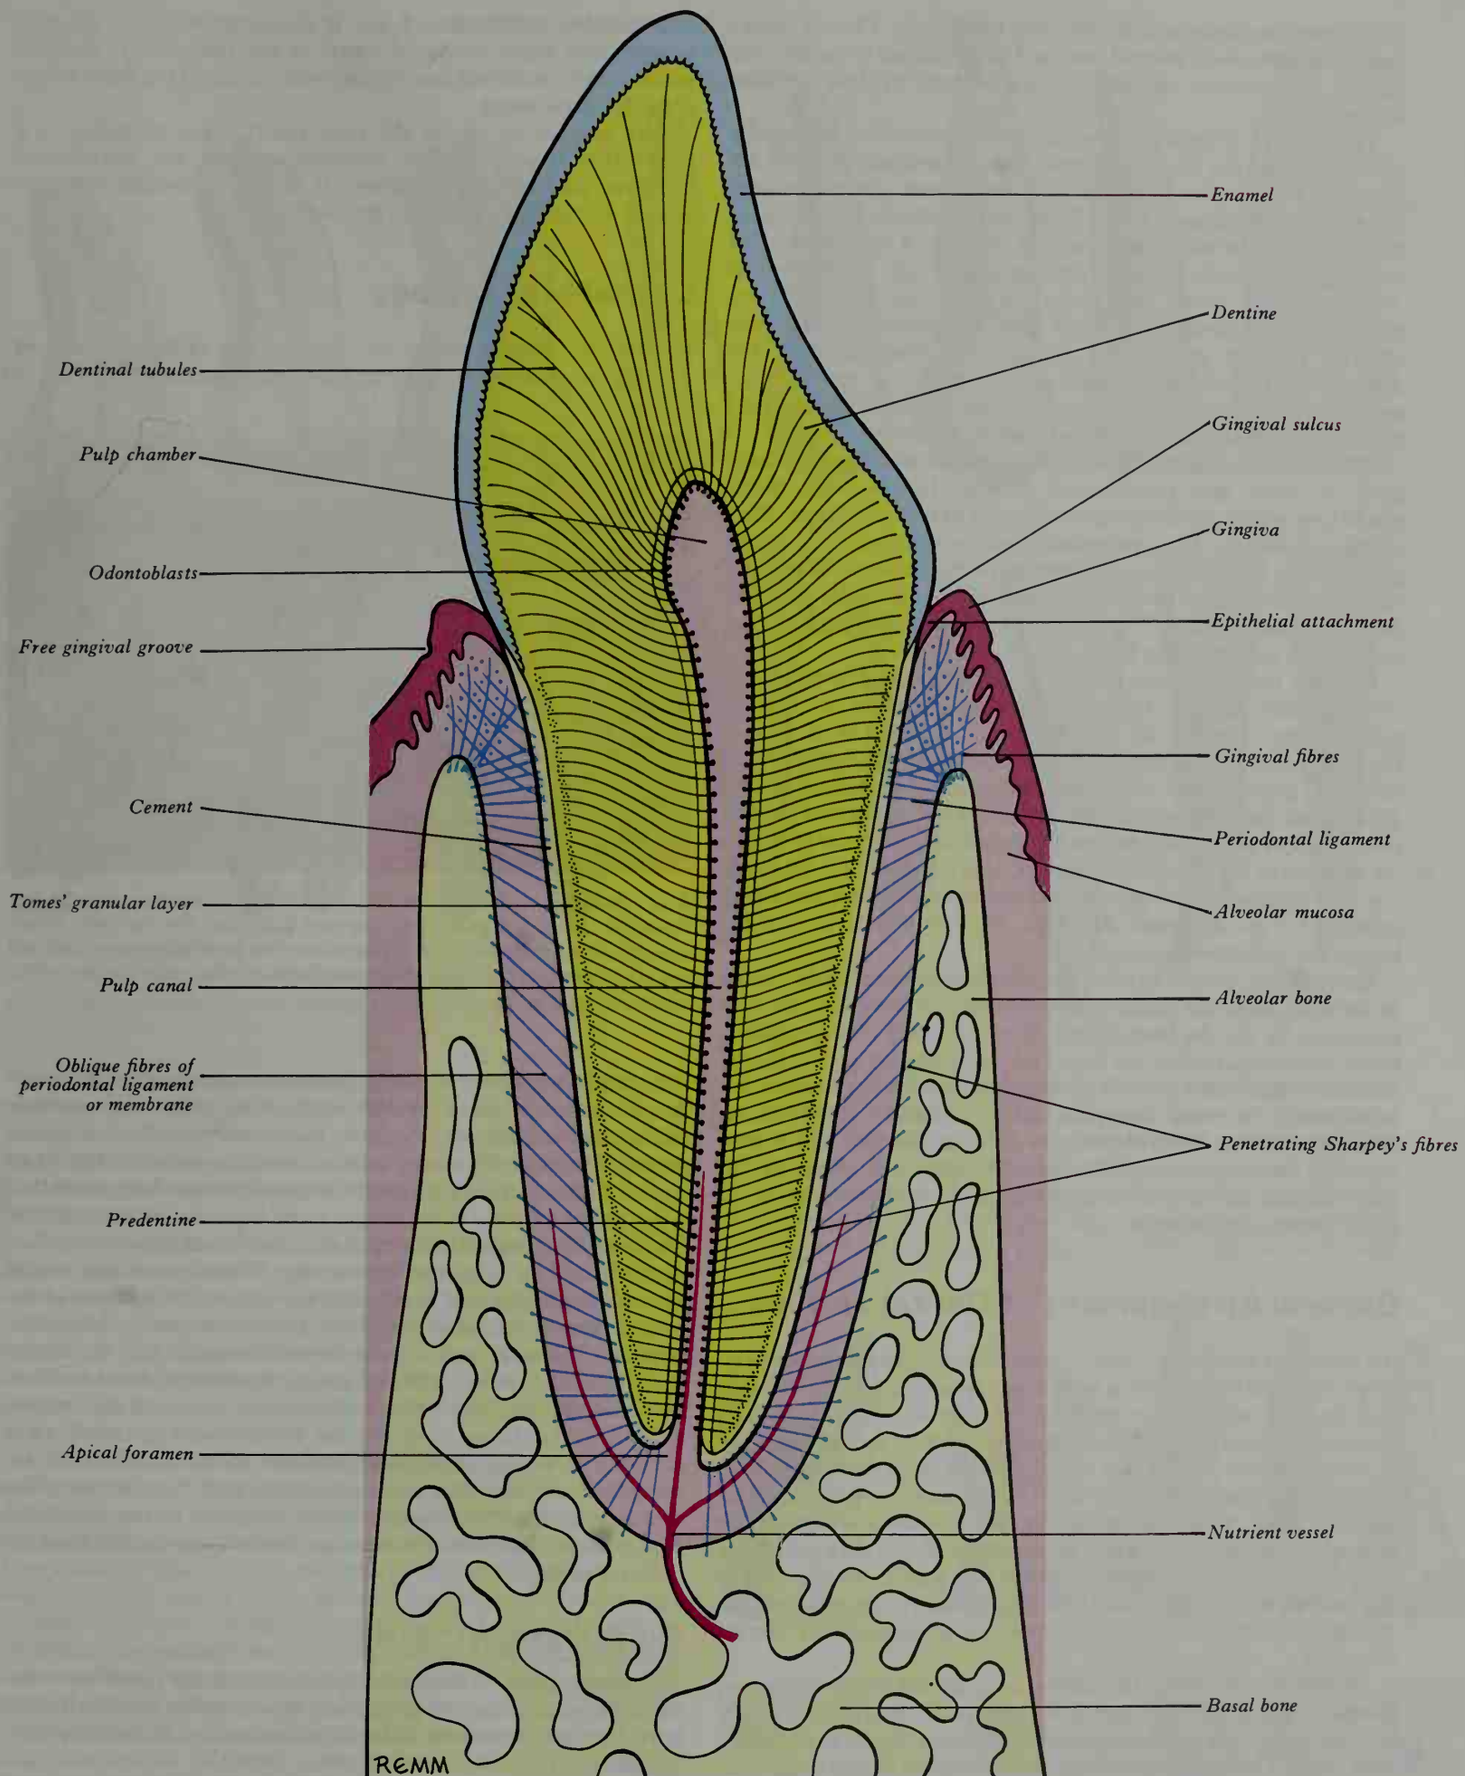
The emergence and success of diphyodonty was probably related to the evolution of the condition in which upper and lower teeth meet during mastication. In non-mammalian vertebrates the jaw joint is formed between the *quadrate bone* of the upper jaw and the *articular bone* of the lower jaw, homologous with the incus and malleus of mammals respectively. The lower teeth are set on a curve which lies so far inside the upper teeth that, together with the very restricted lateral movement which can be produced by the jaw muscles, they cannot be moved into a position where they meet the upper teeth. The phylogenetic history of mammals shows that their evolution was closely linked to a posterosuperior growth of the *dentary*, one of several lower jaw bones present in all bony non-mammalian vertebrates, towards the *squamosal bone*, which is homologous with the squamous part of most mammalian temporal bones. At the same time the jaw muscles were rearranged with the result that the mandible (dentary) could be moved more laterally and medially. Together with these trends there was a change in tooth morphology. From the simple conical teeth of their reptilian ancestors, the mammals evolved teeth with complex shearing planes. The wide lateral movements which were possible with the (new) mandible allowed the shearing edges of the lower jaw teeth to grind across those of the upper jaw teeth, with the result that the food could be more effectively comminuted.

It has been argued that in those reptiles ancestral to mammals, the articular and quadrate bones of the jaw joint conducted to the stapes of the ear sound vibrations, which were received by a tympanum which was partly attached to the *angular bone* of the lower jaw (Allin 1976). The backward growth of the dentary had the selective advantage that it reduced the mass of these post-dentary bones which vibrated with the tympanum, thereby enhancing their auditory functioning. Finally, with the evolution of the new jaw joint, the angular bone with its tympanum moved to the cranium, and became the tympanic part of the temporal bone. The quadrate and articular bones remained in contact with each other and with the stapes, and formed the incus and malleus, respectively. The three auditory ossicles then became encompassed within the definitive tympanic cavity. The evolution of the single-boned mammalian lower jaw was thus associated with an increasingly efficient auditory apparatus.



After a few months of active use the newly erupted teeth of a

mammal become precisely worn down so that the upper and lower shearing edges are neatly matched. Under such conditions the continued eruption of new teeth would constantly disrupt these matching edges, and therefore, there was selective pressure for reducing the numbers of replacement teeth. However, because there was still the necessity of accommodating teeth in the small jaws of the young, a deciduous dentition was, and is, nearly always maintained in mammals. Thus the deciduous molars, situated in a position of maximum mechanical advantage close to the muscles of mastication, have a shape like that of the permanent molars which at a later age erupt into the mechanically equivalent posterior position in the older, longer jaws.



With the reduction of the number of replacement teeth, tissues

8.41 An extracted upper right canine tooth viewed from its mesial aspect. Note the root covered by cement, and the shiny enamel-covered crown. The sinuous cervical margin projects towards the cusp of the tooth both mesially and distally.

8.42 A bucco-lingual longitudinal ground section of a young lower first premolar tooth, photographed with transmitted light. Note the large buccal and small lingual cusps; the enamel tapers to a knife-edge at the cervical margin. The coarse dark lines perpendicular to the enamel surface are cracks produced during grinding; the fine lines parallel to the

cracks indicate the long axes of the enamel prisms; the oblique lines which curve towards the apex of the cusp are the striae of Retzius (the incremental lines of enamel—compare with **8**.55). The primary (S-shaped) curvatures of the coronal dentinal tubules become less pronounced in the root. A thin layer of cement covers the dentine. The apical foramen is wide open and the pulp cavity is large, in this young tooth.

8.43 (above) Diagram of a longitudinal section of a similar tooth *in situ* and of its environs.

evolved which minimized the effects of tooth wear. Thus, a harder and thicker *prismatic enamel* emerged in mammals to replace the thinner *non-prismatic enamel* covering the teeth of their reptilian ancestors.

The teeth of all reptiles, apart from the crocodiles, are rigidly anchored to the jaw bone by cement, but in mammals the teeth are suspended in sockets by a relatively soft tissue, the *periodontal ligament* or membrane. This allows slight individual movement impossible in the ankylosed teeth of reptiles. The independent suspension permits slight movements of the teeth which compensate for wear, and permit a tooth to be moved by masticatory or other forces into what is presumably its most effective position in the jaw. Appropriate innervation of the deformable periodontal tissues also provides a much more comprehensive flow of proprioceptive data to the nervous centres concerned with the control of masticatory patterns.

With the manufacture of refined carbohydrates, man became prey to caries and periodontal disease. In the wild, these conditions would probably have led to the extinction of any other species. However, by appropriately preparing and, in a sense, predigesting his food, man can overcome the problem of passing suitably comminuted food to the action of the catabolic enzymes of the alimentary canal. The teeth are therefore no longer of vital importance in sustaining life.

It seems probable that, provided civilization continues, there will be only limited selective pressures leading to further evolutionary changes in the dentition of man as a whole. However, there are several variations between the dentitions of different populations. Amongst these are the shovel-shaped incisors of the Mongoloid races, and racial variations in the percentage of upper first molars having an accessory cusp, and in the absence of the lower third molars. It is possible that the latter is a relic of an ancestral population which at one time was being selected for its shortened dentition, but for which there is no longer any selective pressure.

Because they are the hardest and chemically most stable tissues in the body, teeth are selectively preserved and fossilized, thereby providing by far the best record of evolutionary change. Thus, many evolutionary data are based on the evidence of dentitions. Because of this, teeth provide excellent models for the study of the relationship between ontogeny and phylogeny. Further, in modern societies, the durability of teeth in the face of fire and bacterial decomposition often makes them invaluable in the identification of otherwise unrecognizable bodies—a point of great forensic importance.

General Arrangement of Dental Tissues

An extracted tooth (**8**.41) can be seen to consist of two parts—the *crown* which is covered by a very hard translucent tissue, *enamel*, and the root which is covered by a yellowish bone-like tissue, *cement*. The root meets the crown at the neck or *cervical margin*.

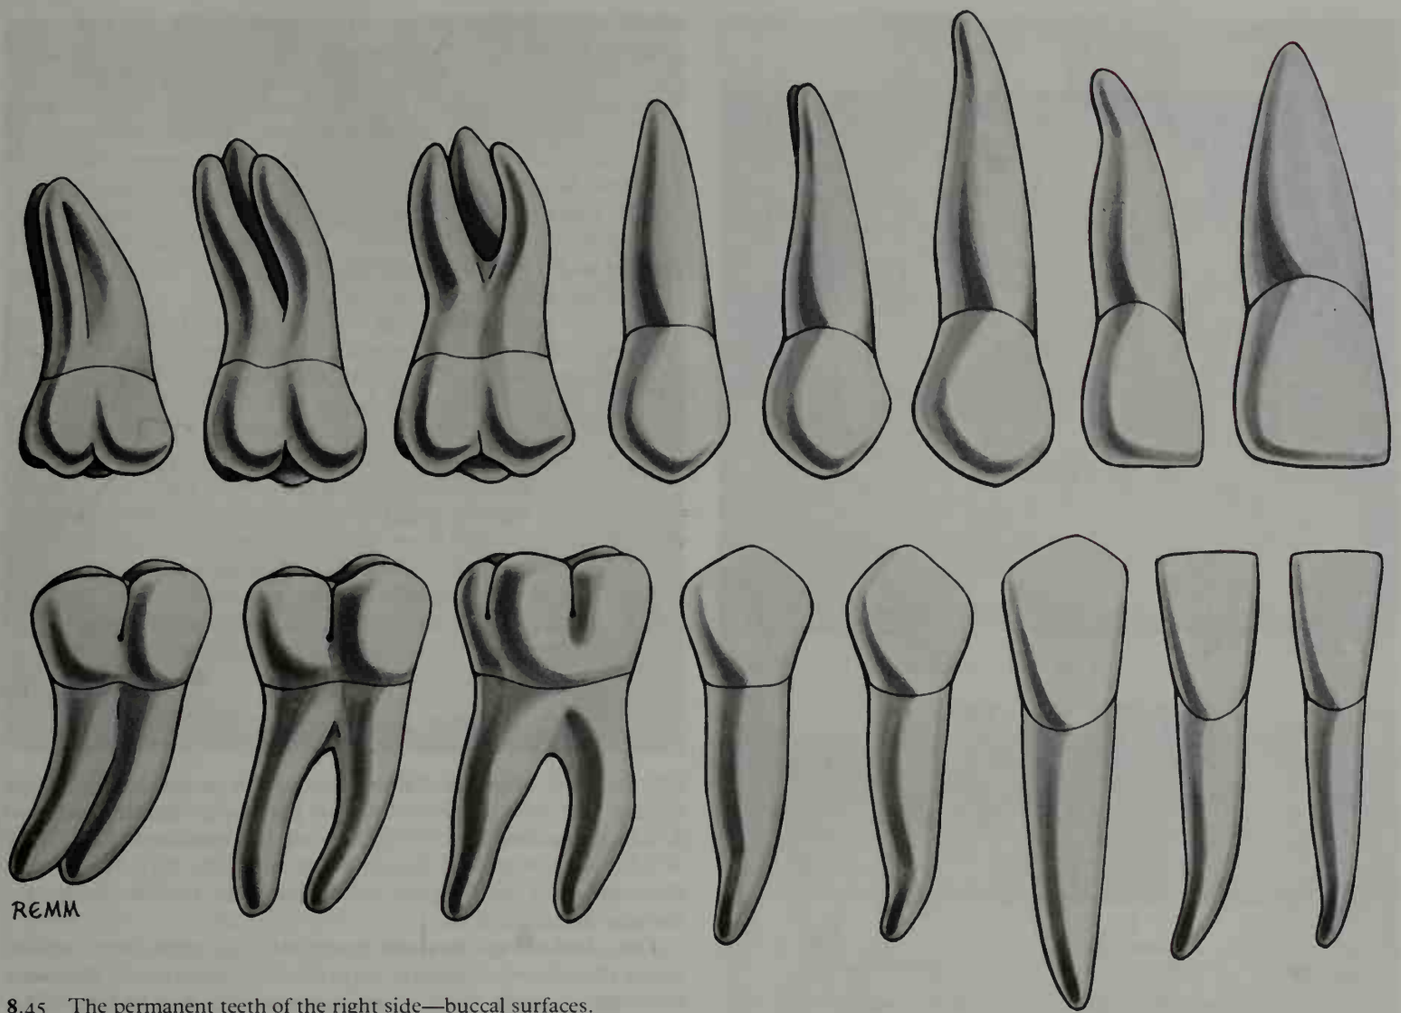
A longitudinal section of a tooth (**8**.42) reveals that the bulk is composed of *dentine* (ivory) and that the enamel covering is about 1·5 mm thick, while the cement covering is usually very much thinner. The dentine contains a central canal, the *pulp cavity*. At its coronal end the cavity is expanded into a *pulp chamber* and in the root region it is narrowed into a *pulp canal* opening at or near the tip of the root into an *apical foramen*, or occasionally several foramina.

During life the root of the tooth is surrounded by alveolar bone; however, the cement of the root is separated from the bony socket by soft tissue, the *periodontal ligament* (**8**.43) which is about 0·2 mm wide. Thick collagen fibres are embedded at one end in the cement and cross in the periodontal ligament to enter into the wall of the bony socket at their other ends. In most non-mammalian vertebrates the teeth are rigidly cemented directly to the bone providing a rather brittle attachment. Only in mammals (and crocodiles) is there a periodontal ligament which provides an independent and tough suspension for each tooth. Towards the cervical margin (the neck of the tooth), the periodontal ligament is covered by the *gingiva* (or gum) (**8**.43). This covering tissue can be clearly recognized in the healthy mouth because of its pale pink and stippled appearance (**8**.44): it is continuous with the red, smooth and shiny lining of much of the oral cavity, the *oral mucosa*, and is attached near the cervical margin of the tooth by the *epithelial attachment*.

The *pulp*, from which the pulp cavity takes its name, is a connective tissue, directly continuous with the periodontal ligament via the apical foramen. It carries a vascular nutritive supply and sensory nerves to the dentine.

Dental Morphology

Because the dental arches are curved, the ordinary terms of descriptive anatomy such as anterior and posterior, if applied to the teeth, would be confusing. Dental anatomists, therefore, use special terms to describe the surfaces of teeth. The surface adjacent to the lips or cheeks is known as the *labial* or *buccal* surface. (Because the dental arch is curved the labial surface of an incisor faces anteriorly while that of a cheek tooth faces laterally.) The surface adjacent to the tongue is the *lingual* or *palatal* surface. The labial and lingual surfaces of an incisor meet its *mesial* surface medially and its *distal* surface laterally. These two terms, mesial and distal, are retained to describe the equivalent surfaces of the premolar and molar—'cheek' or *postcanine* teeth. However, because the dental arch is curved it will be noted that the mesial surfaces of the cheek teeth face anteriorly and the distal surfaces face posteriorly. Thus, the median point between the central incisors is the datum point for the terms *mesial* (proximal) and *distal*. The biting, or *occlusal*, surfaces of the cheek teeth are composed of tubercles, or *cusps*, separated by fissures. The occlusal pattern of each tooth is characteristic of its position in the dental arch. The incisors have an *incisal edge* rather than an occlusal surface.



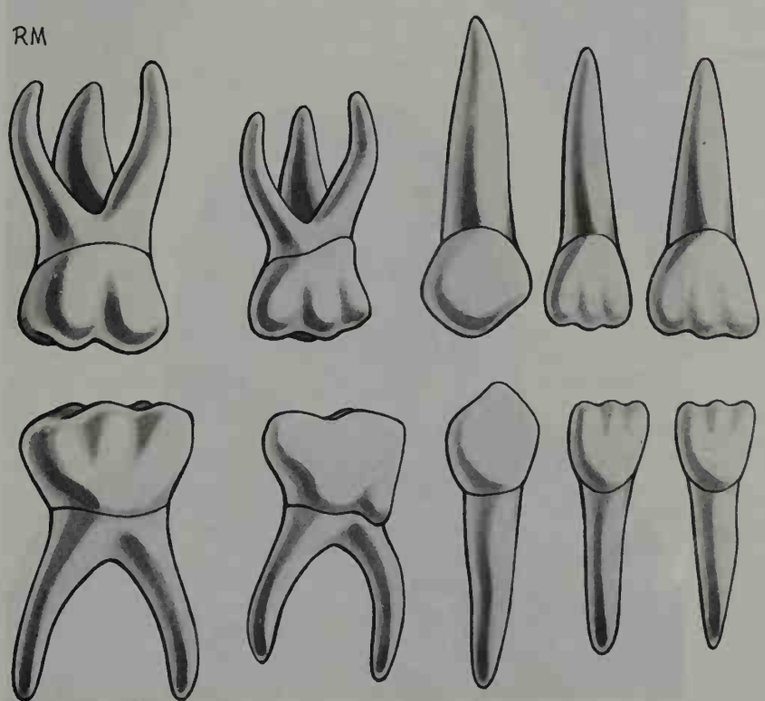
8.44 Anterior view of the dentition in centric occlusion, with the lips retracted. Note the pale pink, stippled gingivae, and the red, shiny, smooth alveolar mucosa. The degree of overbite is rather pronounced, and the gingiva and its epithelial attachment have receded on to the root of the upper left canine.

THE PERMANENT TEETH

The names given to the teeth of all mammals are based on either the appearance, function or position of equivalent teeth in human jaws: they are the *incisors*, *canines*, *premolars* and *molars* (**8**.45, 46, 47, 48).

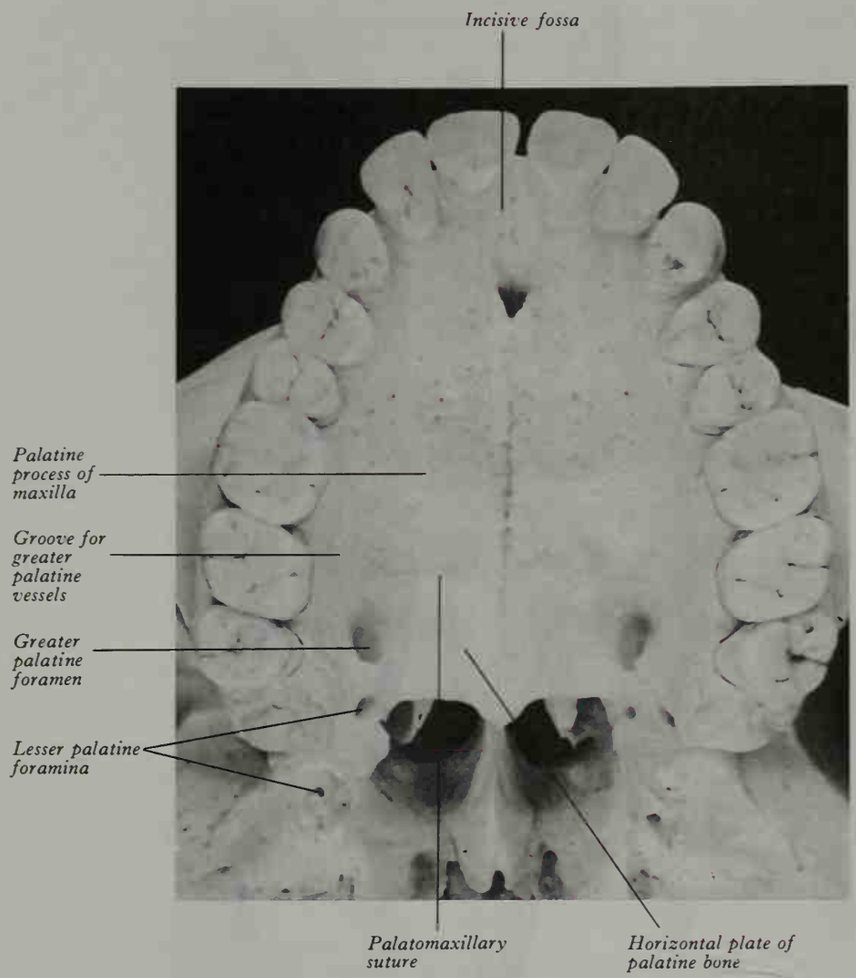
The incisor teeth are so named in man because they are used to incise food. The biting or incisal edges originally have three small cusps but these are rapidly smoothed by wear. There are two incisors in each jaw quadrant, a central and a lateral incisor. In buccal view the crowns are roughly trapezoid, the maxillary, particularly the central incisor, being considerably larger than the mandibular. In mesial or distal view, the labial profiles are convex; the lingual surfaces are concavo-convex (ogival) (**8**.43), the convexity towards the cervical margin being provided by

8.45 The permanent teeth of the right side—buccal surfaces.



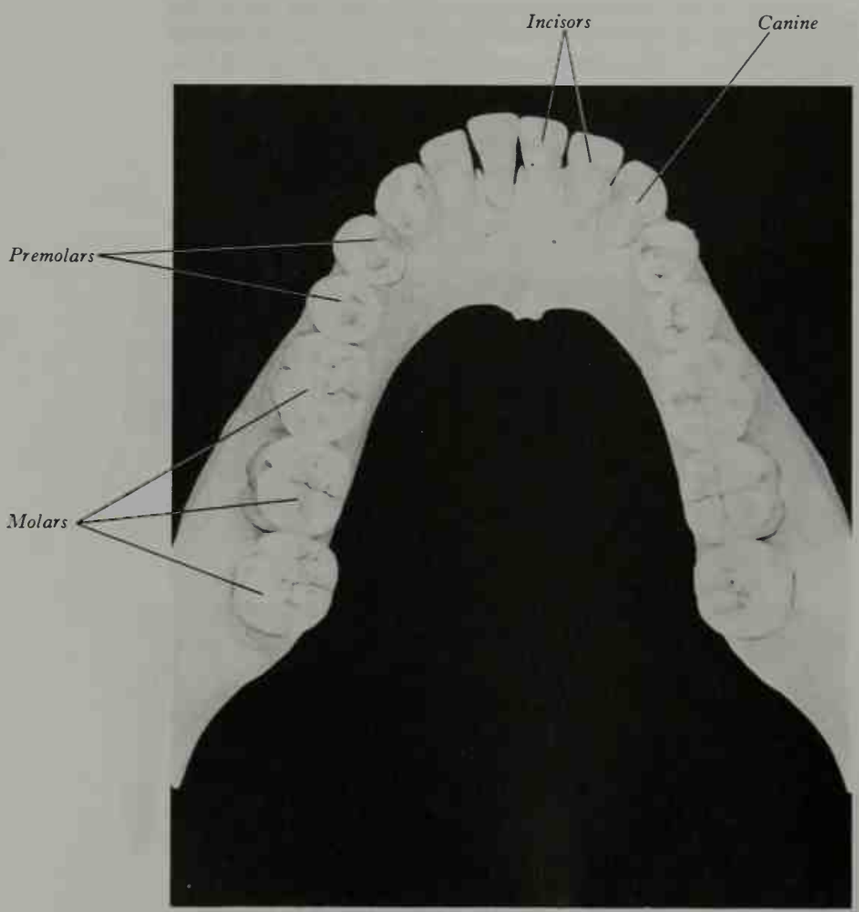
a low horizontal *ridge* or *cingulum*, which is prominent only on the upper incisors. The roots of the maxillary incisors are rounded while those of the mandibular are flattened mesio-distally. The maxillary lateral incisor may be congenitally absent in about 2 per cent of the population (Brothwell *et al.* 1963), alternatively it may be peg-shaped.

Distal to each lateral incisor is a **canine tooth**, which is rather larger, and each has a single cusp (hence the American term *cuspid*), instead of an incisal edge. Apart from this they are not unlike the incisors, particularly when, in old age, their cusps have been worn flat. The canine roots are the longest in the jaws, and each bulges the associated bone externally, and this can be readily palpated on the face. Occasionally the lower canine may have two roots (Kraus *et al.* 1969).



Distal to each canine are two **premolars**, each with a buccal and a palatal cusp (**8**.42) enclosing an occlusal surface (hence the American term *bicuspid*). The second premolars may be congenitally absent in about 2 per cent of individuals (Garn and Lewis 1962). The occlusal surfaces of the upper premolars are oval (the long axis is bucco-palatal), and a mesiodistal fissure separates the buccal from the palatal cusp. In buccal view the premolars have a shape similar to that of the canine, but they are a little smaller. The *upper first premolar* generally has two roots, one buccal and the other palatal, but may have one root and very occasionally three roots (two buccal and one palatal), the condition in apes. The *upper second premolar* generally has one but may have two roots (one buccal and one palatal).

The occlusal surfaces of the lower premolars are more nearly circular or square than those of the uppers. The buccal cusp of the *lower first premolar* towers over the lingual cusp, to which it is connected by a ridge; the latter separates mesial and distal occlusal pits. In the *lower second premolar* a mesio-distal fissure usually separates the buccal cusp from two poorly separated lingual cusps. Both lower premolars have one root, but very occasionally the root of the first premolar is bifid.



Posterior to each second premolar are three **molars** whose size progressively decreases posteriorly; each has a large rhomboid (upper jaw) or rectangular (lower jaw) occlusal surface, with four or five cusps. The *upper first molar* carries a cusp at each corner of its occlusal surface, the mesio-palatal cusp being joined to the disto-buccal cusp by an *oblique ridge*—a primitive feature which man shares with many lower primates. A fifth cusp may be present

8.46 The deciduous teeth of the right side—buccal surfaces.

8.47 The permanent teeth of the upper dental arch—inferior aspect.

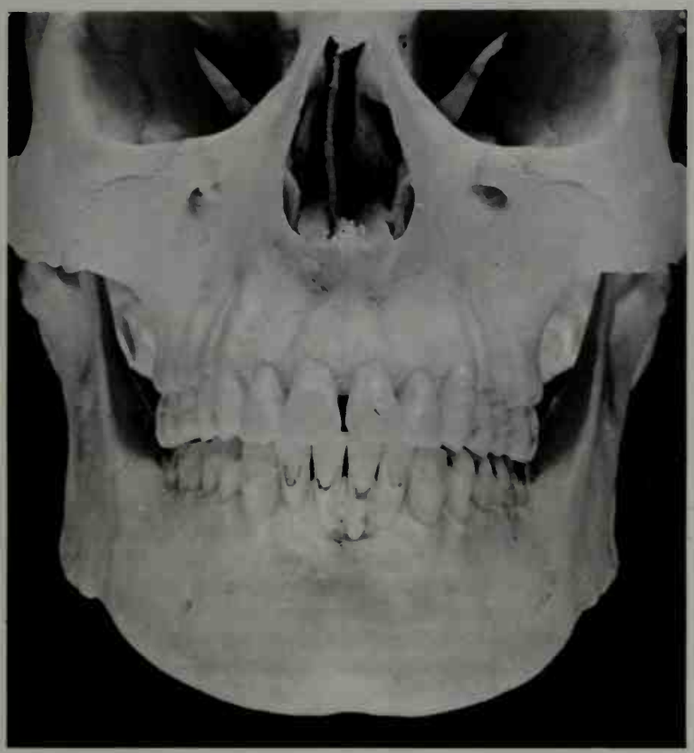
8.48 The permanent teeth of the lower dental arch—superior aspect.

on the mesio-palatal surface—the *cusp of Carabelli*. It is most commonly present in Caucasoid races (Kraus 1959, Alvesalo *et al.* 1975). The tooth has three widely separated roots, two labial and one palatal. The *upper second molar*, smaller than the first, may have a disto-palatal cusp which is reduced or occasionally absent, and its roots are less divergent; often two roots may be fused together. The *upper third molar* is smaller still, usually bears only three cusps (the disto-palatal being absent), and commonly has only one root. However, its structure is very variable and it is congenitally absent in up to 25 per cent of some populations (Brothwell *et al.* 1963).

The *lower first molar* carries three buccal and two lingual cusps on its rectangular occlusal surface, the smallest cusp being disto-buccal in position. The cusps are all separated by fissures. It has two widely separated roots, mesial and distal. The *lower second molar* is like the first, except that it very rarely has a disto-buccal cusp, and its roots are closer together. The *lower third molar* is smaller still, and often has only one root. However, like the upper third molar its shape is variable and occasionally it may have four or even five very small roots. Because it erupts anterosuperiorly, the *lower* third molar is often impacted against the second; in contrast the *upper* third molar erupts posteroinferiorly and so is rarely impacted. Varying with the population concerned, it is absent in from 0·2 to 25 per cent of individuals (Brothwell *et al.* 1963).

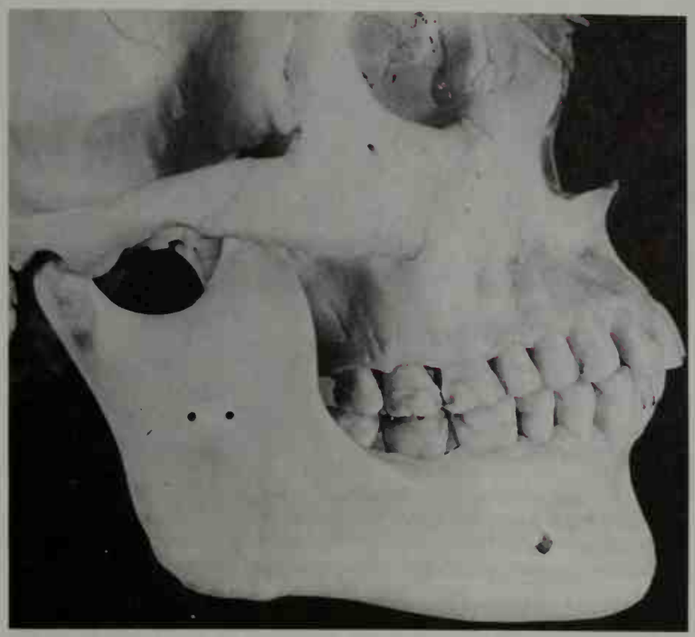
THE DECIDUOUS TEETH

The incisors, canine and premolars of the permanent dentition replace two deciduous incisors, a deciduous canine, and two deciduous molars respectively, in each jaw quadrant (**8**.46). The deciduous incisors and canine are shaped like their successors. However, they are smaller and whiter, and become extremely worn in the older child.



The deciduous molars resemble the permanent molars rather than their successors, the premolars. Each *second deciduous molar* has a crown form which is almost identical to that of the posteriorly adjacent first permanent molar. However, the *first upper deciduous molar* has a somewhat triangular occlusal surface (the very rounded 'apex' being lingual), and a fissure separates a double buccal cusp from the palatal cusp. The *lower first deciduous molar* is long and narrow with a central mesio-distal fissure separating long, serrated, buccal and lingual cusps.

Like the permanent molars, the upper deciduous molars have three roots, and the lowers have two roots. However, the roots are more divergent than those of the permanent teeth, each developing premolar being temporarily accommodated directly beneath the crown of its deciduous predecessor.



The roots of the deciduous teeth are progressively resorbed by osteoclasts prior to their being replaced by the permanent teeth. Thus, an extracted deciduous tooth may have very short roots.

DENTAL OCCLUSION

It is possible to bring the jaws together so that the cheek teeth meet, or *occlude*, in innumerable ways (Kraus *et al.* 1969). When the opposing occlusal surfaces meet in such a position that there is maximum '*intercuspation*' (i.e. maximum contact between the teeth of opposing arches), the teeth are said to be in *centric occlusion* (**8**.49, 50). In this position the lower teeth normally lie symmetrically just lingual to the upper teeth. The following are a few important features of centric occlusion in a normal dentition. Each lower cheek tooth is slightly in front of the equivalent upper cheek tooth. In the same way the lower canine is in front of the upper canine. The buccal (lateral) cusps of the lower cheek teeth lie between the buccal and palatal cusps of the upper cheek teeth. Thus the lower cheek teeth are slightly lingual and mesial to the equivalent upper teeth. At the front of the jaw the lower incisors bite against the lingual surfaces of the upper incisors, the latter normally obscuring about one-third of the crown length of the lower incisors. The amount by which the upper incisors cover the lower incisors in centric occlusion is called the amount of *overbite*. The extent to which the upper incisors lie anterior to the lower incisors is the extent of *overjet*.

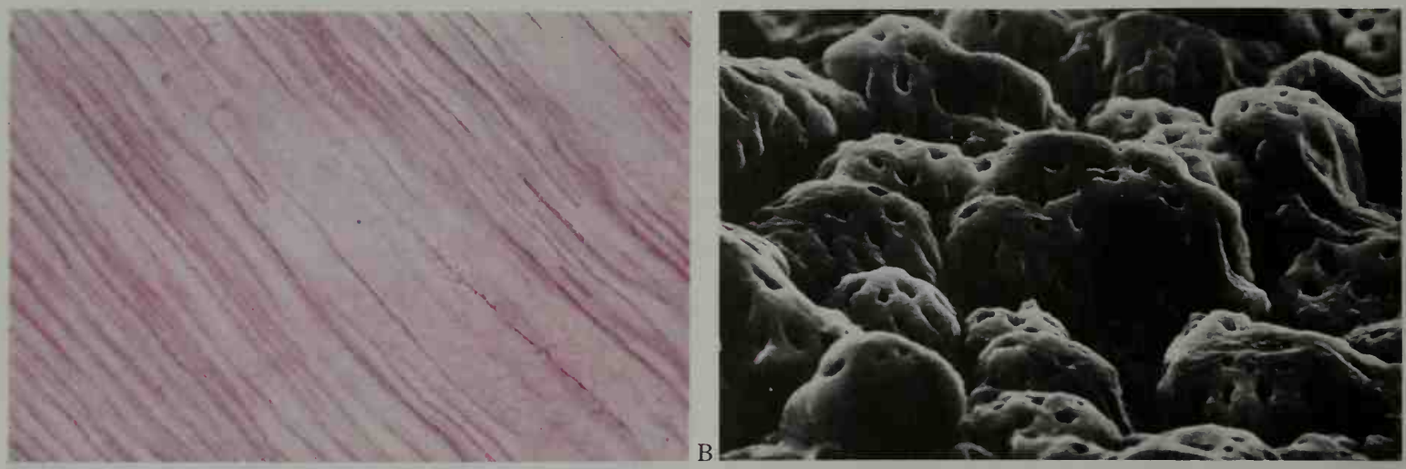
8.49 Anterior view of the dentition in centric occlusion. There has been some resorption of bone around the lower incisors.

8.50 Lateral view of the dentition in centric occlusion.

8.51 A vertical section through the right half of the body of the mandible and its dentition. Note: (1) the pulp cavities in the molar teeth; (2) the flat table of bone surmounting the interdental bony septa; (3) the cancellous nature of much of the bone; (4) the cortical plate of compact bone lining the sockets of the teeth (the lamina dura of radiographs—see **8**.71, 72); (5) the compact bone forming the base of the mandible; (6) the inferior dental canal which, in this specimen, is widely separated from the roots of the teeth.

In the most habitual jaw posture, the teeth are normally held slightly apart from that of centric occlusion. The resulting space between the teeth is called the *freeway space* or *interocclusal clearance*.

Each dental arch approximates to a *catenary shape* (i.e. the form assumed by a dependent chain attached at its two extremities)—*see* MacConaill and Scher (1949)—the lower arch being slightly narrower than the upper (**8**.47, 48). When viewed from the side, a line joining the buccal cusps of the lower (or upper) cheek teeth is curved (the *curve of Spee*), the concavity being upwards (Kraus *et al.* 1969). The lower cheek teeth are tilted slightly lingually, so that a line joining the buccal and lingual cusps of the lower left and right first molars (for instance) is curved (*curve of Monson*) with its concavity upwards. The upper cheek teeth have an equivalent tilt outwards. The tilt of each tooth represents to some extent the direction in which the tooth originally erupted. The above curves are of importance in the construction of dentures.



DENTAL BLOOD AND LYMPHATIC VESSELS

The *inferior alveolar artery* is a branch of the maxillary artery. It enters the mandibular foramen and then passes anteriorly in its bony canal, to divide into its *incisive* and *mental* branches, for the supply of the lower teeth, their supporting structures and the body of the mandible, including its cortical bone (Saunders and Röckert 1967). About eight to twelve main channels and a variable number of finer channels supply the alveolar bone together with the teeth (Castelli 1963). There appear to be very few anastomotic channels across the symphyseal region (Howkins 1935). Veins from the alveolar bone and teeth collect either into large veins in the interdental septa or into networks of veins which surround the apex of each tooth, and from thence pass into one of several *inferior alveolar veins*. Some of these drain anteriorly through the mental foramen to join the facial vein, others pass back through the inferior dental foramen to join the pterygoid plexus of veins (Cohen 1959).

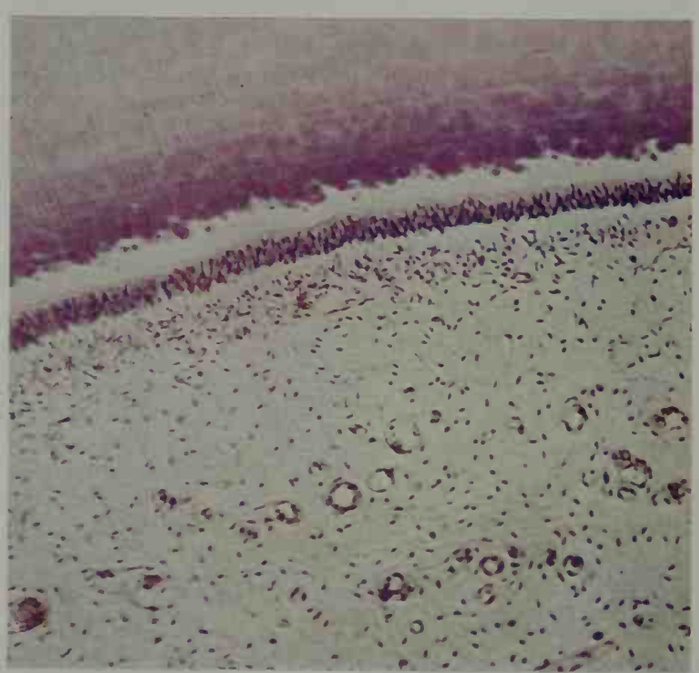
The upper jaw is supplied by the *anterior* and *posterior superior alveolar arteries*. The latter branches, from the maxillary artery, course tortuously over the maxillary tuberosity dividing into small stems which supply the alveolar bone, mucosa and teeth of the molar region, together with the adjacent buccal mucosa, where there is an anastomosis with penetrating branches of the facial artery. Other branches supply the lateral wall of the maxillary sinus. The *anterior superior alveolar artery* is a branch of the infraorbital artery. It takes a curving course through the *canalis sinuosus* (Jones 1939). The canal passes laterally from the infraorbital canal and then downwards and medially below it within the wall of the maxillary sinus. It now follows the curve of the margin of the nasal cavity between the sockets of the canine and incisor teeth and the nasal cavity, to end beside the nasal septum where its terminal branch emerges. The canal may be up to 55 mm long. Occasionally there is a small *middle superior alveolar artery* which forms anastomotic arcades with the anterior and posterior superior dental arteries.

On the palatal side of the upper teeth, the *greater palatine artery* gives branches to the palatal gingivae. Unlike the nasopalatine nerves, the nasopalatine artery does not extend through the incisive canal into the palate.

The veins accompanying the superior alveolar arteries either drain anteriorly to join the facial vein, or posteriorly to the pterygoid venous plexus.

(Kindly provided by Dr. D. Whittaker, The Dental School, University of Wales, Cardiff.)

The periodontal ligaments are supplied by the *dental branches* of the alveolar arteries (Melcher and Bowen 1969). One branch enters the periodontium apically and gives off smaller branches, two or three of which pass into the pulp of the tooth, through the apical foramen, and others which ascend the periodontal ligament. *Interdental arteries* ascend in the interdental septum, ultimately supplying the epithelial attachment and the gingiva. The interdental arteries also give branches which pass at right angles through the bone forming the tooth socket and into the periodontal ligament. Thus, the latter receives its arterial supply from three sets of arteries: one enters from the apical region, a second from the ascending interdental arteries, and a third descending from the crest of the interdental septum. These sets anastomose with each other.



Veins drain the periodontal ligament either into the *interdental veins* or into a *periapical plexus of veins*. It seems probable that the longer vessels seen in the periodontal ligament are veins rather than the anastomosing arteries (Folke and Stallard 1967).

There is little precise knowledge of the lymphatic drainage of the jaws and teeth of man (Saunders and Röckert 1967). Injection techniques applied to the monkey (MacGregor 1936) have shown that the upper jaw drains mainly towards the submandibular lymph nodes and thence to the supraclavicular nodes. The lower jaw drains mainly towards the submental group and thence to the paratracheal nodes.

Because many dental abscesses in man lead to enlargement of the submandibular and upper deep cervical lymph nodes, this must be considered the common path for lymphatic drainage of both upper and lower teeth. Occasionally there is a buccal lymph node within the cheek and this may be enlarged following infection of the upper cheek teeth. The lower incisors drain to the submental nodes and thence either posteriorly to the submandibular or postero-inferiorly to the lower deep cervical nodes. It is presumed that the alveolar bone, periodontal ligament or membrane, and gingivae share the same lymphatics as the teeth.

DENTAL INNERVATION

The upper teeth are supplied by the *anterior* and *posterior superior alveolar nerves* together with an inconstant *middle superior*

8.53 A transverse section of a demineralized tooth showing pulp below, followed sequentially above by: (1) the layer of odontoblasts, whose stained nuclei show as a purple line; (2) the pale predentine, which adjoins (3) the darkly stained calcospherites which border the dentine at the top of the field.

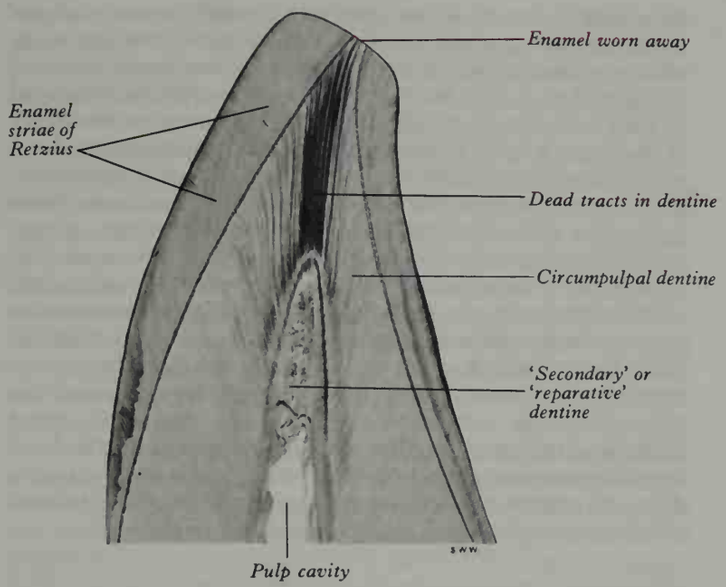
alveolar nerve (Fitzgerald and Scott 1958). The teeth are supplied by a plexus which extends from the posterior to the anterior wall of the maxillary antrum, lying partly on the posterior surface of the maxilla and partly in bony canals in the lateral and anterior surfaces of the bone. The *buccal nerve* provides a variable contribution to the buccal molar gingivae, and the *greater palatine* and *nasopalatine* nerves pass to the palatal gingivae, communicating in the region of the canine tooth.

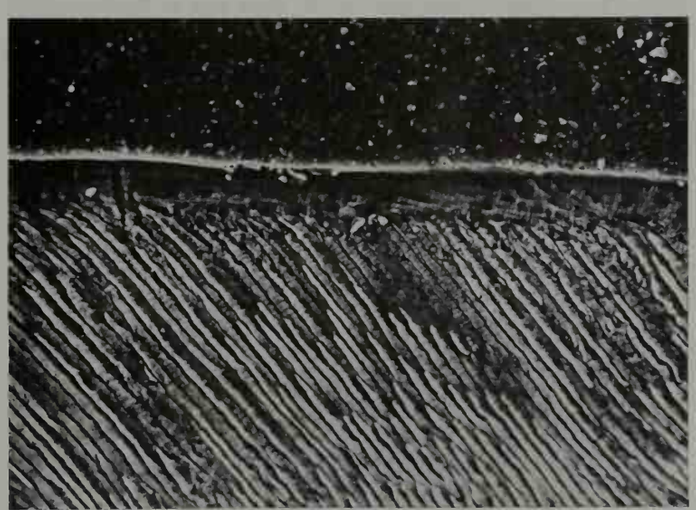


The posterior superior alveolar nerves consist of two or three trunks which arise from the postorbital section of the maxillary trunk. They divide to form a leash of up to eight elements which are invested by the dense periosteum covering the posterior surface of the maxilla. These nerves enter several posterior dental foramina, postero-inferior to the commencement of the infra-orbital groove. The higher branches descend outside the mucous membrane of the antrum to meet the lower branches as they pass forwards above the molar teeth. The variable middle superior alveolar nerve may arise at any point from the infraorbital extension of the maxillary nerve; the anterior superior alveolar nerve runs in the *canalis sinuosus* already described (p. 1287). The bony canals which contain the superior alveolar nerves also contain the corresponding arteries, and it is appropriate therefore to refer to *superior alveolar neurovascular bundles*.

The lower jaw and alveolar bone are largely supplied by branches of the *inferior alveolar nerve* together with branches of the *buccal nerve* to the buccal gingiva of the molar and premolar teeth, and branches of the *lingual nerve* to the lingual gingiva of all the lower teeth. All, of course, are derived from the mandibular division of the trigeminal nerve.

In its simplest and most common form (six out of eight mandibles studied—*see* Carter and Keen 1971) the inferior alveolar nerve is a large trunk travelling through a well-defined osseous mandibular canal close to the roots of the teeth, and giving discrete branches to the teeth and interdental septa. In the region between the premolar teeth, the mental nerve, often multiple, exits via the mental foramen. A small intra-osseous *incisive nerve* continues to supply the first premolar, canine and incisor teeth. From the mental nerve bundle, branches pass anteriorly to form an *incisor plexus* buccal to the teeth. This probably supplies the buccal periodontium and gingiva of these teeth. From the incisor plexus, thick branches curve inferiorly and then lingually to open on to the lingual surface of the mandible opposite the premolar teeth, where they probably communicate with the mylohyoid nerve.

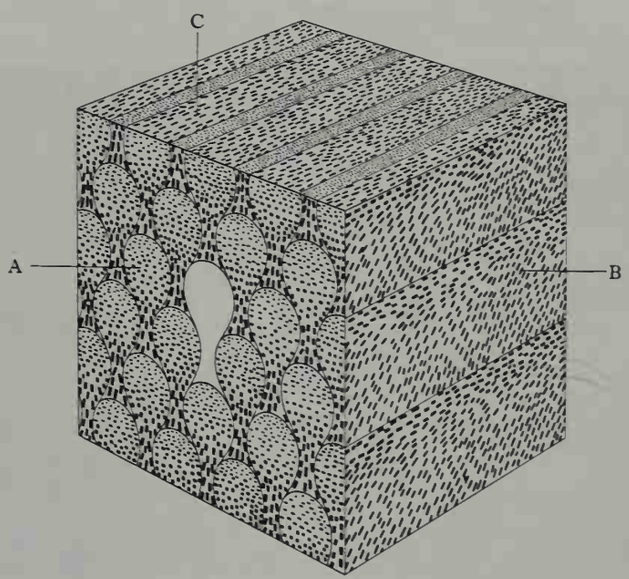
Less commonly (two out of eight mandibles studied), the inferior alveolar nerve lies close to the lower border of the mandible, a considerable distance from the roots of the teeth (**8**.51). From the nerve a variable number of large trunks travel anterosuperiorly towards the roots of the teeth before breaking up into branches to the teeth and interdental septa.



In three out of eight mandibles (in this admittedly small series, which requires amplification) nerves passed from the temporal muscle to enter the mandible through the retromolar fossa and communicated with branches entering the roots of the third to first molar teeth. Buccal to the teeth, fine networks of neurovascular bundles were demonstrated in the molar and incisor regions, the former developed from perforating branches of the bundles to the masseter and temporalis muscles together with the buccal nerve, the latter from branches of the mental nerve (*vide supra*). In the pig (Wedgewood 1966), no fibres of the inferior alveolar nerve have been found supplying teeth on the opposite side of the mandible.

8.55 Longitudinal ground section of an incisor tooth. Compare the brown striae labelled on this section, with those visible on **8**.42.

8.56 Longitudinal demineralized section of a tooth stained with a silver impregnation technique. Note the vertical nerve trunk (left of centre) within the pulp, with fine nerve fibres, one of which crosses transversely to pass between the odontoblasts lining the surface of the predentine (the pale-staining vertical layer, right of centre).



8.57 A scanning electron micrograph of enamel prisms. Each prism is about 5 μm wide and separated from adjacent prisms by interprismatic material which has been removed from this specimen by acid etching. A thick structureless surface layer is present. Dental Histology

DENTINE

Dentine (Miles 1967; Symons 1968), which forms the bulk of a tooth, is a hard, elastic, yellowish-white, avascular tissue which is about 70 per cent by weight mineralized (largely by crystalline hydroxyapatite, but some in the form of amorphous calcium phosphates). The remaining 30 per cent is mainly water and collagen, which gives it toughness. Its most characteristic

microscopic feature is the pattern of evenly spaced *dentinal tubules*, about 1–2 μm in diameter, which extend from the pulpal surface of the dentine out to the *enamel-dentine* (amelo-dentinal) *junction* (**8**.42). The tubules have a characteristic S-shaped *primary curvature* (**8**.42) which is more pronounced in the crown of the tooth. A spiral *secondary curvature* is less regular and has a periodicity and amplitude of a few microns. Towards the enamel-dentine junction the tubules bifurcate and trifurcate, some being continuous with short extensions into the enamel (the *enamel spindles*), particularly beneath the summits of the cusps. The tubules often have many short lateral branches which may communicate with adjacent tubules (**8**.52A). Each tubule contains the membrane-covered cytoplasmic process of a cell body (an *odontoblast*) which is situated in the pulp cavity. The process contains a few mitochondria, lysosomes, microtubules and fine filaments. It is not known whether the processes extend throughout the whole length of a tubule. Recent studies (Holland 1975) suggest that the odontoblast process may only extend a short way into the dentine, and that the remainder of the dentinal tubule may be filled with fluid. Against this interpretation, it is possible that the difficulty of securing adequate histological fixation of the contents of dental tubules may result in their autolytic loss during the preparation of sections for light or electron microscopy. The odontoblasts are arranged as a pseudo-stratified layer of cells lining the pulpal surface of the dentine (**8**.53). Around most tubules there is a very heavily mineralized cylinder of *peritubular dentine* which is devoid of, or has a very sparse, matrix. The remainder constitutes the *intertubular dentine*. The highly mineralized, matrix-deficient, peritubular dentine is lost during the decalcification necessary to produce wax embedded sections. The resultant space seen under the light microscope is, therefore, an artefact.

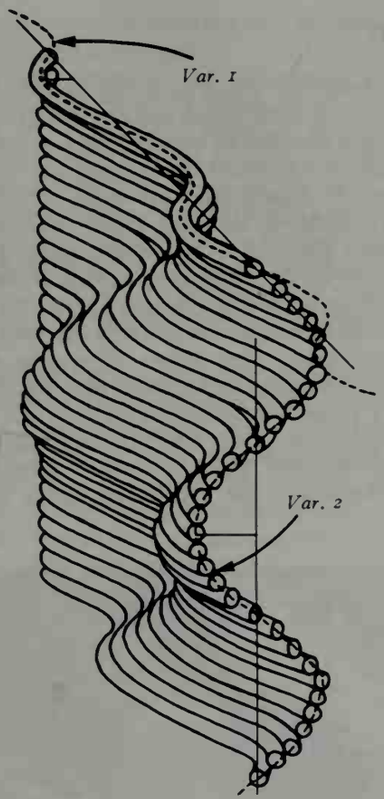
8.58 Diagram showing how the orientation of the crystallites in the enamel determines the appearances when the rods or prisms and the interprismatic substance are cut transversely (face A), longitudinally (face B) and at right angles to both these planes (face C). Note that in this diagram the U-shaped prism sheaths have been arbitrarily extended to meet the subjacent sheaths to produce 'keyhole-shaped' prisms. (Reproduced by kind permission of A. H. Meckel, W. J. Griebstein and R. J. Neal from *Tooth Enamel*, eds., M. V. Stack and R. W. Fearnhead, Bristol, 1965.)

Throughout life a layer of nonmineralized dentine separates the odontoblasts from the mineralized part; it is called *predentine*. The predentine-dentine border has an irregularly scalloped appearance (**8**.52B). This is because dentine commonly mineralizes in the form of microscopical spheres (*calcospherites*), although mineralization may be linear, as in bone. The enamel-dentine junction appears more regularly scalloped, the convexities facing the dentine. (This feature is not related to the pattern of mineralization.) The region adjacent to the enamel-dentine junction is less mineralized than the remaining intertubular dentine. It is called *mantle dentine* to distinguish it from the remainder, which is the *circumpulpal dentine*. The collagen fibres in mantle dentine consist predominantly of *Von Korff fibres* arranged parallel to the tubules: those in circumpulpal dentine are arranged at right angles to the tubules.

All the mineralized dental tissues are deposited incrementally and because, unlike bone, dental tissues are rarely remodelled (only cement can be remodelled), each carries a permanent record of its changing shape during development. Dentine has two types of incremental line. In one form the secondary curvatures of adjacent tubules come into phase; this produces a microscopically recognizable *contour line of Owen*. In the other form, junction lines of less mineralized tissue present as the *incremental lines of von Ebner*. The latter are generally much less well marked than the incremental lines in bone. Sometimes there may be slight disturbances during dentine development. These result in the failure of fusion of calcospherites and the production of *interglobular spaces*. They are so common close to the enamel-dentine junction that here they cannot be regarded as pathological.

Immediately internal to the cement, and sometimes indistinguishable from it, is a thin, clear, *hyaline layer* (Owens 1972), followed by the *granular layer of Tomes* (**8**.54). The granularity of the latter layer may either be due to minute interglobular spaces, or it may be due to tiny expansions of the processes of the odontoblasts (Ten Cate 1972).

Throughout life dentine is deposited at an ever-slowing rate. Thus the pulp cavity becomes progressively diminished in size. The dentine produced after a tooth has erupted is called '*regular*' *secondary dentine*. It can sometimes be distinguished from the earlier formed, *primary dentine* because of a sudden change in the direction of the dentinal tubules. If the dentine receives a severe stimulus (for example by the attack of caries), an irregular or '*reparative*' *secondary dentine* is laid down (**8**.55). This is a poorly mineralized dentine containing few and irregular tubules, and it may include blood vessels and cell spaces. A less severe stimulus (for example, abrasion of the neck of a tooth due to toothbrush trauma) leads to the sealing of the pulpal ends of the dentinal tubules by a knob of 'reparative' secondary dentine. The region containing the sealed-off tubules is called a *dead tract* (the tubules no longer communicate with odontoblasts).



The peritubular dentine increases in thickness at the expense of the tubule, particularly in the root. Thus in the root region, peritubular dentine gradually obliterates the tubules which now have almost the same refractive index as the rest of the dentine. The result is that in ground sections viewed by transmitted light the dentine appears transparent and is called *translucent dentine*.

THE DENTAL PULP

Within the dentine lies the vascular pulp (Symons 1968), whose surface is covered by odontoblasts; it is continuous with the periodontal ligament and tissue spaces of the alveolar bone via the apical foramen of the tooth. Apart from odontoblasts, the pulp contains all the cells normally found in loose connective tissue (**8**.53).

Several arterioles usually enter the apical foramen and run longitudinally through the tooth giving branches which ultimately form a subodontoblastic capillary plexus in the young tooth (Kramer 1960). The arterioles have remarkably thin walls, possibly related to their inclusion in a small rigid-walled pulp cavity. Several small veins emerge from the pulp. There is a moderate network of lymphatics (Saunders and Röckert 1967; Bernick and Patek 1969), some being perivascular and perineural, others being more isolated trunks.

Non-myelinated postganglionic sympathetic nerve fibres enter the pulp with the arterioles. Myelinated fibres also run longitudinally through the pulp giving branches which ramify in a subodontoblastic *plexus of Raschkow* (Scheinin and Light 1969). Here the fibres lose their myelin sheaths and they continue as beaded axons which pass between the odontoblasts (**8**.56), and

8.59A Diagram illustrating the relationships existing between a vertical stack of enamel prisms. Each prism undulates in the transverse plane of the tooth, but its undulations are out of phase with those of vertically adjacent prisms. Hence, when a section is viewed by reflected light, the undulations are responsible for the characteristic alternation of dark and light bands which cross the prisms obliquely (the Hunter-Schreger bands). Var. 1 and 2 indicate the sine-wave undulations in the transverse and vertical planes, which vary in amplitude and periodicity in the enamel of different species. (From J. W. Osborn in: *Calcified Tissue Research*, **5**, 1970, by courtesy of the author and publishers, Springer.)

8.59B A reconstruction of enamel prisms in the dog. Each prism is represented by a thread. Note the gradual change in direction between vertically adjacent prisms which are viewed from the cuspal aspect in this photograph. Only a part of one complete prism undulation is shown in each case. Compare with **8**.59A. (Preparation by Dr. J. W. Osborn, Department of Anatomy, Guy's Hospital Medical School.)

may form loops in the predentine (Fearnhead 1967). A few nerve fibres enter the dentinal tubules to lie adjacent to the cytoplasmic processes of odontoblasts for a short distance into the dentine. Although preliminary electron microscopy of this region has been carried out (Symons 1968), the technical difficulties of a comprehensive study of the terminations of such fibres are great. It is assumed that some kind of 'functional connexion' is established with the odontoblast processes; as yet typical synaptic arrangements have not been identified. (For a discussion consult Symons 1968.) It has been implied, therefore, that when dentine is stimulated as, for example, during the cutting of a tooth cavity, some form of impulse may be propagated along the process of the odontoblast and then somehow transmitted on into the nerve fibres; the mechanism is, however, uncertain. Further, this does not explain the sensitivity of newly erupted teeth, which do not yet contain nerve fibres in the dentinal tubules. Also, only about 1 in 2,000 mature tubules contain a nerve fibre, and this appears to be a very sparse innervation for such a sensitive tissue as dentine.

As an alternative to the above hypothesis it is usually suggested that stimuli cause movement of fluid along the dentinal tubules (either intra- or extra-cellular fluid) and that this causes a change in the volume of tissue fluid in the subodontoblastic plexus, which initiates the nervous impulses (Anderson *et al.* 1970). It should be noted that all effective stimuli to either dentine or the pulp are subjectively perceived as pain. (For alternative views of the possible functional roles of fine nerve fibre tissue afferents, *see* p. 891.)

In a recent study (Pimendis and Hinds 1977), labelled proline was injected into the trigeminal ganglion of adult rats, and this was subsequently observed in dentinal tubules close to the enamel—dentine junction, where it had presumably been carried by axoplasmic flow. This observation may re-open the question of dentine sensitivity.

As mentioned above, the pulp cavity diminishes progressively throughout life due to the formation of 'regular' secondary dentine.

THE ENAMEL

Enamel (Fearnhead and Stack 1965, 1971; Miles 1967; Osborn 1973; Boyde 1976), which is the extremely hard translucent tissue covering the crown of the tooth, contains about 96 per cent by weight of inorganic material; this is about 88 per cent by volume. It reaches a thickness of some 2·5 mm over the cusps of teeth and thins down to a knife-edge at the cervical margin.

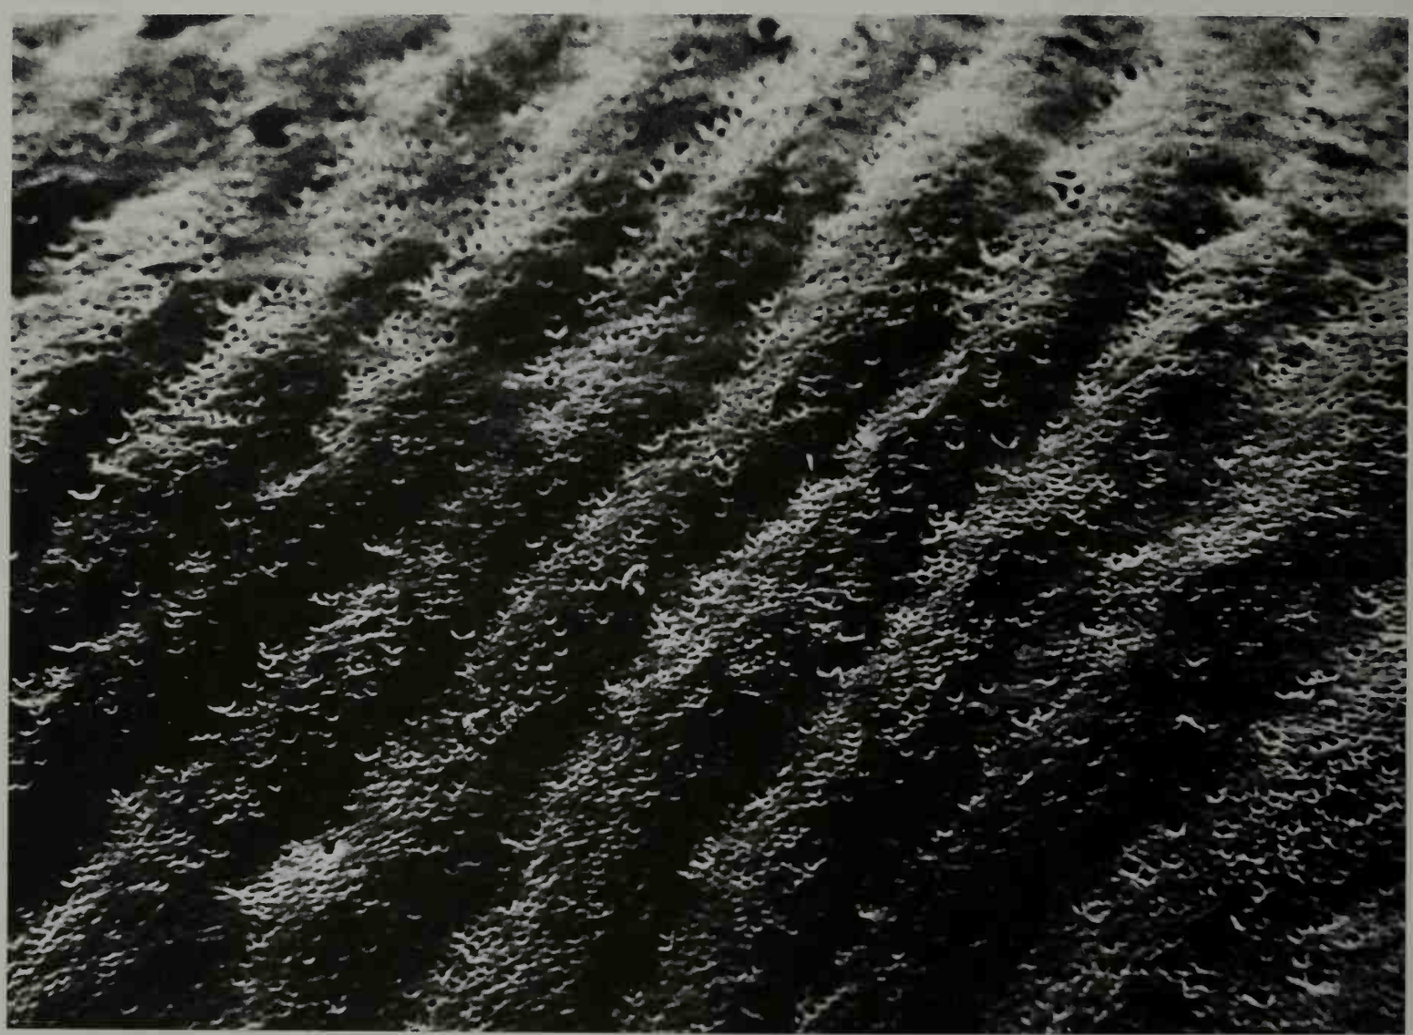
Enamel is composed of closely packed rods or prisms which are roughly circular in transverse section (**8**.57) extending from the enamel-dentine junction toward the surface of the tooth. Each is separated from the *interprismatic region* by a *prism sheath* which has a U-shape in cross-section, with its convexity towards the tip of the cusp. The concavity of the U-shaped sheath is continuous with the interprismatic region. Prisms are about 3–4 μm wide at the enamel-dentine junction and increase to about 6 μm wide near the tooth surface (Osborn 1968*a*). For a thickness of about 6 μm the surface enamel is often structureless. The prism sheath is a region of microporosity about 75nm wide. At intervals of about 4 μm along its length each prism is crossed by a dark *striation*. Each 4 μm section is believed to present one day's growth.

The prisms are packed with hydroxyapatite crystallites (**8**.58) which have a preferred orientation depending on their positions in the prisms or interprismatic region. There is a sudden change between crystallite orientation on each side of the prism sheath. However, there is no reason to believe that the interprismatic region and prism body differ in any way, apart from crystallite orientation. Because of this, enamel is sometimes said to be constructed from keyhole-shaped prisms in which the interprismatic region is equivalent to the 'tails' of the keyholes. This difference of opinion is purely one of terminology (Osborn 1968*a*).

Each prism undulates from side to side in the transverse plane of the tooth (Osborn 1968*b* and *c*), the undulations of one prism being slightly out of phase with those above and below it, but being matched by those laterally adjacent to it (**8**.59). Similar regular undulations over the tips of cusps give rise to the

appearance of *gnarled enamel* when sections of this region are examined.

The incremental lines in enamel (**8**.55) are termed the *striae of Retzius* (Osborn 1971; Weber *et al.* 1974). They are brown when viewed by transmitted light and blue when seen by incident light. This suggests that light is scattered in the region of striae by some differences in crystallite size or orientation. Where the striae meet the surface of the tooth slight depressions called *perikymata* develop (**8**.60). These can be clearly seen ringing the surface of newly erupted teeth (Weber *et al.* 1974). They become flattened by wear.



A well-marked Retzian stria is seen in the enamel of those teeth whose mineralization spans birth (all deciduous teeth and the first permanent molars). This is the *neonatal line* (Whittaker and Richards 1978). The presence of neonatal lines in the teeth of a dead infant is of forensic importance: it indicates that the infant survived the perinatal period for a few days, because the lines develop during this period.

THE CEMENT

Cement is the bone-like tissue covering the roots of the teeth (Selvig 1965; Furseth 1969; Frank and Steuer 1977). It is about 50 per cent by weight mineral. In terms of the newly erupted tooth, cement generally just overlaps the enamel, but it may also just meet the enamel or occasionally fall short, leaving the dentine exposed to the periodontal ligament. However, in old teeth when the root becomes exposed in the mouth (getting 'long in the tooth'), the cement is often worn away and the dentine is revealed.

The cement is perforated by *Sharpey's fibres*, the extensions of collagen fibres which cross the periodontal ligament to be inserted into the alveolar bone. New layers of cement are deposited throughout life to compensate for tooth movements. In this way new Sharpey's fibres are incorporated into the new cement surface while the deeper, older fibres become mineralized.

The thin first-formed layer of cement generally does not contain cells. However, the apical two-thirds of the root is commonly covered by cement which contains *cementocytes*, occupying lacunae joined together by canaliculi which are mainly directed towards the periodontal ligament—their source of nutrition. The *acellular* (**8**.54) and *cellular* forms of cement differ only in the absence or presence of cells; either form may exist over any part of the root (*see* p. 1299).

8.60 A scanning electron micrograph of the enamel surface showing perikymata. The holes (about 4 μm wide) were occupied by Tomes' processes of ameloblasts when the development of the enamel was completed. (Kindly provided by Dr. D. Whittaker, The Dental School, University of Wales, Cardiff.)

In transverse sections of teeth, tuft-like projections from the enamel-dentine junction can be seen to penetrate between prisms and extend about one-third of the way through the enamel. These are the *enamel tufts*. The 'leaves' of the tufts appear to correspond with thickened prism sheaths and they spread for considerable distances in the longitudinal plane of the tooth (Osborn 1969).

From the outer surface of the enamel, longitudinal sheets of organic or hypocalcified material penetrate the enamel, often as far as, or a little further than, the enamel-dentine junction. They are called the *enamel lamellae*. The extensions into the enamel of the dentinal tubules are *enamel spindles*.

PERIODONTAL LIGAMENT (MEMBRANE)

The periodontal ligament (Melcher and Bowen 1969) is about 0·2 mm wide. Its main functions are to suspend the tooth in its socket

and to provide sensory information by means of pressure receptors (Anderson *et al.* 1970).

The main components of the periodontal ligament are the collagenous *principal fibres*, of which there are several named groups (**8**.43, 61). The *gingival fibres* pass from the more coronal cement and the crest of alveolar bone into the lamina propria of the gingiva, anchoring it firmly against the tooth. They are aided by a *circular group* arranged concentrically around the neck of the tooth. Just apical to these fibres are the *horizontal fibres* which restrict tilting of the tooth. The most numerous elements are the *oblique fibres*. An essential element is the hydrophilic ground substance, providing visco-elastic support (Melcher and Walker 1976).

Each periodontal ligament derives its nerve supply from several sources (*vide supra*). The chief role of these axons seems to be that of subserving mechanoreceptors. They have been described as terminating in 'knob-like' endings, elongated and spindle-shaped endings, Meissner's corpuscle-like endings, and irregularly branched endings. Physiological investigations suggest that such structural variations of these mechanoreceptors are unimportant, but that their spatial arrangement within the ligament determines their response characteristics (Anderson *et al.* 1970; Hannam 1976). The information derived from activity of these nerves probably provides an input to many brainstem centres, including the cerebellum, where the masticatory cycle of jaw movement may, in part, be controlled.

The remaining tissues in the periodontal ligament are, with the following exception, typical of any connective tissue. A network of epithelial cells is scattered through the ligament. These constitute the *epithelial debris of Malassez*, and are remnants of the root sheath (p. 1299). The cells have no obvious function: they give rise to the commonly occurring *dental cysts*.

There is a remarkably rapid turnover of collagen in the periodontal ligaments. Old fibres are removed by fibroblasts acting as fibroclasts (Ten Cate 1974). It is possible to distinguish, ultrastructurally, *fibroblasts* active in fibrogenesis, *fibrocytes* which are largely inactive, and *fibroclasts* which are removing collagen. Alternatively, one cell may be forming and degrading collagen at the same time. The status of the periodontal ligament is determined by a balance between the rate at which fibres are removed and replaced.

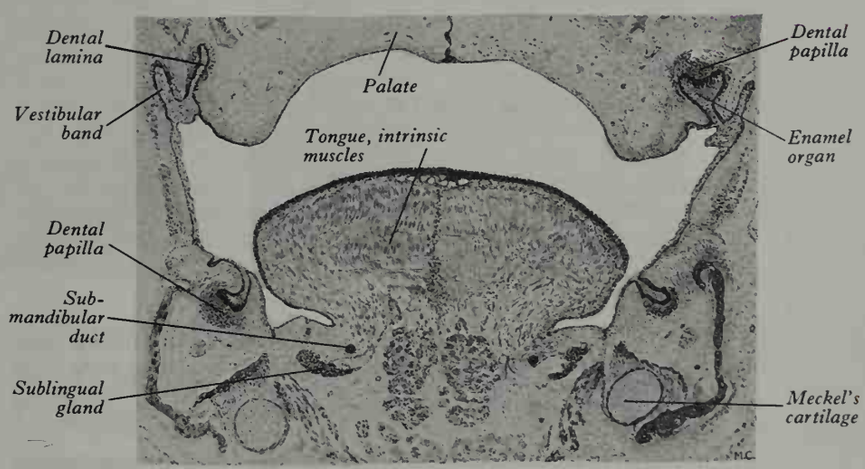
THE GINGIVAE (GUMS)

The tissue surrounding the necks of the teeth is the gingiva (Miles 1967; Melcher and Bowen 1969; Squier *et al.* 1976). In a healthy mouth it can be distinguished from the rest of the oral mucosa because it is pale pink and stippled (**8**.44), whereas the adjacent *alveolar mucosa* is red, shiny and smooth; the gingival and palatal epithelia are keratinized (or parakeratinized), the alveolar epithelium is not keratinized (*see* pp. 40, 41).

Around the neck of the tooth, the gingival epithelium is reflected towards the root of the tooth so that its outer surface is attached to the tooth—the *epithelial attachment*. Surrounding the tooth is a shallow *gingival sulcus* which is bordered on one side by the tooth, on the other by the gingiva, its floor being the epithelial attachment. The epithelium attached to the tooth is the *junctional epithelium*, and that lining the gingival sulcus is the *sulcal epithelium*. Junctional epithelium has particularly wide intercellular spaces, is non-keratinized, and has a rapid rate of cellular turnover. By means of hemidesmosomes its superficial cells adhere to a basal lamina covering the attached surface of the tooth (Listgarten 1970), and they are shed into the gingival sulcus. It is evident that this basal lamina is produced in its entirety by ectodermal cells. The sulcular epithelium is a non-keratinized stratified squamous epithelium (*see* **8**.32).

Early Dental Development

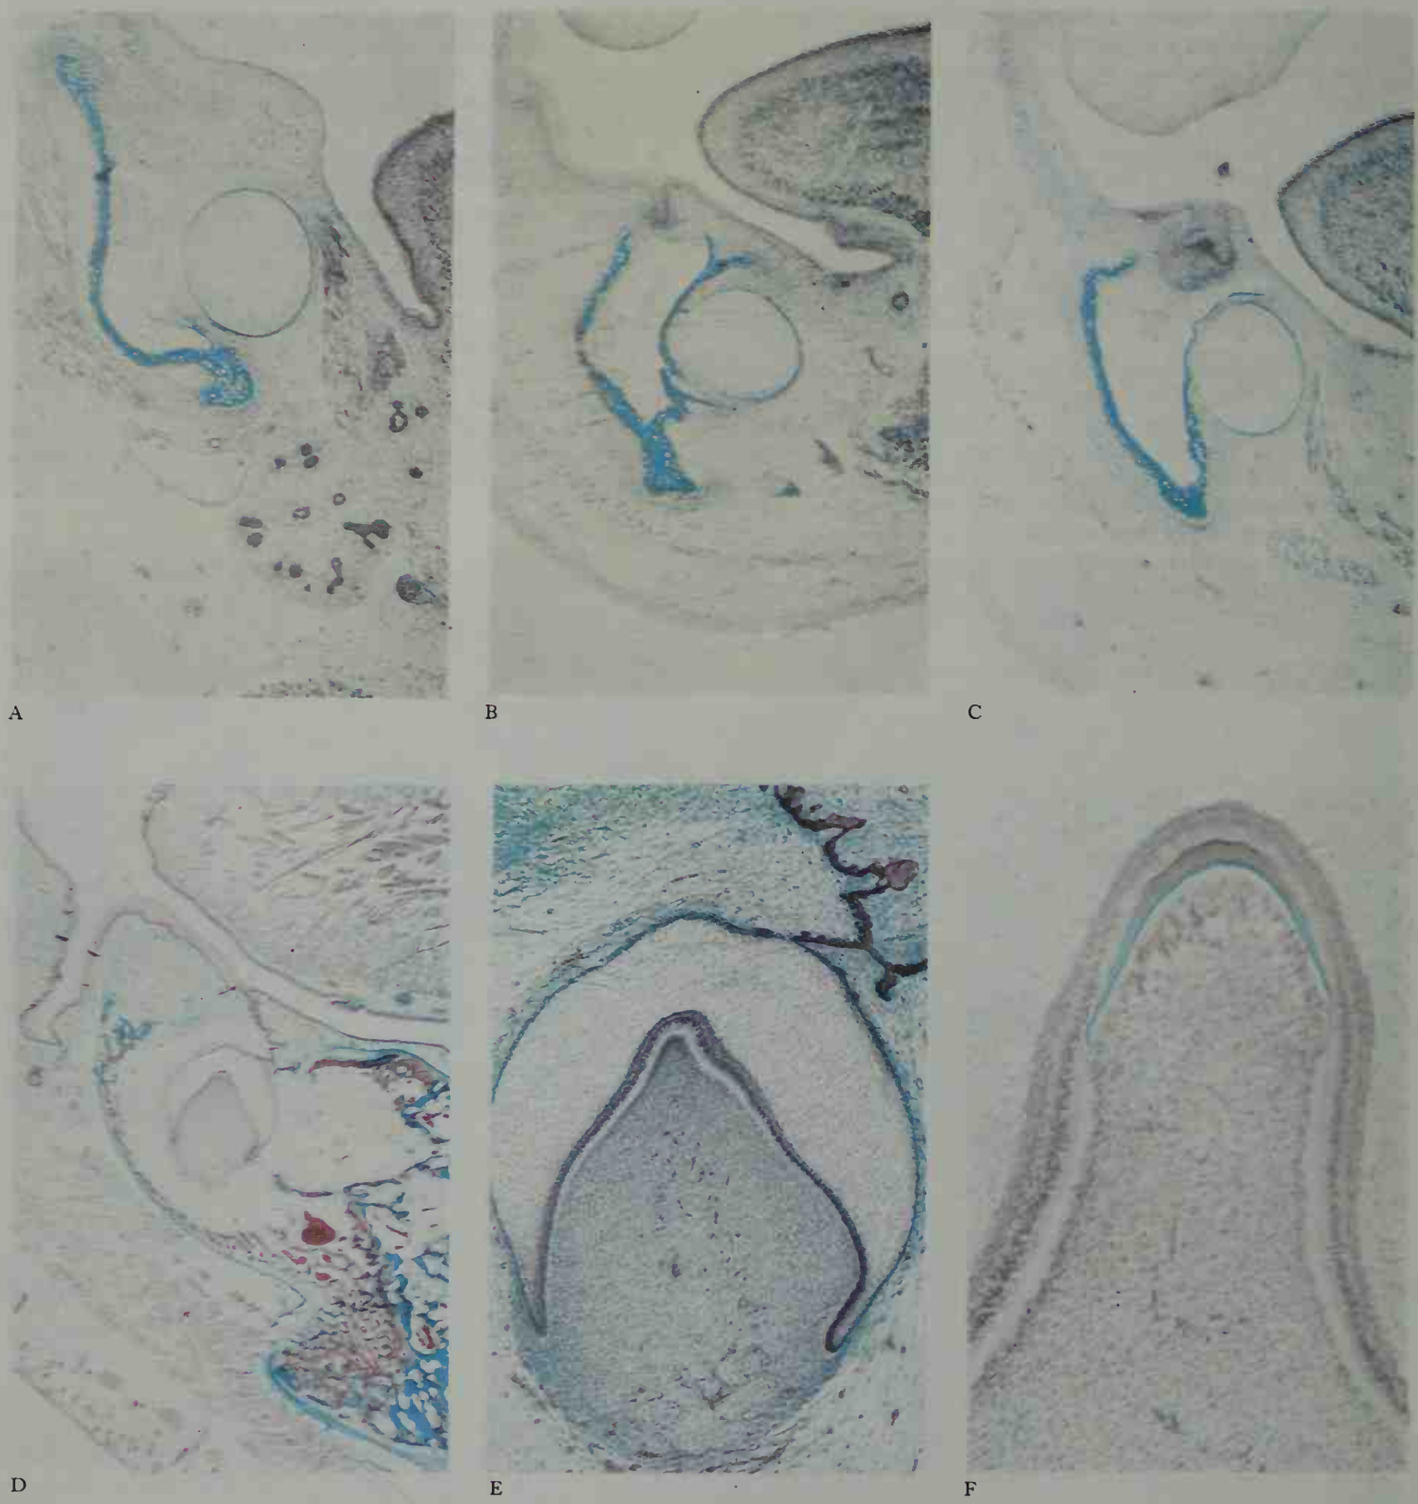
DECIDUOUS TEETH



At about the 8–9 mm embryonic stage of development the primitive oral epithelium (**8**.63A) begins to bulge into the underlying mesoderm in the region which will later be occupied by the teeth (**8**.62–66). This horseshoe-shaped thickening in each jaw is at first incomplete across the midline; it is the *dental lamina* (**8**.63B), and from it, and the surrounding cells, are produced the discrete *tooth buds* which later develop into the teeth (Gaunt *et al.* 1971; Provenza and Sisca 1971).

It has been shown that in amphibia, and probably mammals, the dental lamina proliferation is induced by cells of neural crest origin (ectomesenchyme) which have migrated into the developing jaws (Gaunt and Miles 1967; Slavkin 1974). The original site of the embryonic oral membrane has not been traced with certainty in developing jaws and therefore it is not known whether the dental lamina is derived from ectoderm or endoderm or from both these germ layers.

At about the 20 mm stage discrete outgrowths of the dental lamina push towards isolated clumps of ectomesenchyme which are found in regions of increased capillary density. An ectodermal outgrowth together with the adjacent ectomesenchyme is known as a *tooth bud*. The ectoderm starts to grow around the



8.61 Demineralized vertical section of a young rat molar tooth *in situ*. Note: (1) the alveolar bone with marrow spaces; (2) the fibres of the periodontal ligament which connect the alveolar bone to the cement of the root; (3) the large pulp cavity typical of a young tooth; (4) the absence of enamel in this demineralized section; and (5) the gingiva adjacent to the enamel space at the neck of the tooth.

ectomesenchyme; at this stage the ectodermal part of the tooth bud is called the *enamel organ*, the ectomesenchymal part is the *dental papilla* (**8**.65). Soon, peripheral cuboidal cells of the enamel organ can be distinguished from centrally placed polygonal cells. The encircling edge of the enamel organ is called the *cervical loop* (**8**.63E).

The roughly spherical dental papilla increases in volume, but the cervical loop of the growing enamel organ continues to

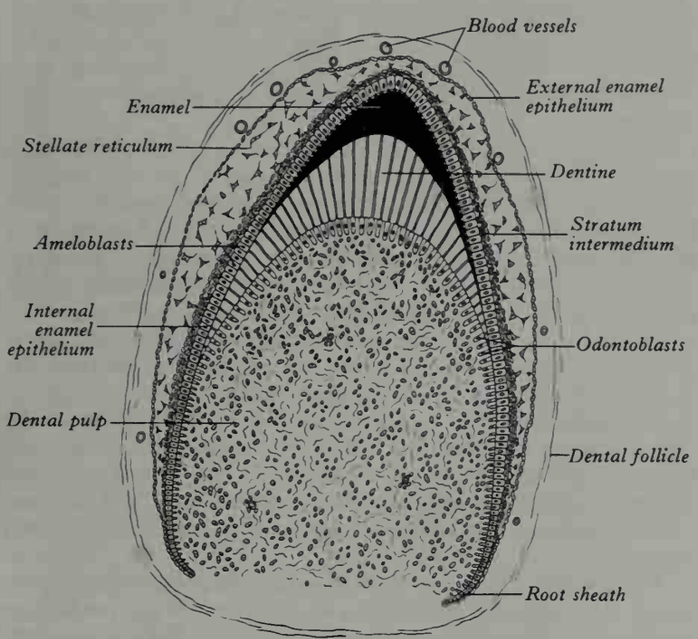
C The cap stage of development. The enamel organ is growing from the dental lamina around the condensation of cells which forms the dental papilla.

8.63D–F Slightly later stages in tooth development than shown in **8.63A–C.**

D The bell stage of development. The external enamel epithelium of the enamel organ is connected to the oral mucosa by an irregularly-stranded dental lamina. Lateral to the buccal plate of the mandible the vestibular band has atrophied centrally to initiate the oral vestibule. The tooth germ is separated from the bone by the tooth follicle.

E A photograph at higher magnification of the bell stage. Note from above downwards: (1) the degenerating dental lamina, top right; (2) the fibrous tooth follicle surrounding the developing tooth; (3) the external enamel epithelium; (4) the delicate stippled appearance produced by the nuclei of the stellate reticulum; (5) the darkly stained, somewhat flattened cells of the stratum intermedium, which is seen more clearly in F; (6) the columnar cells of the internal enamel epithelium; (7) the more closely packed cells of the dental papilla which extend outside the cervical loop; and (8) the capillaries of the pulp and tooth follicle.



F Dentine formation beginning at the cuspal tip. From above downwards note: (1) loose stellate reticulum; (2) stratum intermedium; (3) layer of columnar ameloblasts; (4) a thin strip of enamel matrix (mauve); (5) mineralized dentine (pink); (6) predentine (pale blue); (7) layer of odontoblasts.

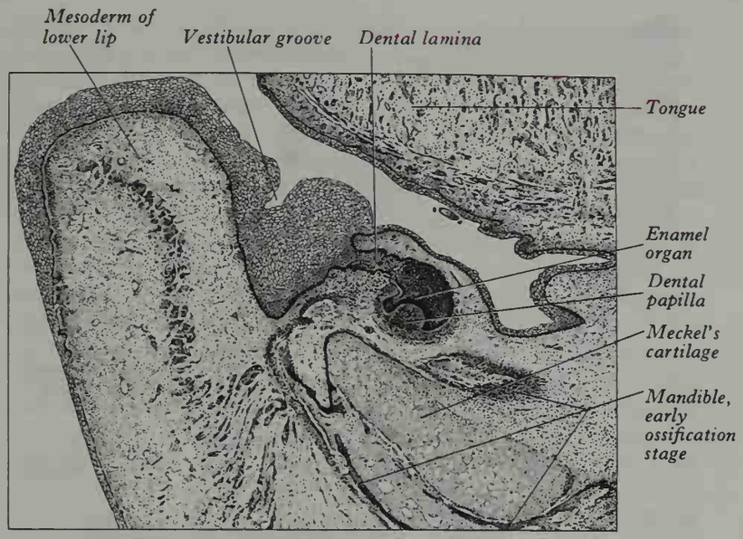
encompass a greater proportion of its periphery until it is sitting on the dental papilla like a cap—the *cap stage* of tooth development (**8**.63C). Meanwhile, the polygonal central cells of the enamel organ have been secreting glycosaminoglycans into their intercellular spaces. This hydrophilic material attracts water into the spaces, which now swell up and compress the cytoplasm of these cells. Because they maintain their desmosomal connexions, the central cells of the enamel organ now look stellate and the tissue is called the *stellate reticulum* (**8**.63E, 64). The original cuboidal cells adjacent to the dental papilla begin to lengthen into columnar cells to form the *internal enamel epithelium* (**8**.63E). The remaining peripheral cells form the *external enamel epithelium* (**8**.63E) which is continuous with the dental lamina.

By its continued growth, the cervical loop now surrounds about three-quarters of the periphery of the enlarging dental papilla, giving the tooth germ the appearance of a bell; *the bell stage* of tooth development (**8**.63D, E).

During the cap and bell stages a clump of ectodermal cells bulges into the stellate reticulum from the internal enamel epithelium. This is the *enamel knot*. From the enamel knot a cord of cells extends through the stellate reticulum towards the connexion between the external enamel epithelium and the dental lamina; this is the *enamel septum* (Berkovitz 1967).

Near the time when the cap stage is merging into the bell stage, a layer of more flattened cells, about three or four cells thick, develops between the inner enamel epithelium and the stellate

8.64 A simplified diagram of a developing tooth, to show the approximate arrangement of its principal components. Compare with **8**.63F.



reticulum. This is the *stratum intermedium* (**8**.63E, 64); possibly it is derived from the enamel knot or from the *internal enamel epithelium*. Following the bell stage dentine formation starts.

The development of the nerve supply of the deciduous teeth has attracted little attention. Alveolar nerves have grown into the maxillary and mandibular processes at about 5 weeks as the dental laminae are forming. At the 'cap' and 'bell' stages individual bundles of fibres have entered the mesenchymal masses which will produce the dental papillae. (For further details *see* Pearson 1977.)

The Tooth Follicle

A growing enamel organ compresses the surrounding adjacent cells so that they assume a concentric arrangement (Melcher and Bowen 1969). These cells comprise the *tooth follicle* (**8**.63E) which will ultimately be bordered by the developing alveolar bone of the jaw (**8**.63D, 66), the depression in the bone containing the tooth germ and follicle being called a *tooth crypt*.

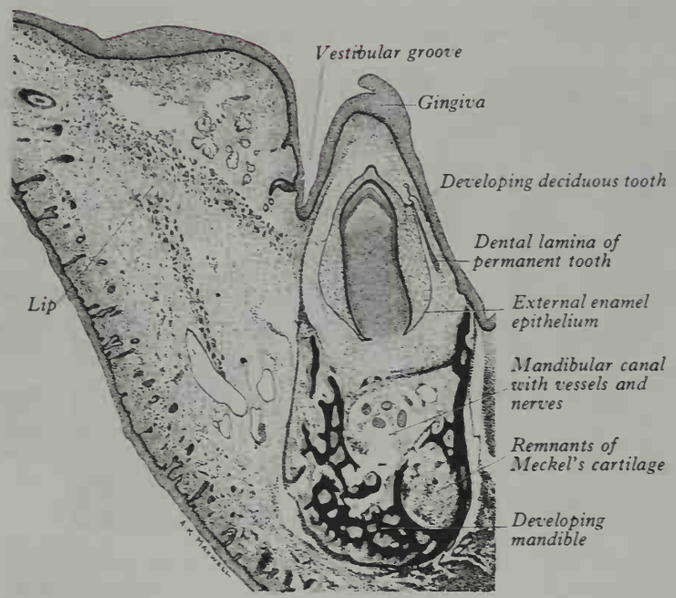
The growing edge of the cervical loop pushes some

8.65 Part of a sagittal through the head of a human embryo (C.R. 60 mm), passing through the right lower central incisor tooth germ. Stained with haematoxylin and eosin. × 12. (Drawn from a photomicrograph kindly given by Prof. C. H. Tonge, Anatomy Department, King's College, Newcastle-upon-Tyne.)

ectomesenchymal cells aside so that they come to lie outside and adjacent to the external enamel epithelium (**8**.63E). This is the *investing layer of the tooth follicle* and from it probably develops the cement of the root. From the outer layer of the tooth follicle develop the osteoblasts and osteoclasts which fashion the bony crypt, and later the socket, of the developing tooth. The middle layer provides further cells and fibres to the periodontal ligament.

The Vestibular Band

At about the same time that the dental lamina appears, there is a similar horseshoe-shaped ingrowth of epithelial cells buccal to it (Tonge 1966). This ingrowth is not associated with demonstrable aggregation of ectomesenchymal cells. It is called the *vestibular band* (**8**.62, 65). (In some accounts of tooth development it is suggested that there is a single primary ingrowth (the *primary epithelial band*), and that this subsequently bifurcates into a buccally placed vestibular band, and the more lingual dental lamina.)



The vestibular band grows deeply into the primitive jaw arches (**8**.65), to separate what will ultimately be the lips and cheeks from the oral mucosa covering the alveolar bone of the jaws; that is to say it will become the site of the vestibule of the mouth. The ectodermal cells divide rapidly to broaden and deepen markedly the vestibular band. A cleft appears within the central cells of the band (**8**.66) at about the time when the tooth germs have reached the cap stage, thereby separating the cheeks and lips from the developing jaws.

THE PERMANENT TEETH

As the jaws grow in length the dental lamina penetrates posteriorly through the jaw mesenchyme as a solid core. From its deep border the buds for the permanent molars develop in mesiodistal sequence, each being initiated within the ramus of the jaw (Scott and Symons 1977); but, with the progressive resorption of the anterior border of the coronoid process, they come to lie within the body of the jaw.

From each of the tooth buds for the deciduous teeth there grows lingually a *successional lamina* out of the region where the external enamel epithelium is in continuity with the dental lamina (**8**.66). Each extends down into the mesenchyme on the lingual side of the deciduous tooth and from its end a tooth bud develops, later to generate the permanent successor.

Each permanent successor to the deciduous incisors and canine, lying lingual to its predecessor, becomes surrounded by its own tooth follicle and bony crypt. However, the follicle maintains a fibrous connexion with the overlying lamina propria

8.66 Developing tooth with mandible and lip *in situ*. (Drawn from a photograph by F. Harrison, Dental Department, University of Sheffield, and reproduced by permission of Messrs. Blackie & Son, Ltd., from *Our Teeth* by R. D. Pedley and F. Harrison.)

of the oral mucosa. These connexions are called *gubernacular cords*. Their original positions, which can easily be seen in young dried skulls, are called *gubernacular canals*. The cords are said to guide the erupting permanent teeth into their correct positions (Scott 1967).

The Fate of the Dental Lamina

About the time dentine and enamel start to develop, the cells of the dental lamina begin to degenerate (**8**.63E), breaking up into discrete clumps, many of which have a whorl-like appearance. These can be found over the developing deciduous teeth, in which position they may occasionally proliferate to become cystic cavities of minor importance known as *eruption cysts*. The latter are recognizable as bluish swellings over the erupting tooth.

In the newborn there can be seen a horseshoe-shaped *dental groove* slightly buccal to the alveolar crest. This is the site of origin of the *dental lamina*. In the upper jaw a more palatally sited *gingival groove* separates the gingival from the palatal epithelium (Scott and Symons 1977).

DEVELOPMENT OF DENTINE

Just prior to dentinogenesis (Miles 1967; Symons 1968), a small space separates the cells of the dental papilla from the, by now, tall columnar cells of the internal enamel epithelium (**8**.63F). The latter, which are still dividing, lie on a basement membrane.

During the late bell stage, the sheet of cells, comprising the inner enamel epithelium, folds in a genetically determined way to take up the definitive outline of the future enamel-dentine junction (Gaunt and Miles 1967; Gaunt *et al.* 1971). Because there are only slight regional variations in the thickness of the enamel, this folding process determines the ultimate shape of the tooth; that is to say, the number and positions of cusps. At the tip of a presumptive dentine cusp the cells of the internal enamel epithelium lengthen towards the undifferentiated cells of the dental papilla and induce the adjacent ectomesenchymal cells to differentiate into presumptive *odontoblasts*, the cells which will lay down the dentine (**8**.63F, 67). Deep to this, a thicker layer of cells differentiates into active fibroblasts; this is the *subodontoblastic layer*, whose cells act as satellites to odontoblasts; they appear to produce many collagen fibres, which penetrate between the odontoblasts and seem to fan out parallel to the presumptive enamel-dentine junction. These are the argyrophylic *von Korff fibres*. It has been demonstrated (Ten Cate *et al.* 1970) that this fibrous appearance may be an artefact produced by the precipitation of silver stains in the intercellular spaces between the odontoblasts (the penetrating parts of the 'fibres'), and between the odontoblasts and the internal enamel epithelium (the fanned-out ends of the 'fibres').

The newly differentiated odontoblasts, which now have a well-developed endoplasmic reticulum and Golgi apparatus, start secreting the dentine matrix into the region enclosed on one side by the internal enamel epithelium and on the other by their own secreting ends, which are united by desmosomes. At this time each odontoblast sends out several cellular projections towards the basement membrane, some penetrating between the cells of the overlying inner enamel epithelium, ultimately to become the enamel spindles. The accumulation of matrix pushes the odontoblasts back into the papilla and the first layer of unmineralized matrix has been formed. The cellular projections of the odontoblasts lengthen as their perikarya recede, becoming the processes of the odontoblasts enclosed within tubules of matrix. As soon as a few microns of matrix have been laid down, the matrix adjacent to the internal enamel epithelium begins to mineralize (Silva and Kailis 1972), and the basement membrane disappears. *Matrix vesicles* have been described in association with the first layer of dentine to be mineralized (Bernard 1972; see also p. 260).

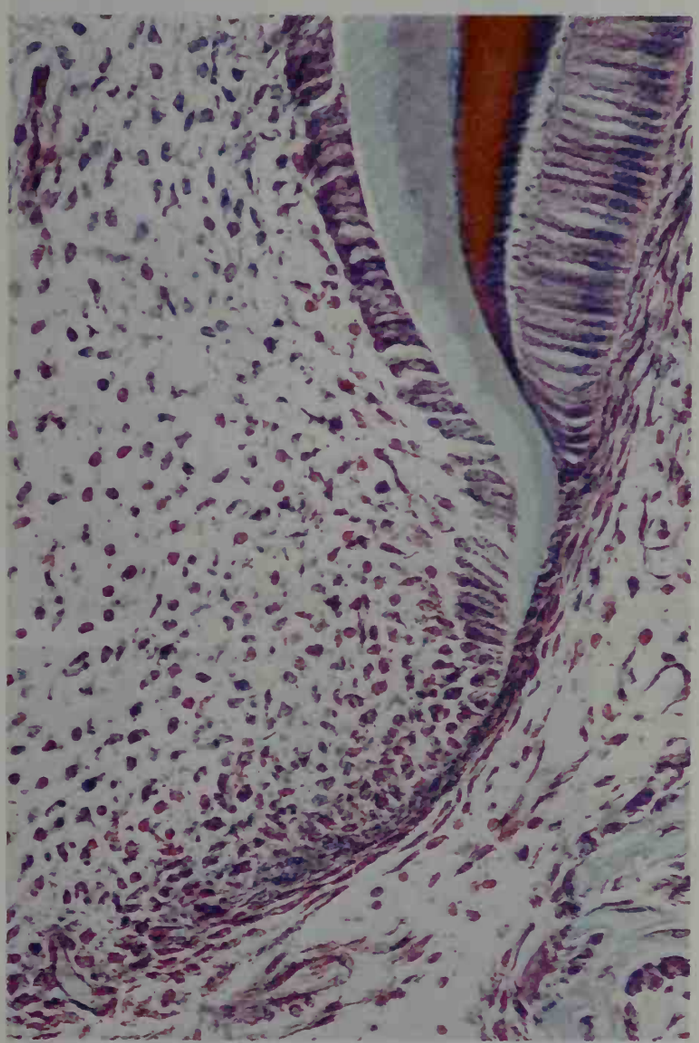
From this region, at the tip of the presumptive dentine cusp, a wave of differentiation of odontoblasts from dental papilla cells slowly spreads down towards the growing cervical loop. As soon as each odontoblast has differentiated, matrix is laid down, pushing the united layer of cells into the papilla (Osborn 1967). The layer of unmineralized matrix adjacent to the odontoblasts is called the *predentine* (**8**.67). The mineral in dentine is commonly laid down as microscopic spheres, the *calcospherites* (**8**.52B), giving the predentine-dentine junction an irregularly scalloped appearance.

In association with the von Korff fibres, or the intercellular spaces between the odontoblasts (*vide supra*), the first formed, rather thin, layer of dentine is less heavily mineralized. It is called '*mantle dentine*' (Moss 1974) as opposed to the remaining, later formed dentine, which is called *circumpulpal dentine*. The matrix of circumpulpal dentine contains fine collagen fibres which interlace in planes at right angles to the dentinal tubules.

At first, within the mantle dentine, each odontoblast has several processes (Silva and Kailis 1972), but as a cell recedes from the enamel-dentine junction its processes unite so that finally it has a single, main process. This accounts for the bifurcation of the tubules near the junction. However, during dentinogenesis, odontoblasts are constantly developing small lateral processes (Symons 1968), presumably at the predentine level, and these are later surrounded by mineralized dentine to become the fine lateral tubules.

During development it can be seen that the dentinal tubules are much thinner in the mineralized dentine than in the predentine and that this thinning starts near the predentine-dentine junction. It is due to the development of a cylinder of the highly mineralized *peritubular dentine* (**8**.52B) which comes to line the original tubule and progressively reduces its diameter (Miles 1967). Peritubular dentine formation starts at the level where mineralization of the predentine is beginning. Its thickness gradually increases with age. It does not develop in interglobular spaces. (The development of root dentine is considered later in the section on root development.)

DEVELOPMENT OF ENAMEL

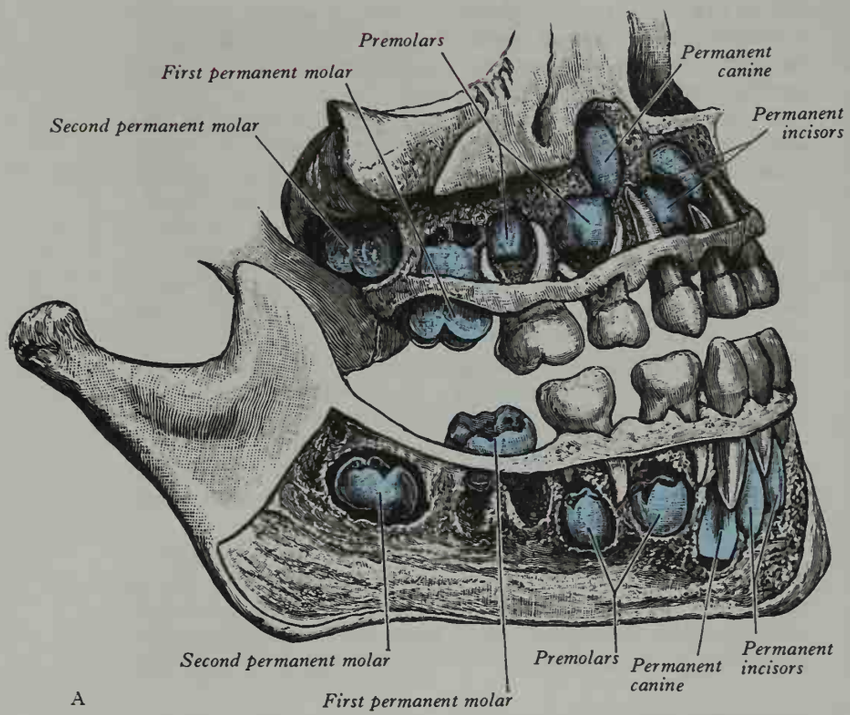


Prior to differentiating into ameloblasts the cells of the internal enamel epithelium lengthen and induce the differentiation of odontoblasts from cells of the dental papilla. It is while they are lengthening that they manufacture the intracellular organelles required for producing enamel matrix (Fearnhead and Stack 1965, 1971; Miles 1967; Boyde 1969; Osborn 1970*a*). At this time the polarity of the cells becomes reversed; the mitochondria which were originally dispersed throughout the cytoplasm become aggregated at the basal (non-secreting) end of the cell where they are joined by the centrioles, whilst the Golgi apparatus migrates to the middle region of the cytoplasm. The cisternae of endoplasmic reticulum increase in amount and together with the

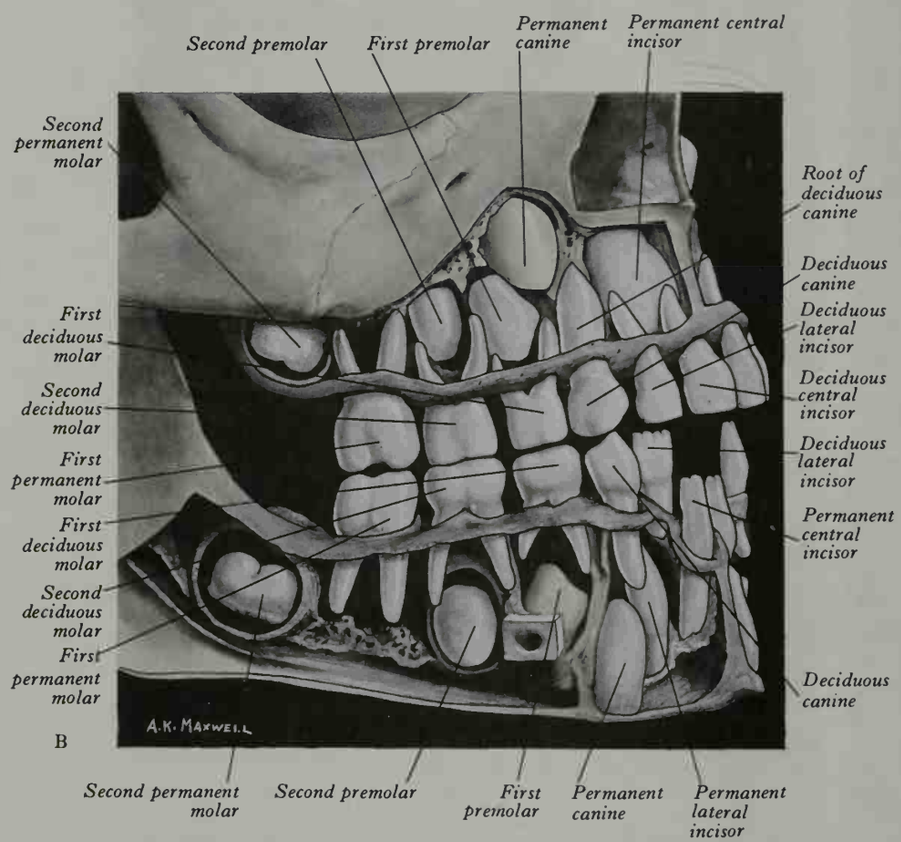
Golgi apparatus become stacked in rows which are parallel to the long axis of the cell; this is now about 40 μm long and 5 μm wide. In cross-section the secretory ends of the cells are regular hexagons, accounting for the classical descriptive term 'honeycomb appearance'. Both the apical and basal margins of adjacent cells are interconnected by junctional complexes (p. 7). Their basal ends are attached by desmosomes to the stratum intermedium, an arrangement which has been suggested as facilitating the transport of materials elaborated by the stratum intermedium to the ameloblasts (Kurahashi and Yoshiki 1972). It is of interest that alkaline phosphatase, an enzyme found in the other cells concerned with the formation of hard tissues (osteoblasts, odontoblasts and cementoblasts), is found in all the cells of the enamel organ apart from the ameloblasts—the cells which actually secrete the enamel precursor.

As soon as mineralized dentine has been formed, the adjacent ameloblasts start secreting enamel precursor material and it is considered that the presence of the dentinal matrix is necessary as an inducing agent to initiate the secretory process. Thus, developing enamel spreads down the sides of the presumptive enamel-dentine junction at the same rate as developing dentine, but lags behind it (**8**.67). From this it can be visualized that the enamel precursor material is secreted into a region bordered on one side by mineralizing dentine and on the other by the ameloblasts. It seems probable, therefore, that the rise or potential rise in hydrostatic pressure produced by the accumulation of enamel precursor in this enclosed region, provides the force which pushes the ameloblasts away from the enamel-dentine junction (Osborn 1970*b*).

At the start of amelogenesis, in each region of the tooth, the adjacent stellate reticulum seems to collapse so that the enamel organ is progressively reduced from four layers (external enamel epithelium, stellate reticulum, stratum intermedium, ameloblasts) to three layers. It is usually suggested that the purpose of this is to bring the ameloblasts, which are on the inside of an avascular enamel organ, closer to their source of nutrition; namely the capillaries which have sprouted prolifically adjacent to the external enamel epithelium. Meanwhile, the cells of the external enamel epithelium, which were originally cuboidal, have become squamous and the surface of the enamel organ is thrown into microscopic folds thereby increasing the area available for diffusion. Apart from the ameloblasts, the remainder of the cells of the enamel organ contain alkaline phosphatase, an enzyme which is probably concerned with transport of materials from the bloodstream to the ameloblasts.



As soon as the ameloblasts have moved a few microns away from the enamel-dentine junction they develop somewhat conical extensions into the developing enamel. These are the *Tomes' processes* of the ameloblasts, whose bases are limited by the apical junctional complex of the cell, and they bear a basal peripheral collar of microvillous projections (for further ultrastructural details of these cells consult Reith 1970). The Tomes' processes project into the mineralizing enamel which, therefore, has a regularly pitted surface (Boyde 1969). Adjacent to each Tomes' process is an unmineralized layer about 50–100 nm thick; this is the enamel precursor material. It is stippled when seen under the electron microscope, and similar material is seen within vesicles in the Tomes' processes. On the enamel side of the stippled material are long thin tape-like crystallites separated by unmineralized material. The first formed enamel contains very irregular prisms and ultrastructurally the enamel (recognized by its long



8.67 A vertical section through the neck of a developing tooth with the crown above and the developing root below. crystallites) appears to merge into the dentine (recognized by the presence of collagen and small crystallites).

Depending upon its position in the enamel prism, the long axis (*c*-axis) of each crystallite has a preferred orientation (**8**.58). Thus, the more cuspal of the crystallites (plane C in **8**.58) are roughly parallel to the long axis of the prism, whereas the crystallites which are more cervical in position are more nearly perpendicular to this axis. The crystallites also have a preferred orientation in plane B which is at right angles to plane C (**8**.58). The central crystallites are roughly parallel to the long axis, whilst the peripheral crystallites are angled to the sides of the prism. There is always a sudden change between crystallite orientation on the two sides of a prism sheath. The hexagonal transverse sectional profiles of the ribbon-like crystallites are randomly orientated with respect to each other.

The mineralizing enamel front appears much the same until amelogenesis is almost complete. As the ameloblasts move outwards the deeper crystallites grow in thickness by the accretion of material from the surrounding matrix. The diminishing volume of calcium-rich matrix is replenished by material secreted by the ameloblasts while water and protein are reabsorbed. The matrix can travel long distances through the developing enamel. Finally, the crystallites which are hexagonal in cross-section can enlarge no more because no further space is available between them. Theoretical analysis suggests that about 12 per cent by volume of unmineralized enamel matrix would thus remain (Carlström 1964), and this accords well with the observation that enamel is 96 per cent by weight mineral (i.e. 88 per cent by volume). No new crystallites appear to be added to the enamel other than at the mineralizing front (Rönnholm 1962).

A large part of the original enamel matrix is removed as the crystallites grow. A proline-rich fraction accounts for much of the protein, but there is also a considerable volume of water (Eastoe 1963; Robinson *et al.* 1975). All this material is removed via the ameloblasts, probably where the interprismatic region develops, because (in the rat), the adjacent region of ameloblasts contains coated vesicles, and their surfaces are beset with microvilli (Reith 1967*a*).

The sequence of mineralization of enamel can be followed using microradiography (Miles1967). It appears that a thin layer of enamel is mineralized rapidly down the presumptive enamel-dentine junction, and from here spreads peripherally more slowly. From this layer, mineralization also spreads rapidly up through the full thickness of the cusp, and from here down the outside of the tooth; it thence passes centrally to fill the less mineralized regions, sandwiched between the fully mineralized inner and outer layers.

When they have finished secreting, the previously conical Tomes' processes of the ameloblasts become flattened and fold into numerous microvilli, which have been shown to reabsorb matrix (Reith 1967*b*). Over some of the enamel surface developed at this time, the crystallites are parallel to each other and there are no prism sheaths. Thus there are non-prismatic regions about 6–12 μm thick (Gwinnett 1967; Osborn 1968 *b* and *c*). Furthermore, the surface layer is more highly mineralized than the rest of the enamel, possibly because of the closer packing of the crystallites permitted by their parallel orientation.

ROOT DEVELOPMENT

During crown development the cervical loop continues to encircle the expanding dental papilla. It now starts to grow away from the developing crown, but still around the lengthening papilla, as a double-layered structure called *Hertwig's root sheath* (Gaunt *et al.* 1971); the two layers of the root sheath are derived from the external and internal enamel epithelia (**8**.67).

The inner layer of the root sheath, like the cells of the inner enamel epithelium from which it is derived, induces the differentiation of odontoblasts from the surface cells of the dental papilla. The odontoblasts now lay down a tube of dentine on the surface of the papilla, under the inner layer of the root sheath (**8**.68). The root sheath continues to grow, outlining the ultimate shape of the roots and inducing the differentiation of more odontoblasts.

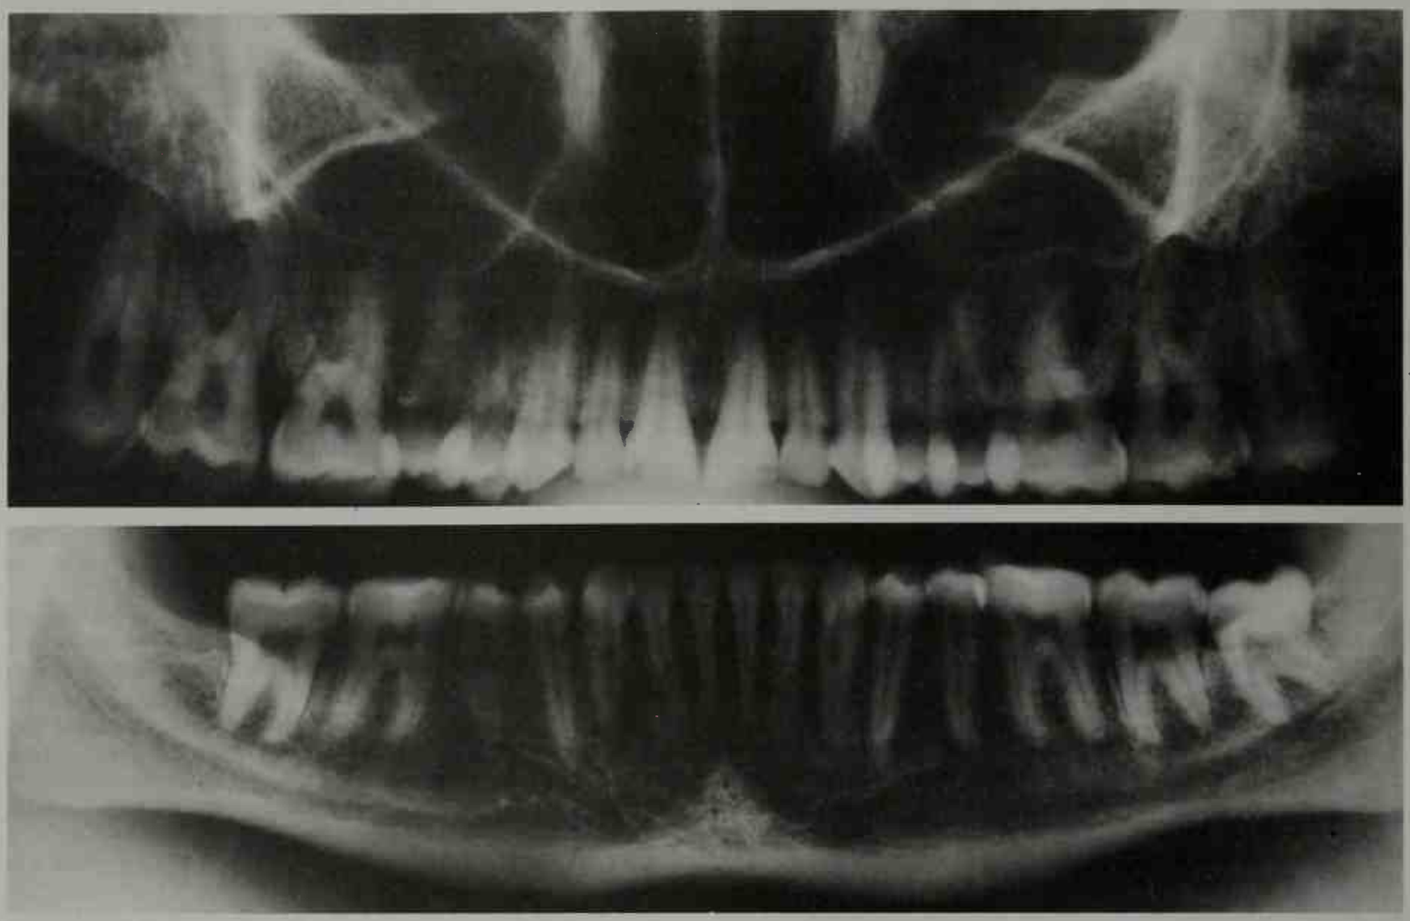
As soon as a layer of dentine has been developed in the root region, the adjacent root sheath seems to break up and become fenestrated, probably because the erupting tooth is now pulling the sheath towards the oral cavity (Gaunt *et al.* 1971). This exposes the outside of the thin layer of newly formed dentine to the tooth follicle. From the investing layer of the tooth follicle cementoblasts are differentiated. It appears that these early formed cementoblasts do not elaborate matrix fibres of collagen, but rather that they secrete ground substance which mingles with superficial unmineralized tags of dentine matrix, and with fibres which have developed in the tooth follicle. This composite matrix is now mineralized under the influence of the cementoblasts and, it can be visualized, attaches the tooth to periodontal fibres (Selvig 1965; Owens 1975). The junction between dentine and cement is therefore not easy to define in electron micrographs.

The root sheath continues to outline the presumptive surface of the root. It surrounds the vessels and nerves supplying the dental papilla. These vessels remain and it is because of their presence, particularly those aggregated towards the future apex of the tooth, that foramina open through canals in the dentine into the pulp of the fully developed tooth. However, it will be appreciated that accessory foramina can open anywhere into the root.

Prior to root development capillaries are more densely arranged in regions which will ultimately correspond with the roots of a tooth (Gaunt and Miles 1967). Thus a two-rooted tooth has two capillary aggregations, and a one-rooted tooth has only one. The papilla grows more rapidly in the region of capillaries and less rapidly in the intervening regions. In these intervening regions, for instance in a two-rooted tooth, a growing tip of the root sheath is able to penetrate under the papilla and meet a growing tip from the other side, thereby separating two roots from each other.

After the root sheath breaks up, the epithelial cells of which it is composed seem to move away from the cement and they are ultimately found in the periodontal ligament of the erupted tooth, where they are known as the *epithelial rests of Malassez*.

DEVELOPMENT OF CEMENT



After the breakdown of Hertwig's root sheath around the coronal half of the developing root, the newly differentiated cementoblasts do not manufacture collagen precursors. Unlike the condition in this region, the cementoblasts which differentiate over the remainder of the root (Jande and Bélanger 1970; Boyde and Jones 1972), and in all later formed cement, do contribute collagen fibres, so that the matrix consists of *extrinsic fibres* (of Sharpey) derived from the tooth follicle, and *intrinsic fibres* derived from cementoblasts. The former lie roughly at right angles to, and the latter roughly parallel to the developing surface. The intrinsic fibres are the first to be mineralized. Sharpey's fibres are then mineralized on their surfaces, and if the cement is being formed rapidly, their cores remain unmineralized.

Cementoblasts frequently become trapped in later formed cement. Areas in which they are trapped are known as *cellular cement*, whilst the remainder is *acellular cement*. Cellular cement tends to be formed around the apical two-thirds of the root, and also during rapid cementogenesis. Incremental lines develop parallel to the surface of the root.

DEVELOPMENT OF PERIODONTIUM

It will be recalled that some of the ectomesenchyme cells of the dental papilla are pushed aside by the growing cervical loop of the enamel organ and come to lie adjacent to the external enamel epithelium. It seems probable that the cementoblasts and the inner layers of periodontal fibres are derived from these cells (Melcher and Bowen 1969; Ten Cate 1974). The remainder of the periodontal ligament is developed from the outer layers of the tooth follicle which, since the early developmental stages, has separated the tooth from the bone of its alveolar crypt (**8**.63D). Unlike the inner layer of the follicle, these outer layers have not been associated with the early condensation of mesodermal (ectomesenchymal) cells which contributed to the tooth germ.

Throughout eruption of the tooth, as it appears in tissue sections, the oblique fibres of the periodontal ligament run

8.70A and B Pan-oral radiographs of the whole dentition of the upper and lower jaws of a mature human skull. To achieve these radiographs, an X-ray source is introduced into the buccal cavity and directed towards the palate for the upper jaw, and towards the floor of the cavity for the lower jaw. The X-ray beam is deflected magnetically to disperse anterolaterally, and the film is wrapped around the external aspect of the jaws. The clarity of the radiographs is much greater than that possible during clinical radiography of the living head. (The radiographs were kindly prepared by Mrs. D. White of the X-ray Department of the Royal Dental Hospital, London.) Note: the right lower third molar is missing.

coronally from the cement into the bony wall of the crypt (**8**.61). It will be appreciated that if these fibres remained unbroken with further movement of the tooth towards the oral cavity, they would finally be directed apically from the cement to the bone of the crypt. Based on the appearance of tissue sections, it was at one time thought that fibres joining cement to bone were formed, broken, and reformed in an *intermediate plexus* (Hindle 1967) in the middle of the ligament. Autoradiographic studies now suggest that fibres are formed and ruptured in a plane close to the alveolar bone (Melcher 1976).

8.71 A lateral radiograph of the jaws of a newborn child. Note the state of development of the jaws and teeth.

DENTAL ERUPTION

When the deciduous dentition is initiated the five tooth buds in each quadrant occupy jaws which are about 1 mm long. By the time the teeth have erupted into the oral cavity they occupy about 3 or 4 cm of jaw; during development these teeth have migrated apart. It is not known how this movement is brought about.

Very soon after root formation starts, the teeth begin to move from their positions in the crypts up towards the oral cavity (Melcher and Bowen 1969). The origin of the forces which move the teeth is not known (Berkovitz 1975). It has been suggested that the lengthening root could induce the movement, or the progressive constriction of the pulp by the growing dentine, or cellular proliferation in the pulp. Such forces involve *pushing* the tooth out of its crypt. Whatever the origin of the force, it has been shown in the dog that the tissue pressure above an erupting tooth is about 10 mm Hg, and within the crown is about 23 mm Hg; in other words an eruptive pressure of 13 mm Hg (van Hassel and McMinn 1972). It has also been suggested that the tooth is progressively *pulled* out of the socket by contractions of the obliquely placed fibres of the developing periodontal ligament (Berkovitz and Thomas 1969).

The permanent incisors and canines develop lingual to their predecessors (**8**.63D, 66). As they develop they migrate buccally but remain slightly lingual to the deciduous teeth. This movement induces the differentiation of osteoclasts from the periodontal ligament of the deciduous tooth, whose root, and ultimately even enamel of the crown, is now intermittently but progressively resorbed (Furseth 1968). In periods of quiescence the resorbed tissues are temporarily repaired by the deposition of thin layers of cement.

Early in their development each premolar moves directly deep to its predecessor to become lodged between widely divergent roots (**8**.46). As the premolar erupts it induces resorption of the deciduous molar. The enamel of the underlying permanent tooth is protected from resorption by its *reduced enamel epithelium* (*see* p. 1297).

Usual times of eruption of the deciduous teeth. (There are considerable variations in these times. *See* **8**.69A–E.)

Central incisors	6–8 months
Lateral incisors	8–10 months
First molars	12–16 months
Canines	16–20 months
Second molars	20–30 months

Calcification of the permanent teeth proceeds in the following order: first molars at birth; incisors (except the upper lateral) and canines about 4 months; upper lateral incisors about 1 year; premolars about 2 years; second molars about 3 years; and third molars about 9 years.

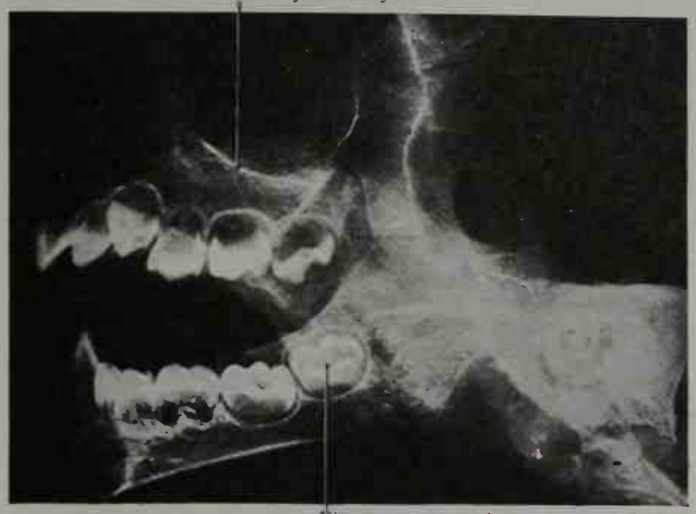
Usual times of eruption of permanent teeth. (The upper teeth erupt a little later than the lower. *See* illustrations **8**.69 A–E.)

First molars	6–7 years
Central incisors	6–8 years
Lateral incisors	7–9 years
Canines	9–12 years
First and second premolars	10–12 years
Second molars	11–13 years
Third molars	17–21 years

ALVEOLAR DEVELOPMENT

The jaws begin to develop at about the time that the dental lamina is being formed. In the lower jaw the growing margin of membrane bone, which remains lateral to Meckel's cartilage, passes backwards caudal to the inferior dental nerve. From this bone, lateral and then medial plates of bone grow cranially (Dixon 1958; Melcher and Bowen 1969). With their apparent down-growth the developing teeth come to lie between the plates (**8**.66). A septum of bone now grows to divide the teeth, above, from the inferior dental nerve; below, and later still, each tooth becomes separated from adjacent teeth by further upgrowths of bone, thereby isolating each tooth in its own *crypt*. These crypts are wide open on their oral sides; bone does not develop over the deciduous teeth, so that in the skeletonized jaws of the neonate, the teeth are usually lost.

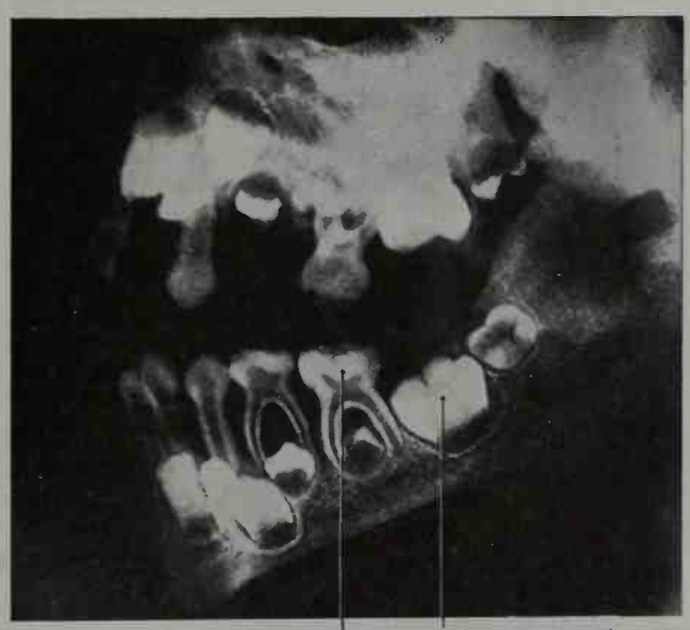
A similar process is involved in the development of crypts in the maxilla.



When the teeth start to move towards the oral cavity, the bone of the socket grows orally, thereby deepening the crypt, increasing the depth of the jaw and carrying the oral mucosa with it. The rate of tooth eruption outstrips the rate of upward bone growth so that the tooth erupts into the oral cavity and finally meets its antagonist. The developing root now starts to penetrate back into the jaw (**8**.68) and some time later the widely open growing apex closes around the nerves and vessels to form the apical foramen.

It is the lengthening of the bony sockets for the accommodation of teeth which leads to the great increase in the depth of the face during and up to puberty (Scott 1967).

CUTICLES AND EPITHELIAL ATTACHMENT



At the end of amelogenesis, the cells of the enamel organ all revert to a squamous shape, becoming a three- or four-cell-thick layer covering the whole surface of the enamel (Gaunt *et al.* 1971). This layer is referred to as the *reduced enamel epithelium*.

When the tooth erupts the reduced enamel epithelium fuses with the oral epithelium so that the junction between the two epithelia cannot usually be recognized. The attachment from tooth to oral epithelium is called the *epithelial attachment* (**8**.32, 68). The oral epithelium grows outside the reduced enamel

8.72A Radiograph of the jaws of an infant, nine months old. (Symington and Rankin's *Atlas of Skiagrams*.) Only the lower central incisor has erupted: the roots of the first lower deciduous molar are just beginning to form; the crown of the first lower permanent molar faces inwards.

epithelium but as the tooth erupts into the oral cavity the reduced enamel epithelium remains attached to the enamel. It is very rapidly worn away from the exposed surface of the tooth. At one time it was thought that the reduced enamel epithelium was separated from the enamel surface by a structureless layer, the *primary enamel cuticle*, about 1 μm thick. This was supposed to be the poorly mineralized, final product of the ameloblasts. Like the reduced enamel epithelium it was rapidly worn from the surfaces of teeth. This cuticle together with the reduced enamel epithelium was called *Nasmyth's membrane*. Because this cuticle cannot be seen under the electron microscope, it is thought to be some form of artefact. However, a form of cement known as *afibrillar cement* has been observed over the enamel around the necks of teeth (Listgarten 1966). Afibrillar cement is only about 100 nm thick, contains no banded collagen, and is probably produced by cementoblasts, following the early disruption of a few cells of the reduced enamel epithelium, at the neck of the tooth.

8.72B Radiograph of the teeth of a boy, aged five years. (Symington and Rankin's *Atlas of Skiagrams*.) In the maxilla the lateral deciduous incisor and the first deciduous molar have been lost, but all the deciduous teeth are present in the mandible. No absorption of the roots of the deciduous teeth has occurred. No permanent teeth have erupted.

Occasionally a cuticle, about 4 μm thick, is found either just beneath the reduced enamel epithelium, or the oral epithelium when it has grown on to the cement. This is the *secondary cuticle*. It may be a product of the epithelial cells, or it may be the remains of blood which has leaked through the epithelial attachment following some slight trauma (Hodson 1966).

Finally, inspissated mucus and debris form a film over the tooth surfaces. This film or cuticle is known as the *acquired cuticle*, and is the foundation of *dental plaque*.

APPLIED ANATOMY

The cortical plate of bone in each jaw is continuous over the alveolar crest with the cortical plate lining each tooth socket (the *lamina dura* of radiographs, **8**.70, 71, 72). Apart from the region of the upper lateral incisor these two cortical plates fuse buccally, with very little trabeculated bone between them (Sicher and Du Brul 1970). It is easier, and obviously more convenient, to extract these teeth by fracturing the buccal plate of bone and removing the tooth buccally than by fracturing the lingual or palatal plate. The apex of the lateral incisor may sometimes be closer to the palate than to the vestibule of the mouth.

In the *lower jaw* both buccal and lingual plates of bone are relatively thin but the buccal plate steadily thickens in the molar region. This thickening is the external oblique line to which the buccinator muscle is attached. Thus, it is mechanically easier to remove an impacted lower third molar through the lingual than the buccal plate of bone. However, great care is necessary to prevent damaging the lingual nerve in this region.

In the *upper jaw* the buccal bone thickens over the molar teeth in the position of the root of the zygomatic arch.

Abscesses developing in relation to the roots of the teeth ultimately perforate either the lingual or buccal plate of bone. The position of the resultant swelling in the soft tissues is largely determined by the relationship of the sinus (the path taken by infected material) in the bone to the muscle attachments. Thus, in the lower incisor region, because the buccal plate of bone is thin, abscesses break through this plate of bone, generally above the level of attachment of mentalis. Therefore, the swelling is usually in the buccal sulcus. However, occasionally the abscess cavity either opens below mentalis and points on to the face, or lingually, when the abscess points in the floor of the mouth. If an abscess on a lower cheek tooth opens out buccally below the attachment of buccinator the swelling is in the neck; if it is above, then the swelling is in the buccal sulcus. If the abscess opens lingually above mylohyoid the swelling is in the lingual sulcus; if it is below, the swelling is in the neck. Because the mylohyoid line rises posteriorly, third molar abscesses tend to discharge into the neck rather than the mouth.

Apart from those of the canine, which has a long root, abscesses on the upper teeth usually open buccally below, rather than above, the attachment of buccinator. Because its root occasionally is nearer the palate, abscesses of the upper lateral incisor may pass back within the submucosa of the palate to 'point' in the soft palate. Abscesses of the upper canine often open into the facial region just below the corner of the eye. Here, the swelling may obstruct drainage from the 'angular' part of the facial vein (p. 739). The angular vein does not possess valves, and it is therefore possible for infected material to travel through the angular and ophthalmic veins, to enter the cavernous sinus. Abscesses on the palatal roots of upper molars generally open on to the palate.

The upper second premolar, and first and second molars are closely related to the maxillary sinus. In individuals with a large antrum the apices of the roots of these teeth may be separated from the sinus solely by its lining mucosa. Sinus infections may stimulate the nerves entering the teeth, simulating toothache. The upper first premolar and third molar may also be closely related to the maxillary sinus.

With the loss of teeth the alveolar bone may be extensively resorbed. Thus, in the lower jaw of the aged edentulous patient, the mental nerve, which originally passes inferior to premolar roots, may come to lie on the crest of the mandible. In the upper jaw, the maxillary sinus may enlarge to approach the oral surface of the remaining alveolar bone. Lingual to the lower premolars or molars, the upper molars, and in the midline of the palate there are occasional marked bony prominences. These are called a *torus mandibularis*, a *torus maxillaris*, and *torus palatinus* respectively (*see* pp. 316, 305, 341). They may need surgical removal before satisfactory dentures can be fitted.

Severe systemic infections during the time the teeth are developing may lead to faults in enamel development. These are often visible as horizontal lines in the incisor teeth (Compare with Harris's growth lines of bone on p. 245).

DENTAL RADIOLOGY

Due to their dense mineralization the enamel and dentine of teeth can readily be seen in radiographs (**8**.70, 71, 72). The pulp appears as a radiolucent region opening into the radiolucent periodontal ligament. Caries, which attacks teeth through the enamel or root surface, can be easily diagnosed by use of intra-oral radiographs because it demineralizes the teeth.

The root of the tooth is separated from the cortical plate of the socket by the radiolucent periodontal ligament. The cortical plate, being formed of compact bone, can be seen as a radio-opaque line, the *lamina dura*. Chronic infections of the pulp of a tooth lead to the spread of infection into the periodontal ligament and then to resorption of the lamina dura around the apex of the tooth. Thus, in a radiograph, continuity of the lamina dura around the apex of a tooth is usually diagnostic of a healthy apical region, except in cases of acute infection in which there has not yet been time for resorption of bone.

Anteriorly the interdental septum forms a sharp crest between teeth; between the molariform teeth it forms a table. With the onset of periodontal disease, which is the eventual outcome of gingival disease, the bony crest or table of the interdental septum is resorbed. Such resorption can be demonstrated by radiographs and the extent of the periodontal involvement judged.

Radiographs are commonly used to analyse the separation between the roots of the upper teeth and the maxillary sinus; it is not uncommon for the roots of the second premolar and the first and second molar teeth to project into the sinus. Lower third molars are commonly prevented from erupting by impaction against the distal sides of the lower second molars. Radiographs are indispensable in assessing the degree of difficulty to be expected when extracting such impacted third molars. Just superior to the mental spines (genial tubercles) many mandibles exhibit a well defined pit terminating in a canal, which presumably contains either a median blood vessel or perhaps some penetrating collagen fibres connected to the lingual frenulum. This pit, together with a radio-opaque ring of compact bone, can nearly always be seen on radiographs of incisors, and can be used to locate the midline in an edentulous mandible.

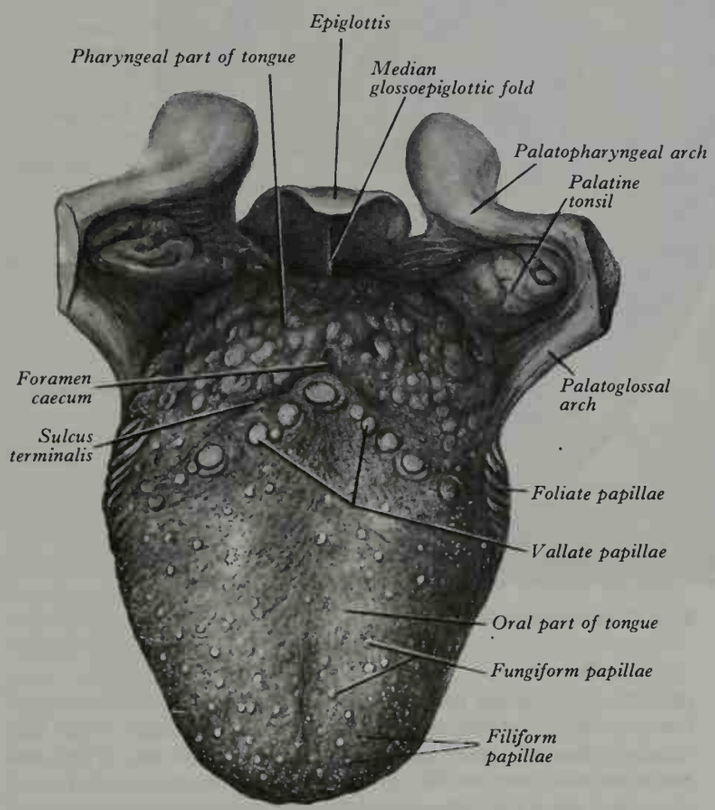
TONGUE, PHARYNX AND OESOPHAGUS

The Tongue

The tongue (**8**.73–75) is a muscular organ associated with the functions of deglutition, taste and speech; it lies partly in the mouth and partly in the pharynx. By its constituent muscles it is attached to the hyoid bone, the mandible, the styloid processes, the soft palate and the wall of the pharynx. It has a root, a tip, a curved dorsum and an inferior surface. Normally, the mucous membrane on its upper surface is moist and pink.

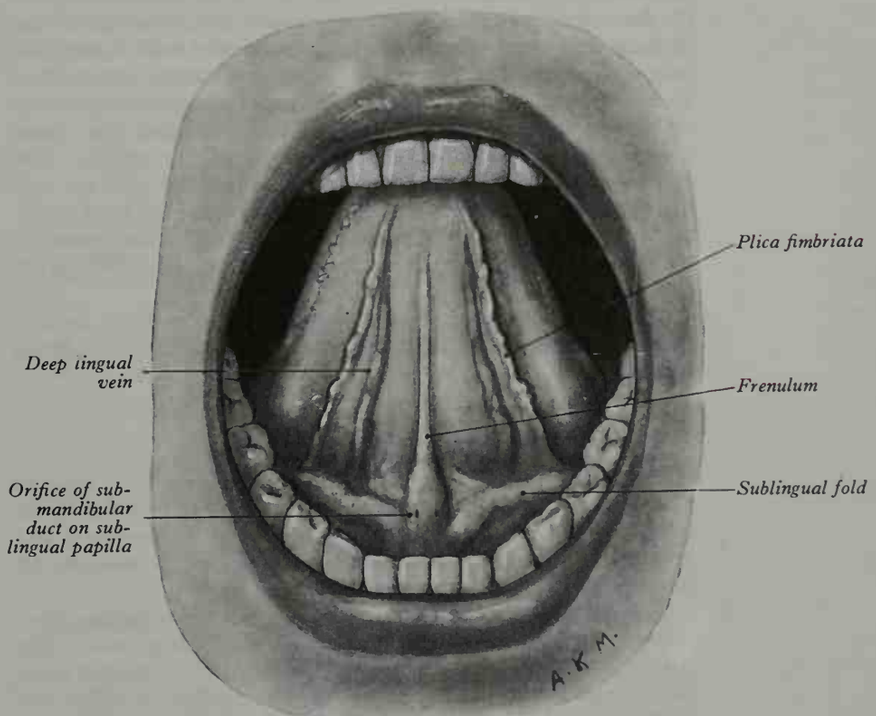
The *root* of the tongue (**8**.74) is attached to the hyoid bone and the mandible, and between these bones is in contact inferiorly with the geniohyoid and the mylohyoid muscles. The *dorsum* (or

posterosuperior surface) is generally convex in all directions in the resting state, and is divided into an anterior part which faces superiorly, and a posterior part which faces posteriorly. These two parts are separated by a V-shaped furrow, termed the *sulcus terminalis*, the limbs of which run laterally and forwards from a median pit, named the *foramen caecum*, to the palatoglossal arches (**8**.73). The foramen caecum marks the site of the upper end of the thyroid diverticulum (p. 198), and the sulcus terminalis serves as the boundary between the oral part (or anterior two-thirds), and the pharyngeal part (or posterior one-third) of the tongue. These two parts differ in the structure of their covering mucous membrane, in their nerve supply and in their development (pp. 197, 1306). (They are more suitably referred to as *presulcal* and *postsulcal* parts.)



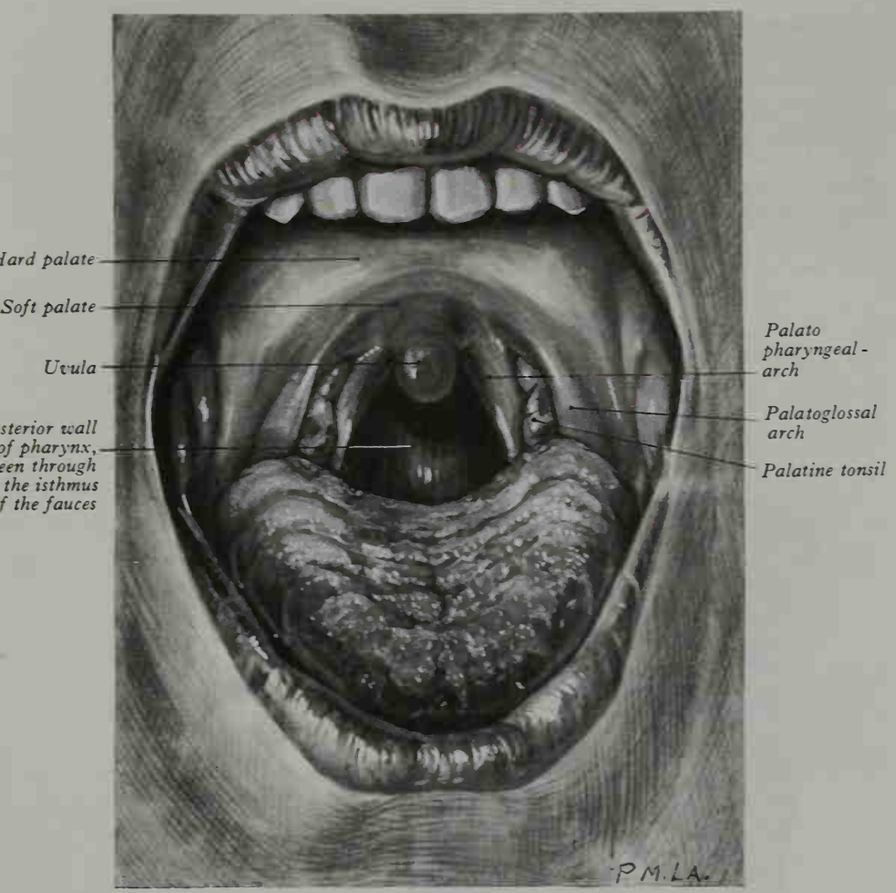
The oral part of the tongue (**8**.73, 74) is placed in the cavity and floor of the mouth; its *apex* rests against the incisor teeth; its *margin* is free and in contact with the gums and teeth; its *superior surface* is in relation with the hard and soft palates. On each border, just in front of the palatoglossal arch, there are four or five vertical folds, named the *foliate papillae* (**8**.73). The mucous membrane of the superior surface of the oral part is marked by a median furrow (**8**.73, 74), is intimately adherent to the subjacent muscle, and is covered with papillae. The mucous membrane on the inferior surface is smooth, and of a purplish colour; it is reflected from the tongue to the floor of the mouth and the gums. In the median plane it is connected to the floor of the mouth by the frenulum linguae (**8**.74). Lateral to the frenulum, the deep lingual vein is visible through the mucous membrane, and at the lateral side of the vein there is a fringed fold of mucous membrane, named the *plica fimbriata*, which is directed forwards and medially towards the apex. The oral part of the tongue is developed from the lingual swellings of the mandibular arch, and to a small extent from the tuberculum impar (p. 197). Its nerve of ordinary sensation is the lingual, its nerve of taste, the chorda tympani. (For the origin of the lingual musculature *see* p. 154.)

The pharyngeal part of the tongue (**8**.73) is posterior to palatoglossal arches; its posterior surface (sometimes named the *base* of the tongue) forms the anterior wall of the oral part of the pharynx. The mucous membrane covering it is reflected laterally on to the palatine tonsils and the pharyngeal wall, and posteriorly on to the epiglottic folds. It is devoid of papillae, but exhibits a number of low elevations, due to the presence of underlying nodules of lymphoid tissue, which are embedded in the submucous tissue and collectively constitute the *lingual tonsil*. The pharyngeal part of the tongue is developed from the hypobranchial eminence (p. 197). Its nerves of ordinary sensation and taste are derived from the glossopharyngeal. The branches of the glossopharyngeal nerve extend beyond the sulcus terminalis to supply taste fibres to the vallate papillae, an arrangement which is explained by the forward extension of the part of the hypobranchial eminence derived from the third pharyngeal arch over the posterior part of the lingual swellings (p. 197).



The papillae of the tongue (**8**.73) are projections of the lamina propria which cause elevations of the epithelium above the general level of the lingual surface. They are thickly distributed over the anterior region of the dorsum, giving to this part its characteristic roughness, and are named *papillae vallatae, fungiformes, filiformes* and *simplices*. The papillae are limited to the anterior, presulcal, area of the tongue and are modifications of the mucous membrane visible to the naked eye and designed to increase the area of mucous membrane coming into contact with the fluid which is being tasted. The taste buds (for details, see p. 1138), however, are microscopic specialized cellular arrangements about the endings of the nerves of taste and are much more widespread than the papillae (e.g. entire dorsum and sides of tongue, epiglottis and lingual surface of the soft palate); each of these regions will therefore be innervated by the appropriate nerve of taste (facial, glossopharyngeal, or vagus). The papillae are more readily visible in the living if the tongue is dried.

The *vallate papillae* (**8**.73) are of large size, and vary from eight to twelve in number. They are situated on the dorsum of the tongue, and form a V-shaped row immediately in front of and parallel with the sulcus terminalis. Each papilla is from 1 mm to 2 mm in diameter, and is attached within a circular depression of the mucous membrane; each depression is surrounded by a wall (vallum) separated from the papilla by a circular sulcus (**8**.76). The papilla is like a truncated cone, the smaller end attached to the tongue; the broader end projects above the general surface of the tongue, and shows numerous small secondary papillae subjacent to the epithelium. The entire papilla and surrounding sulcus are covered with stratified squamous epithelium, and in both walls of the sulcus taste buds abound.



The *fungiform papillae* (**8**.73, 77), more numerous than the

8.74 The cavity of the mouth. The tip of the tongue is turned upwards. In the person from whom the drawing was made the two sublingual papillae formed a single median elevation (*see* p. 1275).

8.75 The cavity of the mouth.

preceding, are found chiefly at the sides and apex of the tongue, but are usually scattered irregularly and sparingly over the dorsum, though sometimes they may be numerous. They are distinguished from the filiform papillae by their large size, round shape and deep red colour; each has secondary papillae beneath the epithelium and bears taste buds.

The *filiform papillae* (**8**.77), also called conical papillae because of the conical epithelial cap they bear, cover the presulcal area of the dorsum of the tongue. They are minute, conical or cylindrical in shape, and arranged in rows which run parallel with those of the vallate papillae, excepting at the apex of the tongue, where their direction is transverse. The filiform papillae display numerous secondary connective tissue papillae, but these are more pointed than the secondary vallate and fungiform papillae. The epithelium covering the filiform papillae may be split up into filamentous processes, each of which forms the apex of one of the secondary papillae; these processes are of a whitish tint, owing to the thickness and density of the epithelium, the cells of which are elongated and keratinized.

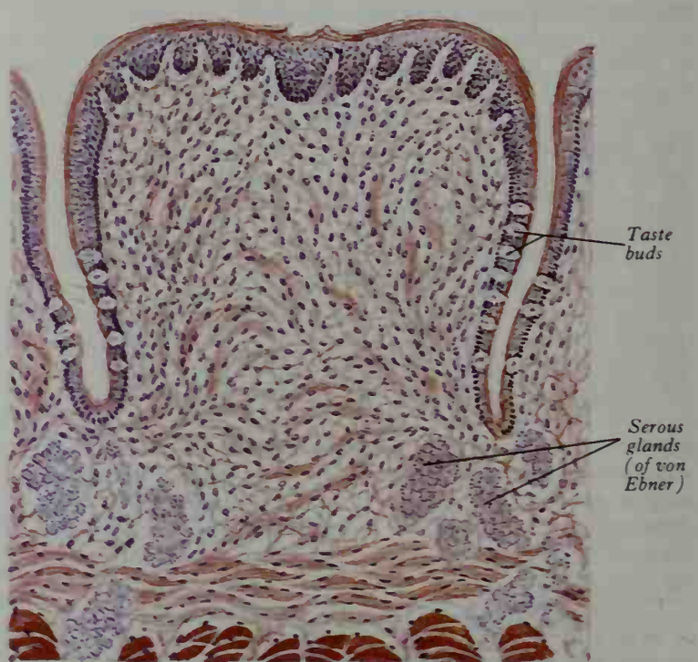
The *papillae simplices* are similar to the papillae of the corium (dermis) of the skin (p. 1217), and cover the whole of the mucous membrane of the tongue, including the larger papillae.

THE LINGUAL MUSCULATURE

The tongue is divided into right and left halves by a median fibrous septum, which is fixed below to the body of the hyoid bone. In each half there are two sets of muscles, extrinsic and intrinsic (**8**.78, 79); the former have attachments outside the tongue, the latter are contained within it.

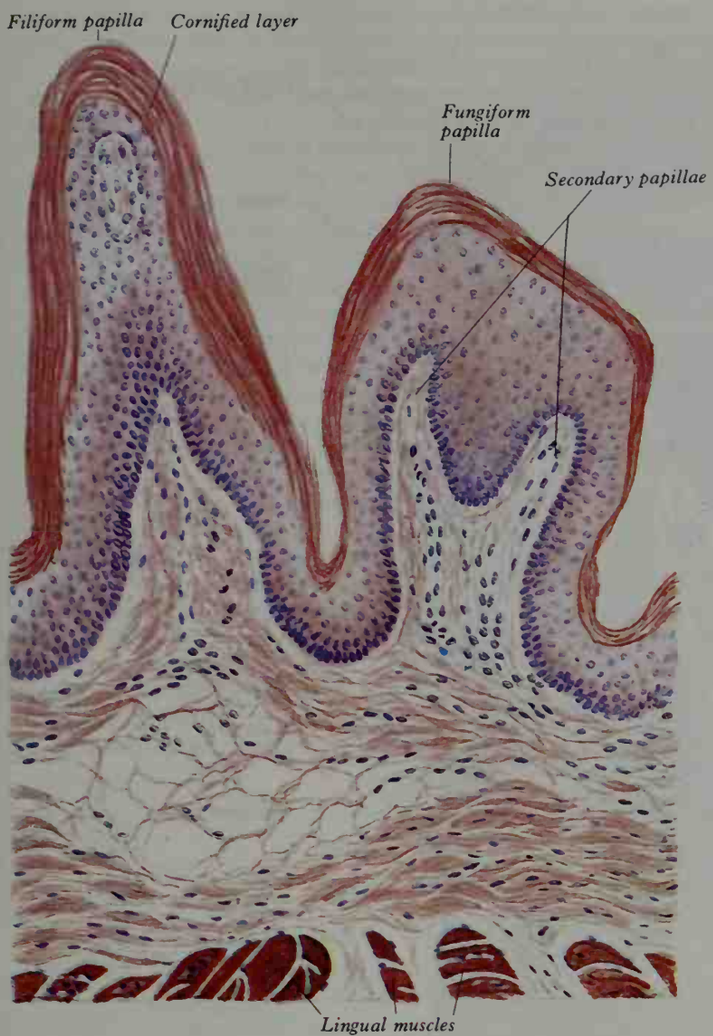
The *extrinsic muscles* (**8**.79) include the genioglossus, hyoglossus, styloglossus, chondroglossus and palatoglossus. The palatoglossus, although one of the muscles of the tongue, is more closely associated with the soft palate in situation, function and nerve supply; it is consequently described with the muscles of that structure (p. 1271).

The genioglossus is a triangular muscle placed close to and parallel with the median plane. It arises by a short tendon from the upper genial tubercle on the inner surface of the symphysis of the mandible, just above the origin of the geniohyoid, and spreads out in a fan-like form. The inferior fibres are attached by a thin aponeurosis to the upper part of the anterior surface of the body of the hyoid bone, close to the midline, a few passing between the hyoglossus and chondroglossus to blend with the middle constrictor of the pharynx; the middle fibres pass backwards, and the superior ones upwards and forwards, to enter the whole length of the ventral surface of the tongue, from the root to the apex, intermingling with the intrinsic muscles. The muscles of opposite sides are separated posteriorly by the septum of the tongue (p. 1306); in front, they are more or less blended owing to the decussation of fasciculi in the median plane. A recent study of this muscle in several mammals, including man, suggest that its fibres fall short of the apex of the tongue (Doran and Baggett 1972).



Actions. The genioglossus draws the tongue forwards and protrudes its apex from the mouth. The two muscles acting in their entirety draw the median part of the tongue downwards so as to make the superior surface concave from side to side.

The hyoglossus, thin and quadrilateral, arises from the whole length of the greater cornu and the front of the lateral part of the body of the hyoid bone; it passes almost vertically upwards and enters the side of the tongue, between the styloglossus laterally, and medially the inferior longitudinal muscle. The fibres arising from the body of the hyoid bone overlap those from the greater horn.



Relations. The hyoglossus is in relation by its *superficial surface* with the tendon of the digastric, the stylohyoid, styloglossus and mylohyoid, the lingual nerve and the submandibular ganglion, the sublingual gland, the deep portion of the submandibular gland and the submandibular duct, the hypoglossal nerve and the deep lingual vein. By its *deep surface* it is in relation with the stylohyoid ligament, the genioglossus, the inferior longitudinal muscle, the lingual artery and the glossopharyngeal nerve. In its lower and posterior part, it is separated from the middle constrictor by the lingual artery. This portion of the muscle lies in the lateral wall of the pharynx, a little below the tonsil. The following structures pass deep to the posterior border of the muscle, in order from above downwards: the glossopharyngeal nerve, the stylohyoid ligament and the lingual artery.

Action. The hyoglossus depresses the tongue.

The chondroglossus is sometimes described as a part of the hyoglossus, but it is separated from that muscle by fibres of the genioglossus which pass to the side of the pharynx. It is about 2 cm long, and arises from the medial side and base of the lesser cornu and contiguous part of the body of the hyoid bone; it

8.76 Section through a vallate papilla. Stained with haematoxylin and eosin. Magnification about × 32. (After Sobotta.)

8.77 Section through a filiform papilla and an adjoining fungiform papilla. Stained with haematoxylin and eosin. Magnification about × 30. (Drawn from a preparation kindly lent by Dr. E. E. Hewer.)

ascends and blends with the intrinsic muscular fibres of the tongue, between the hyoglossus and genioglossus.

A small slip arises occasionally from the cartilago triticea in the lateral thyrohyoid ligament and enters the tongue with the posterior fibres of the hyoglossus.

Action. The chondroglossus assists the hyoglossus in depressing the tongue.

The styloglossus, the shortest and smallest of the three styloid muscles, arises from the anterior and lateral surfaces of the styloid process, near its apex, and from the upper end of the stylomandibular ligament. Passing downwards and forwards, it divides upon the side of the tongue into two portions; one, longitudinal, enters the side of the tongue near its dorsal surface, blending with the inferior longitudinal muscle in front of the hyoglossus; the other, oblique, overlaps the hyoglossus and decussates with its fibres.

Action. The styloglossus draws the tongue upwards and backwards.

Nerve supply. With the exception of the palatoglossus (p. 1272) all the extrinsic muscles of the tongue are supplied by the hypoglossal nerve.

The *intrinsic muscles* are the superior and inferior longitudinal, the transverse and the vertical.

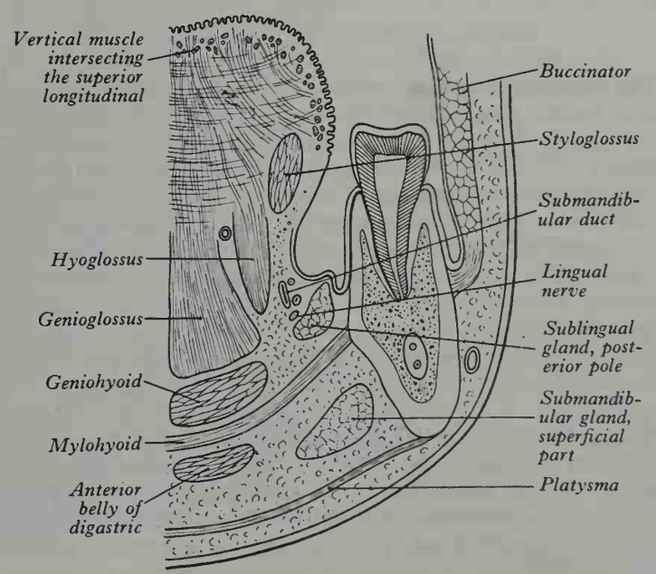
The superior longitudinal muscle of the tongue is a thin stratum of oblique and longitudinal fibres immediately subjacent to the mucous membrane on the dorsum of the tongue. It arises from the submucous fibrous layer close to the epiglottis and from the median fibrous septum, and runs forward to the edges of the tongue, some of its fibres being inserted into the mucous membrane.

The inferior longitudinal muscle of the tongue is a narrow band close to the inferior surface of the tongue between the genioglossus and hyoglossus. It extends from the root to apex of the tongue, some of its posterior fibres being connected with the body of the hyoid bone; in front it blends with the fibres of the styloglossus.

The transverse muscle of the tongue consists of fibres which arise from the median fibrous septum and pass laterally to be inserted into the submucous fibrous tissue at the sides of the tongue, and to blend with the palatopharyngeus (p. 1271).

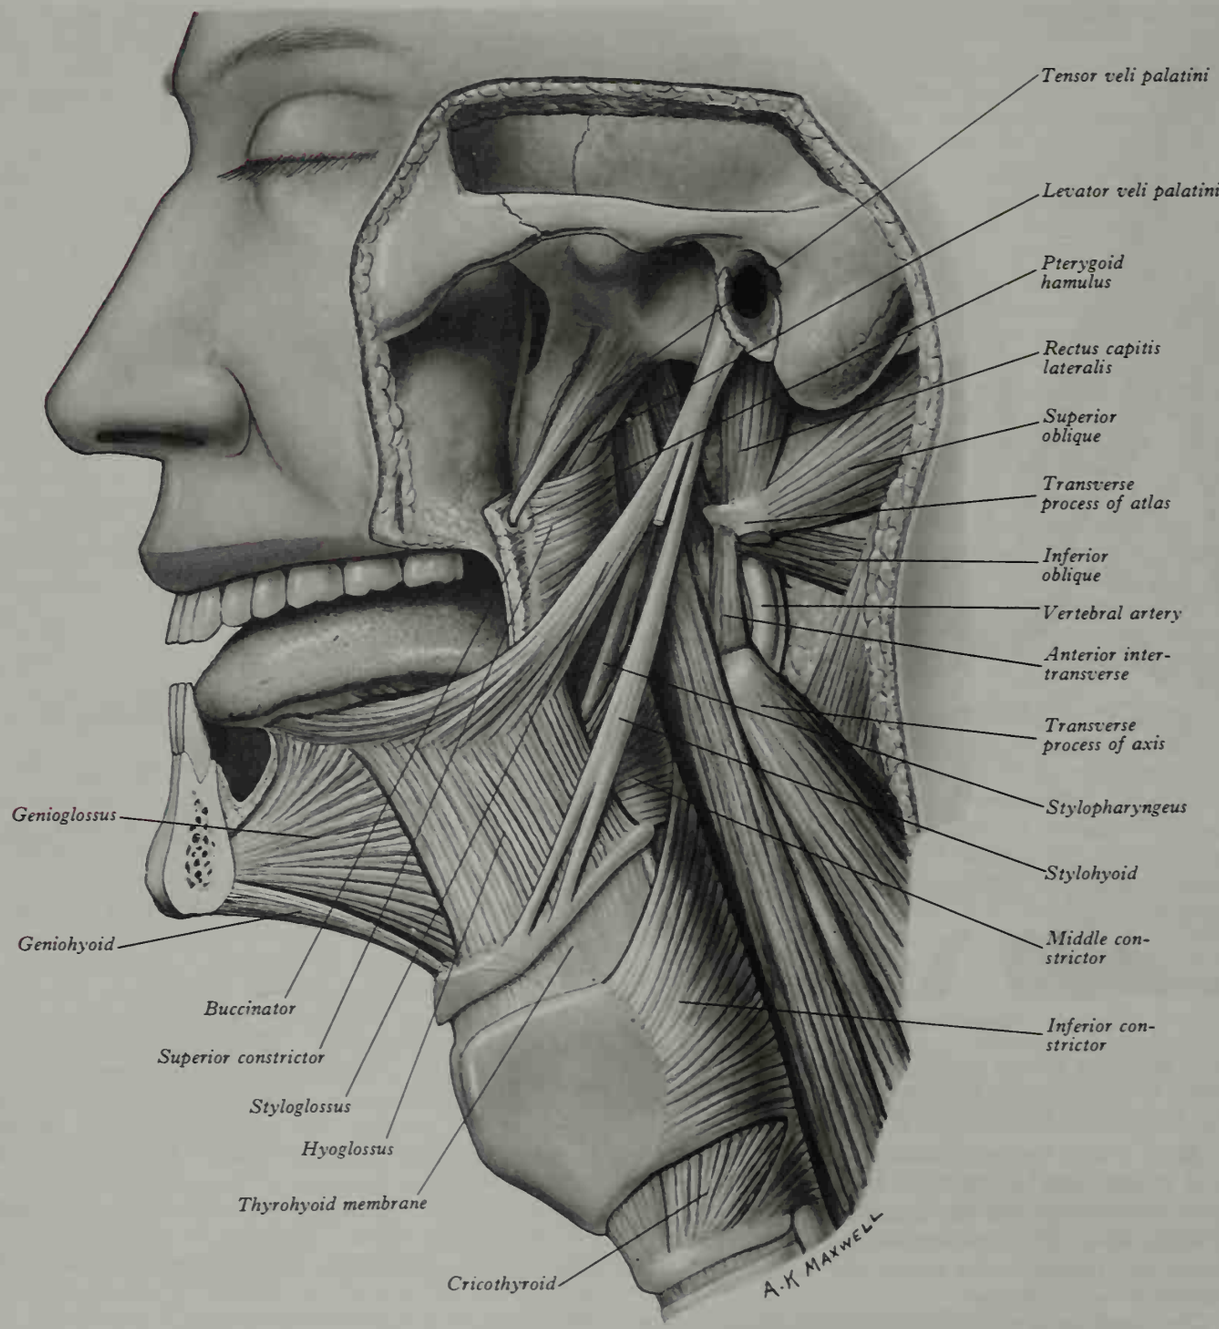
The vertical muscle of the tongue is found at the borders of the fore part of the tongue. Its fibres extend from the dorsal to ventral surfaces of the organ.

Nerve supply. The intrinsic muscles of the tongue are supplied by the hypoglossal nerve.



Actions. The intrinsic muscles are mainly concerned in altering the shape of the tongue; thus, the superior and inferior longitudinal muscles tend to shorten it, but the former, in addition, turns the tip and sides upwards so as to render the dorsum concave, while the latter pulls the tip downwards making the dorsum convex. The transverse muscle narrows and elongates the tongue, and the vertical muscle renders it flatter and wider. Movements of the tongue are concerned in speech, mastication and deglutition.

LINGUAL STRUCTURE



The tongue consists chiefly of striated muscular tissue, partly invested by mucous membrane.

The *lingual mucous membrane* covering the under surface of the tongue is thin, smooth and identical in structure with that lining the rest of the oral cavity. The mucous membrane of the pharyngeal part of the dorsum of the tongue contains a large number of follicles of lymphoid tissue; each follicle forms a rounded eminence, in the centre of which there is a minute orifice leading into a funnel-shaped cavity or recess; numerous round or oval nodules of lymphoid tissue, each enveloped by a capsule derived from the submucous fibrous layer, are grouped around this recess, which receives the openings of the ducts of some mucous glands in its floor. The mucous membrane on the oral part of the dorsum of the tongue is thin, intimately adherent to the muscular tissue, and covered with numerous *papillae* (p. 1221). It consists of connective tissue (*lamina propria*) covered with stratified squamous epithelium, which also covers each papilla.

The *lamina propria* consists of a dense feltwork of fibrous connective tissue, with numerous elastic fibres, firmly united with the fibrous tissue between the muscular bundles of the tongue. It contains the ramifications of the numerous vessels and nerves from which the papillae are supplied, large plexuses of lymph vessels and the glands of the tongue.

8.78 Diagram of a coronal section through the tongue, the mouth and the body of the mandible opposite the first molar tooth.

8.79 A dissection showing the muscles of the tongue and pharynx.

The *lingual glands* are of mucous, serous, and mixed varieties.

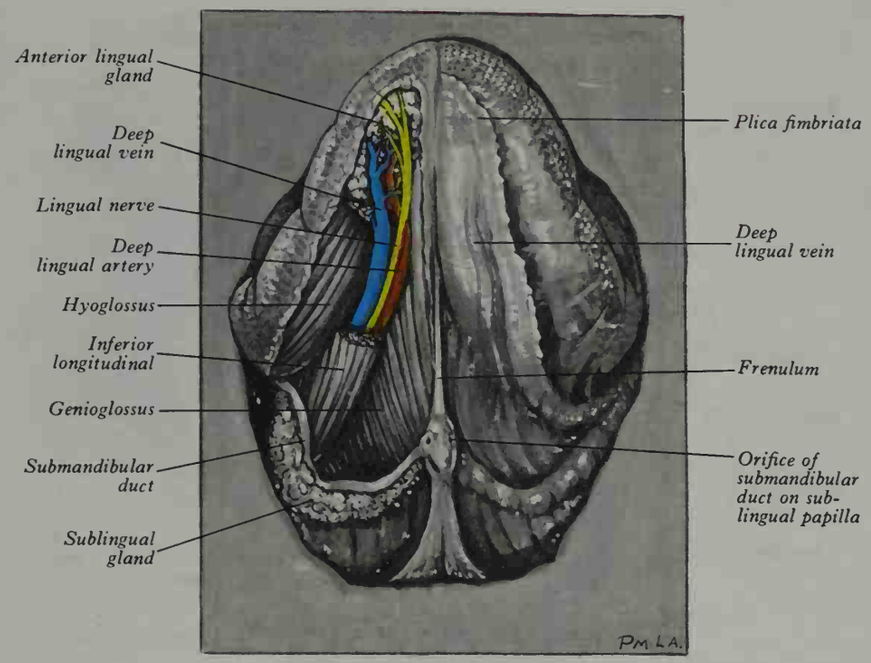
The *mucous glands* are similar in structure to the labial and buccal glands. They are numerous in the pharyngeal region of the tongue, i.e. behind the vallate papillae, but are also present at the tip and margins. The *anterior lingual salivary glands* require special notice. They are situated on the ventral surface of the apex of the tongue (**8**.80), one on each side of the frenulum, where they are covered by the mucous membrane and by a fasciculus of muscular fibres derived from the styloglossus and inferior longitudinal muscles. They are from 12 mm to 20 mm long, and about 8 mm broad; each consists of mucous and serous alveoli, and opens by three or four ducts on the inferior surface of the lingual apex.

The *serous glands* (of von Ebner, **8**.76) occur near taste buds, their ducts opening for the most part into the sulci of the vallate papillae. These glands are racemose; the main duct of each branches into several minute ducts, which end in alveoli lined by a single layer of epithelium. Their secretion is of a watery nature, and probably assists in distributing the substance to be tasted over the taste area, as well as in washing away the substance after it has been tasted.

The *septum* of the tongue is a median fibrous partition which extends throughout the length of the organ, but does not quite reach the dorsum; it gives origin to the transverse lingual muscle, and is well displayed in a coronal section of the tongue. Posteriorly it expands in a transverse direction and forms what is known as the *hyoglossal membrane*; this membrane connects the root of the tongue to the hyoid bone, and the inferior fibres of the genioglossi are attached to it.

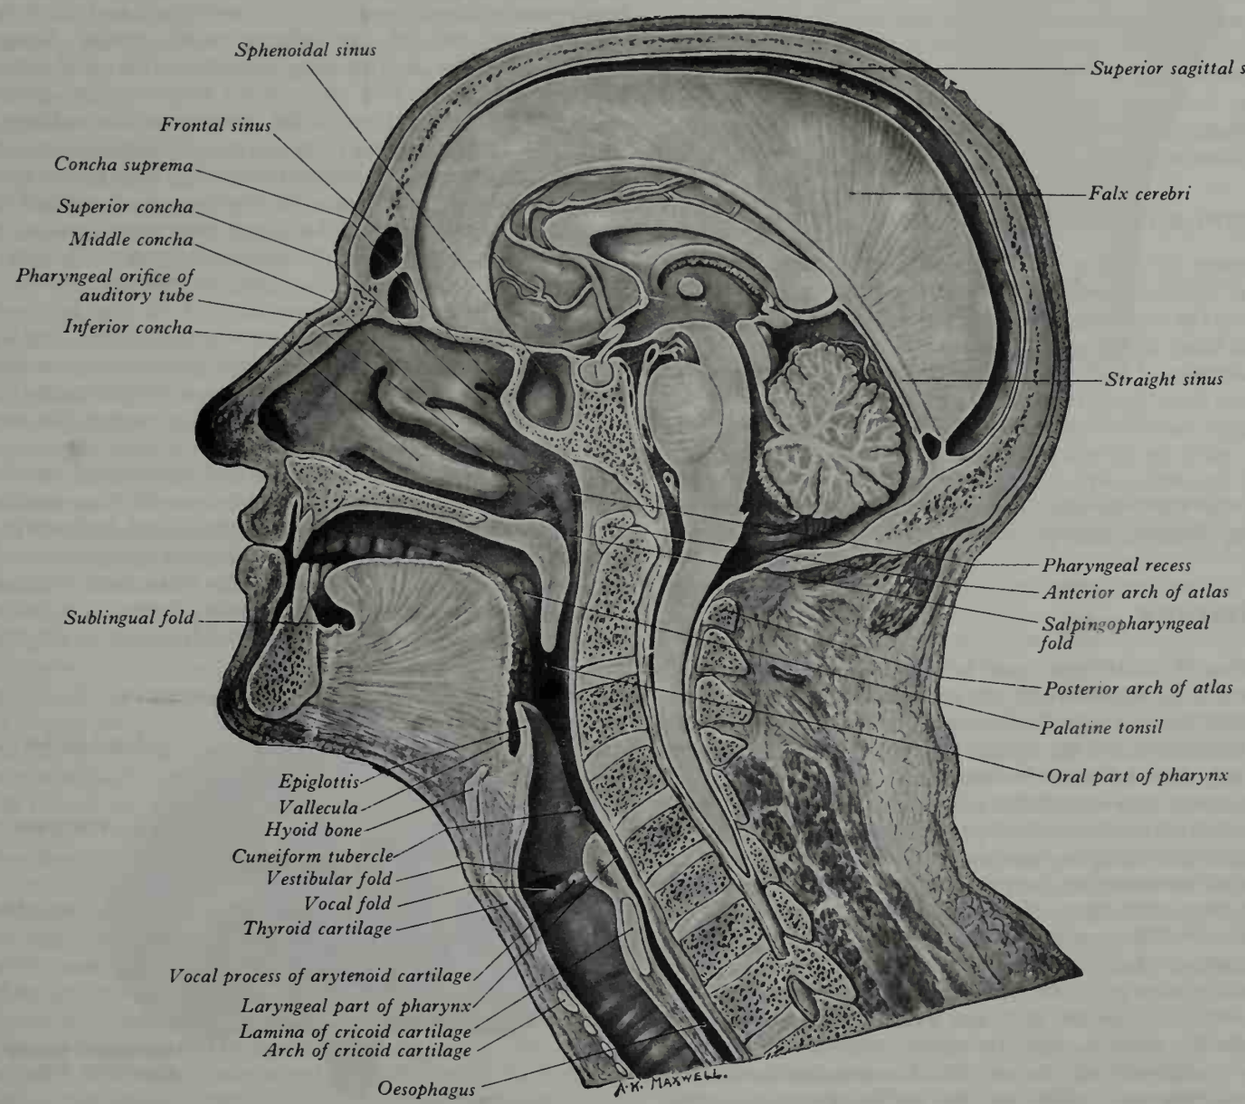
Vessels and Nerves

The main *artery* of the tongue is the lingual branch of the external carotid artery (p. 678), but the tonsillar and ascending palatine branches of the facial and the ascending pharyngeal arteries also give branches to the lingual root. In the vallecula (p. 1231) the epiglottic rami of the superior laryngeal artery anastomose with the inferior dorsal branches of the lingual artery. From this rich anastomotic network the lingual musculature is supplied and a very dense submucosal plexus supplies the mucosa (Combelles 1974). The *veins* are described on p. 742.



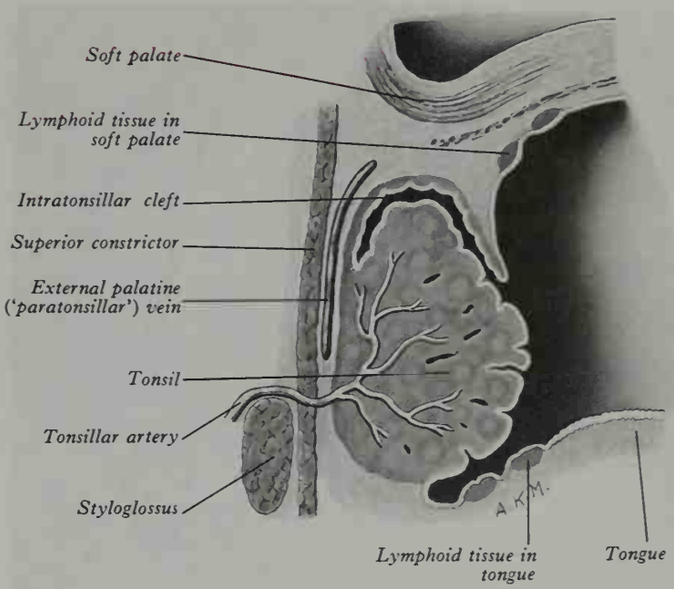
The *lymph vessels of the tongue* are described on **6**.159, p. 788.

The *sensory nerves of the tongue* are: (1) the lingual branch of the



mandibular nerve, which is the nerve of general sensibility for the presulcal region of the tongue; (2) the chorda tympani branch of the facial nerve (p. 1072), which runs in the sheath of the lingual nerve, and is the nerve of taste for the presulcal region exclusive of the vallate papillae (p. 1138) and is partly derived from the nervus intermedius; (3) the lingual branch of the glossopharyngeal nerve (p. 1076), distributed to the mucous membrane at the base and sides of the tongue, and to the vallate papillae, and is the nerve of taste and of general sensibility for this region; (4) the superior laryngeal nerve (p. 1079), which sends some fine branches to the part immediately in front of the epiglottis.

The existence of a proprioceptor apparatus in the tongue is an old problem, the literature of which has recently been extensively reviewed by Fitzgerald and Sachithanadan (1979). Muscle spindles have been demonstrated in monkeys (Bowman 1968) and also in mankind (e.g. Nakayama 1944; Cooper 1953; Kubota *et al.* 1975), and the workers cited above have confirmed these findings on an extensive scale in simian material. The peripheral route of nerve fibres from these undoubted receptor organs is much less clear, the possible pathways being in the lingual or hypoglossal nerves, and also by cervical spinal nerves which communicate with the latter cranial nerve. In the monkey Fitzgerald and Sachithanadan present strong evidence indicating the hypoglossal nerve as the main vehicle of lingual proprioceptor nerve fibres from the intrinsic and extrinsic musculature, while considerable numbers leave the hypoglossal nerve to enter the second and third cervical anterior primary rami.



In the so-called posterior third of the human tongue, that is the

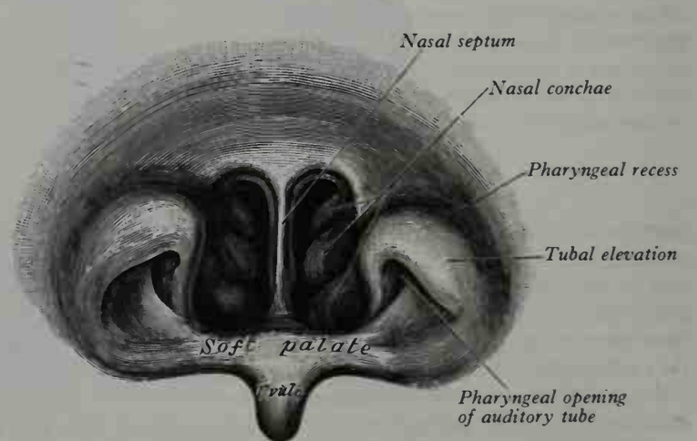
pharyngeal part, caudal to the sulcus terminalis, scattered isolated nerve cells have been observed. It is hypothecated that they are postganglionic parasympathetic neurons, probably innervating glandular tissue and nonstriated muscle in blood vessels (Chu 1968).

Applied Anatomy. Congenital cysts and fistulae may develop from persistent remains of the thyroglossal duct (p. 198).

It is the attachment of the genioglossi to the genial tubercles on the inner surface of the symphysis of the mandible which prevents the tongue from sinking back and obstructing respiration, and, therefore, anaesthetists pull forward the mandible to get the full benefit of this connexion.

THE OROPHARYNGEAL ISTHMUS

The aperture by which the mouth communicates with the pharynx is called the *oropharyngeal isthmus* (**8**.75). Above, it is bounded by the soft palate, below, by the dorsum of the tongue and, at the sides, by the palatoglossal arches.



The *palatoglossal arch* runs downwards, laterally and forwards on each side from the inferior surface of the soft palate to the side of the tongue, and is formed by the projection of the palatoglossus (p. 1271) with its covering mucous membrane. The approximation of the arches, which helps to shut off the mouth from the oral part of the pharynx, plays an important part in the mechanism of deglutition (p. 1313).

The Pharynx

The pharynx (**8**.82–86) is the part of the digestive tube which is placed behind the nasal cavities, the mouth and the larynx. It is a musculomembranous tube, from 12 to 14 cm long, which extends from the basal surface of the skull to the level of the sixth cervical vertebra opposite the lower border of the cricoid cartilage. Its width is greatest at its uppermost part, where it measures 3·5 cm; at the junction of the pharynx with the oesophagus it is reduced to about 1·5 cm, this being the narrowest part of the alimentary canal (exclusive of the vermiform appendix). The pharynx is limited, *above*, by the posterior part of the body of the sphenoid bone and the basilar part of the occipital bone; *below*, it is continuous with the oesophagus; *behind*, it is separated by loose areolar tissue from the cervical portion of the vertebral column and the prevertebral fascia covering the longus colli and longus capitis; *in front*, it opens into the nasal cavity, the mouth and the larynx, and therefore its anterior wall is incomplete. It is attached from above downwards, on each side, to the medial pterygoid plate, pterygomandibular raphe, mandible, tongue, hyoid bone, and thyroid and cricoid cartilages; *laterally*, it communicates with the tympanic cavities through the auditory tubes, and is in relation with the styloid processes and their muscles, the common, internal and external carotid arteries, and some of the branches of the latter artery. The pharynx consists of three parts: nasal, oral and laryngeal (**8**.81).

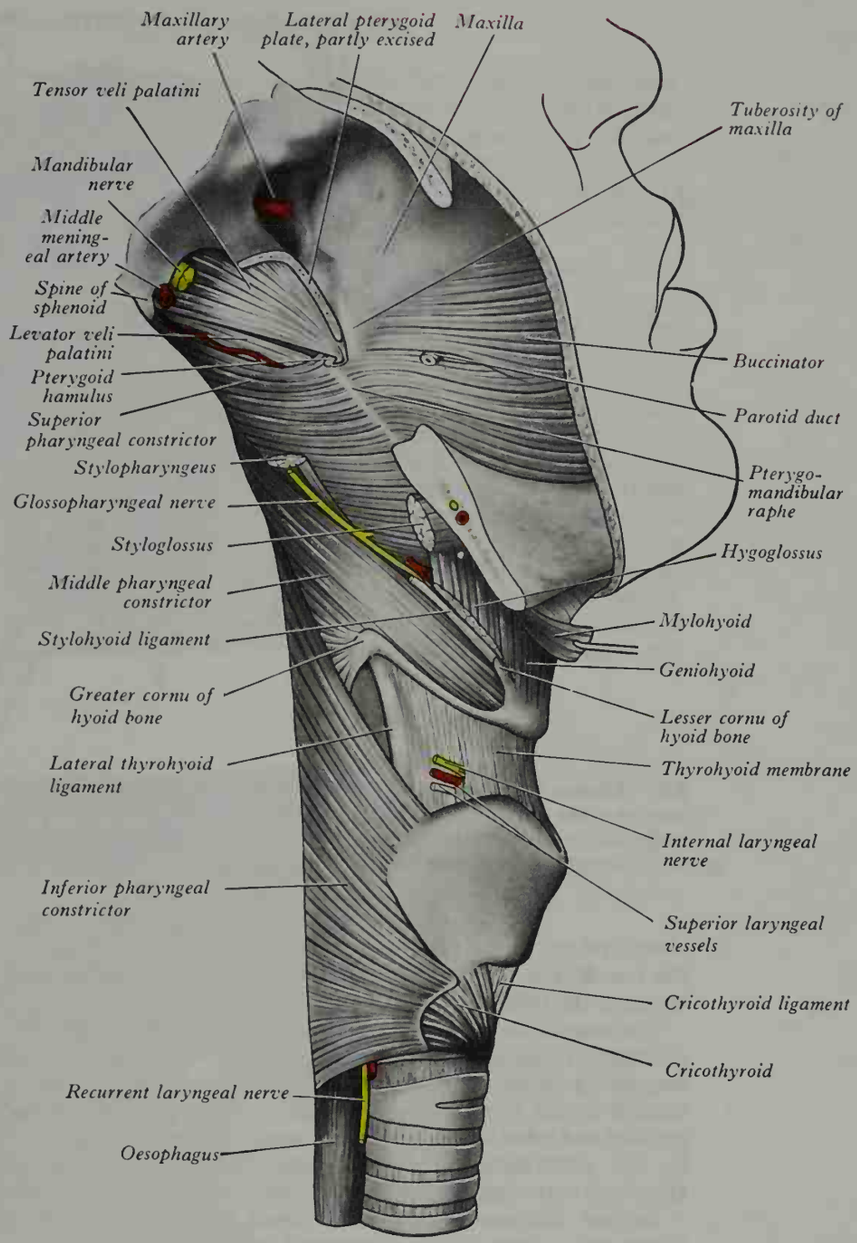
NASAL PART OF THE PHARYNX

The nasal part of the pharynx lies behind the nose and above the level of the soft palate. (From a study of the comparative anatomy of the soft palate, it was suggested by Jones (1940) that the 'nasal part of the pharynx' in man is morphologically an extension of the nasal cavities, and that the soft palate really separates the pharynx from the nasal chambers. This view has been criticized by Leela *et al.* (1974), who consider that the transitional zone between nasal and pharyngeal territories lies just anterior to the orifices of the auditory tubes. They confirm, however, the general concept of nasal and pharyngeal contributions to the region.) With the exception of the soft palate its walls are immovable, and consequently its cavity is never obliterated; in this respect it differs from the oral and laryngeal parts, and resembles the nasal cavities. *Anteriorly* (**8**.81) it communicates with the nasal cavity through the posterior apertures of the nose; these measure about 25 mm vertically, and 12·5 mm transversely, and are separated by the posterior edge of the nasal septum. Between the free edge of the soft palate and the posterior wall of the pharynx the nasal and oral parts of the pharynx communicate through an opening, termed the *pharyngeal isthmus*; in the act of swallowing, this opening is closed by the elevation of the soft palate and the contraction of the palatopharyngeal sphincter (p. 1272). The *lateral wall*, on each side, presents the *pharyngeal opening of the auditory tube*, which lies 10 to 12·5 mm behind and a little below the posterior end of the inferior nasal concha. Somewhat triangular in shape, this opening is bounded above and behind by the *tubal elevation*, a firm prominence which is provided by the underlying pharyngeal end of the cartilage of the auditory tube (p. 1197). The prominent posterior margin facilitates the introduction into the tube of a catheter which has been passed through the nares and along the floor of the nasal cavity. A vertical fold of mucous membrane, termed the *salpingopharyngeal fold*, stretches from the lower part of the tubal elevation downwards in the wall of the pharynx; it contains the *salpingopharyngeus*. A second and smaller fold, termed the *salpingopalatine fold*, stretches from the upper and front part of the elevation to the soft palate. The levator veli palatini, as it enters the soft palate, produces an elevation of the mucous membrane immediately below the pharyngeal opening of the tube (**8**.85). Behind the tubal elevation the mucous membrane lines a recess of variable depth, termed the *pharyngeal recess*. (For literature, radiological and histological details, *see* Khoo *et al.* 1969.) The *roof* and *posterior wall* form a continuous sloping surface which inclines downwards and backwards. It is supported mainly by the basilar part of the occipital bone and, to a lesser extent, by the posterior part of the body of the sphenoid, in front, and the anterior arch of the atlas, below. A collection of lymphoid tissue, best developed in children, lies in the mucous

8.83 Ventral boundary of the nasal part of the pharynx, as seen in posterior rhinoscopy.

membrane of the upper part of this surface and is known as the *pharyngeal tonsil*.

The pharyngeal tonsil is visible to the naked eye during the later months of fetal life and usually increases in size up to the age of six or seven years, after which it not infrequently begins to atrophy. In a child of eighteen months it forms a forwardly projecting pyramidal prominence, the apex of which is near the nasal septum, and the base at the junction of the roof and posterior wall of the nasal part of the pharynx. The prominence consists of a number of folds which radiate forwards and laterally from a median recess, termed the *pharyngeal bursa*, which runs upwards and backwards for some distance into its substance. The folds consist mainly of diffuse lymphoid tissue, but there are also some deeply placed mucous glands. The pharyngeal bursa lies in the base of the pharyngeal tonsil and presents the appearance of a blind recess. In the embryo, the notochord lies for a short distance inferior to the base of the skull, in the region of the developing basilar part of the occipital bone (p. 141); here it is attached to the endoderm forming the roof of the primitive pharynx, and with subsequent growth of this region, the notochordal attachment draws out an angled recess of the endoderm (the *pouch of Luschka*) which forms the pharyngeal bursa. (For bibliographies *see* Cave 1965; Slipka 1972). The lateral prolongation of the pharyngeal tonsil behind the pharyngeal opening of the auditory tube is known as the *tubal tonsil*.

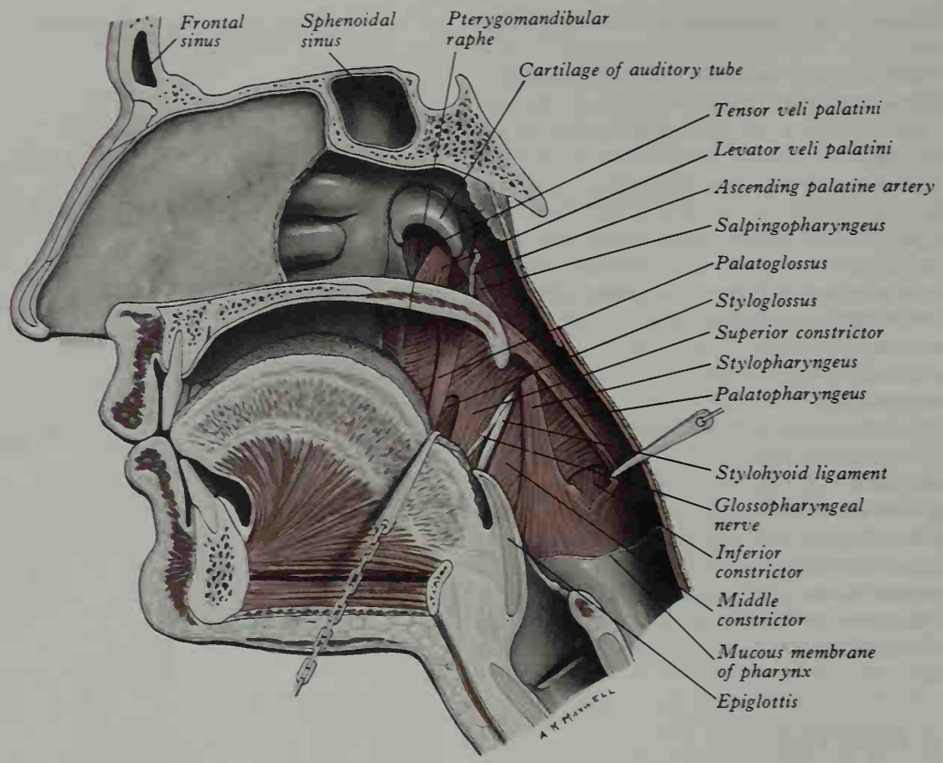


ORAL PART OF THE PHARYNX

The oral part of the pharynx reaches from the soft palate to the upper border of the epiglottis. It opens anteriorly, through the oropharyngeal isthmus, into the mouth and faces the pharyngeal part of the tongue. Its lateral wall presents the palatopharyngeal arch and the palatine tonsil. Posteriorly, it is on a level with the body of the second cervical vertebra and the upper part of the body of the third.

The *palatopharyngeal arch* lies behind and projects further towards the median plane than the palatoglossal arch; it runs downwards, laterally and backwards from the margin of the uvula to the side of the pharynx, and is formed by the projection of the palatopharyngeus (p. 1271), covered with mucous membrane. On each side the palatopharyngeal and palatoglossal arches are separated by a triangular recess, the *tonsillar sinus*, in which the tonsil is contained.

The palatine tonsils (**8**.75) are two masses of lymphoid tissue, situated in the lateral walls of the oral part of the pharynx. Each tonsil is placed in the triangular recess (*tonsillar sinus*) between the diverging palatoglossal and palatopharyngeal arches. Its medial surface is free and forms a conspicuous projection into the pharynx during childhood, but the size of this projection is not a true indication of the size of the organ. Its deep, or lateral, aspect extends upwards, downwards and forwards beyond the limits of the medial surface and is embedded below the level of the mucous membrane. Inferiorly, it extends into the dorsum of the tongue; superiorly, it invades the soft palate; anteriorly, it may extend for some distance embedded beneath the palatoglossal arch. The tonsil is variable in size and is frequently the seat of inflammatory changes involving hypertrophy. As a result it is difficult to decide which of the many varieties encountered is to be regarded as normal. In late fetal life, a free fold of mucous membrane, which extends backwards from the palatoglossal arch, covers the antero-inferior part of the tonsil and is termed the *plica triangularis*. In the child this fold is usually invaded by lymphoid tissue and becomes incorporated into the tonsil; it is only rarely present, as a small, free fold which extends backwards from the lower part of the palatoglossal arch in adults.



The upper part of the tonsil contains a deep *intratonsillar cleft*, frequently and erroneously termed the *supratonsillar fossa*. This cleft does not lie above the tonsil, but actually in its substance, and its upper wall contains a quantity of lymphoid tissue (**8**.82) which may reach a large size and extend into the soft palate. The mouth of the cleft is semilunar in shape and is parallel to the curve of the dorsum of the tongue. After puberty the embedded part of the tonsil diminishes considerably in size and the projecting medial surface becomes flattened and much less prominent.

8.84 The buccinator and the muscles of the pharynx.

The *medial surface* of the tonsil presents from twelve to fifteen orifices leading into deep, narrow recesses, termed the *tonsillar crypts*, which penetrate nearly the whole thickness of the tonsil and from which numerous follicles branch out into the tonsillar substance.

The *lateral* or *deep aspect* is covered by a layer of fibrous tissue, termed the *capsule*. In most of its extent the tonsil and its capsule can easily be separated from the muscular wall of the pharynx, which is formed in this situation by the superior constrictor with the styloglossus laterally (**8**.82, 85). In its antero-inferior part the capsule is firmly connected to the side of the tongue, and behind this point it receives the insertion of some muscular fibres of the palatoglossus and palatopharyngeus. In this situation the tonsillar artery, which is a branch of the facial artery, pierces the superior constrictor and at once enters the tonsil, accompanied by two venae comitantes. An important, and sometimes large, palatine vein (the *external palatine* or 'paratonsillar vein') descends from the soft palate across the lateral aspect of the capsule of the tonsil before piercing the pharyngeal wall (**8**.82). It is this vessel which is responsible for the excessive venous haemorrhage from the upper angle of the tonsillar sinus sometimes encountered in excision of the tonsil (Browne 1928). The muscular wall of the tonsillar sinus separates the tonsil from the ascending palatine artery and, occasionally, from the facial artery itself (p. 679), which, if very tortuous, may be extremely

8.85 Median sagittal section of the head, showing a dissection of the interior of the pharynx, after the removal of the mucous membrane. The bodies of the cervical vertebrae have been removed and the cut posterior wall of the pharynx then retracted dorsolaterally. The palatopharyngeus is drawn dorsally to show the cranial fibres of the inferior constrictor, and the dorsum of the tongue is drawn ventrally to display a part of the styloglossus in the angular interval between the mandibular and the lingual fibres of origin of the superior constrictor.

closely related to the pharyngeal wall opposite the lower part of the tonsil. The internal carotid artery lies 25 mm behind and lateral to the tonsil.

The tonsils form part of a circular band of lymphoid tissue (*Waldeyer's ring*) surrounding the opening into the digestive and respiratory tubes. The anterior and lower part of the ring is formed by the lingual tonsil; the lateral portions consist of the palatine and tubal tonsils; the ring is completed behind and above by the pharyngeal tonsil (p. 1309). Smaller collections of lymphoid tissue exist in the intervals between these main masses.

Surface Anatomy. The palatine tonsil lies behind the third lower molar tooth and is represented by an oval area over the lower part of the masseter, a little above and in front of the angle of the mandible.

Structure. The crypts of the tonsil are lined by stratified squamous epithelium, which is continuous with that of the mucous membrane of the pharynx, and is invaded by numerous lymphocytes; some of the latter pass into the mouth and form the so-called salivary corpuscles. The tonsil consists of lymphoid tissue which is arranged in nodules or follicles. The lymphocytes are less closely packed in the centre of each nodule, which is described as a *germinal centre* (*see* p. 768), because multiplication of the lymphocytes goes on in this situation. The crypts may contain cheesy plugs of living and dead lymphocytes, bacteria and desquamated epithelium; these plugs may be gradually eliminated or may remain and become calcified; the bacteria may cause local infection and suppuration or be absorbed and cause general infection. Unlike lymph nodes, there are no lymph sinuses (p. 769) in the tonsil and it has no *afferent* lymph vessels, but a close plexus of vessels surrounds each follicle and from it *efferent* lymph vessels pass to the upper deep cervical lymph nodes, and especially to the jugulodigastric group of lymph nodes (p. 786).

Vessels and nerves. The chief *artery* supplying the tonsil is the tonsillar branch of the facial artery. In addition, it may receive a few twigs from the dorsal lingual branches of the lingual artery, the ascending palatine branch of the facial artery, the ascending pharyngeal artery, and the greater palatine branch of the maxillary artery.

One or more *veins* leave the lower part of the deep aspect of the tonsil and at once pierce the superior constrictor muscle to join the external palatine ('paratonsillar'), pharyngeal or facial veins.

The *nerves* are derived from the pterygopalatine ganglion, through the lesser palatine nerves, and from the glossopharyngeal nerve. The latter, through its tympanic branch, also supplies the mucous membrane of the tympanic cavity; hence tonsillitis may be accompanied by pain referred to the ear.

LARYNGEAL PART OF THE PHARYNX

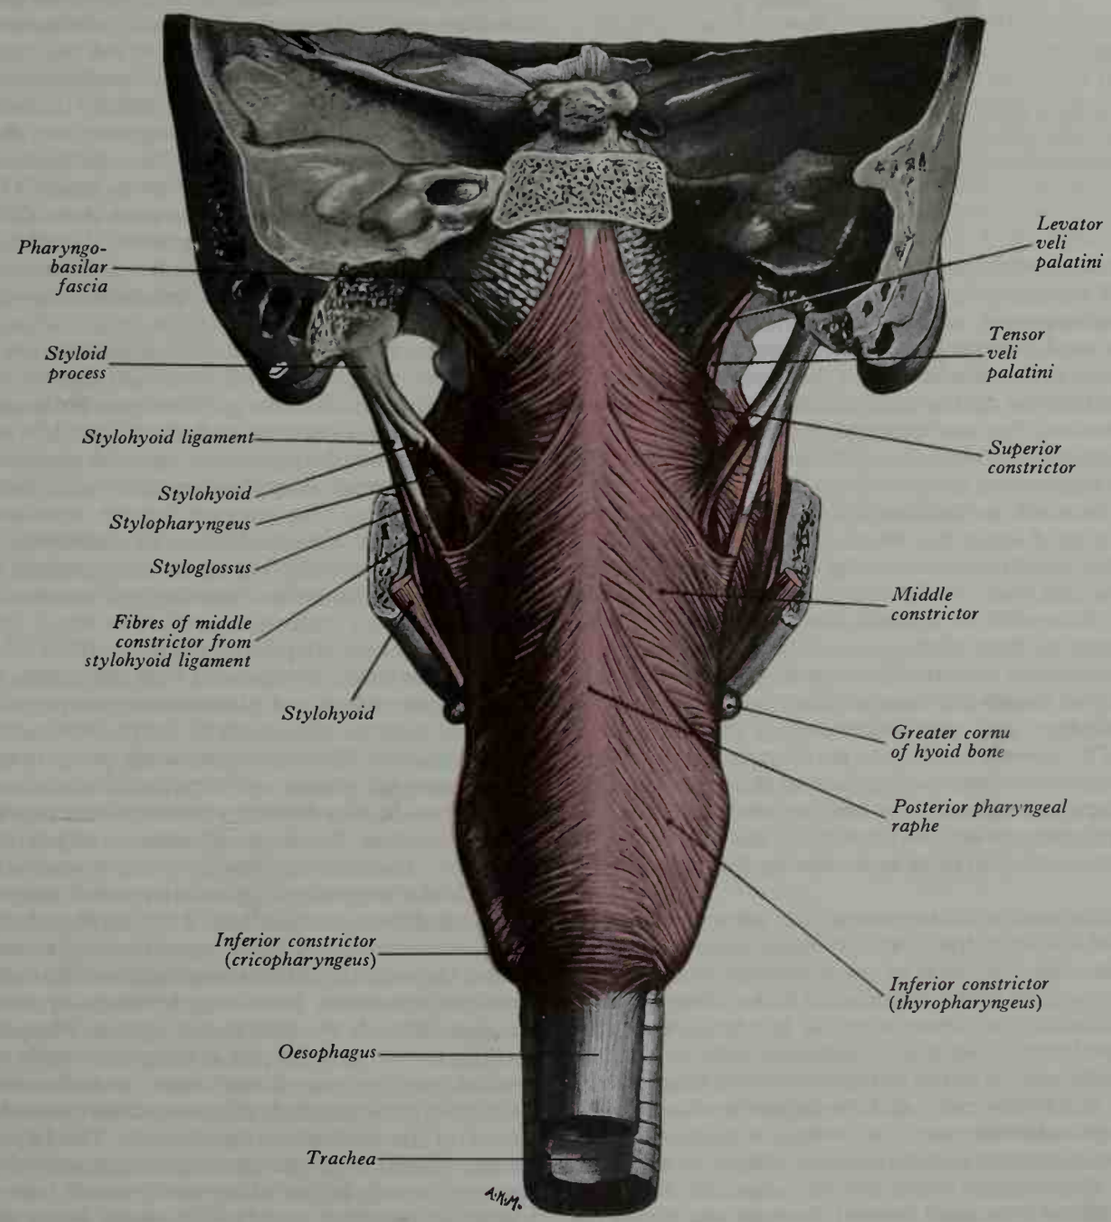
The laryngeal part of the pharynx reaches from the cranial border of the epiglottis to the caudal border of the cricoid cartilage, where it is continuous with the oesophagus. Its anterior wall presents, from above downwards, the inlet of the larynx (p. 1233), and the posterior surfaces of the arytenoid and of the cricoid cartilages. A small recess, termed the *piriform fossa*, lies on each side of the laryngeal orifice; it is bounded, medially, by the aryepiglottic fold and, laterally, by the thyroid cartilage and the thyrohyoid membrane. Beneath the mucous membrane of the piriform fossa lie the branches of the internal laryngeal nerve after they have pierced the thyrohyoid membrane; foreign bodies may lodge in the piriform fossa and, if the instrument employed to remove them pierces the mucous membrane, the nerve is liable to be damaged, with consequent anaesthesia of the part of the mucous membrane of the larynx supplied by the nerve. Posteriorly the laryngeal part of the pharynx is level with the bodies of the third (lower part), fourth, fifth and sixth (upper part) cervical vertebrae.

Structure

The pharynx is usually described as being composed of three tissue laminae from within outwards—mucous, fibrous and muscular, external to the last being the thin buccopharyngeal fascia, which covers the external surface of the constrictor muscles and extends forwards over the pterygomandibular raphe on to the buccinator.

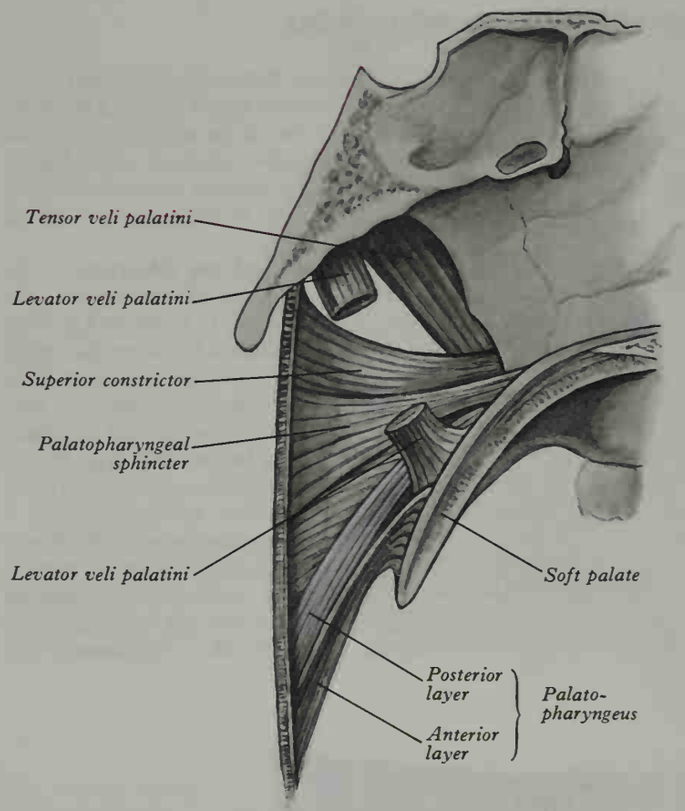
The *mucous membrane* is continuous with that of the auditory tubes, nasal cavity, mouth and larynx. In the nasal part of the pharynx its epithelium is columnar and ciliated; in the oral and laryngeal regions it is stratified squamous. Between the region covered by ciliated columnar epithelium and that covered by

squamous epithelium there is a narrow transitional zone where the epithelium is cubical, and the cilia are imperfect or absent. Superiorly, this zone lies near the nasal septum: laterally it passes over the orifice of the auditory tube and inclines posteriorly at the union of the soft palate with the lateral wall (see also pp. 1270, 1312, 1313). Mucous glands are numerous in the nasal part of the pharynx around the orifices of the auditory tubes.



The *fibrous* intermediate layer lies between the mucous and muscular layers. It is thick above (*pharyngobasilar fascia*) where the muscular fibres are absent, and is firmly connected to the basilar region of the occipital bone and petrous part of the temporal bone medial to the carotid canal, bridging under the auditory tube and extending forwards to be attached to the posterior border of the medial pterygoid plate and to the pterygomandibular raphe. As it descends it diminishes in thickness. It is strengthened posteriorly by a strong fibrous band, which is attached above to the pharyngeal tubercle on the under surface of the basilar portion of the occipital bone, and passes downwards as a median raphe (the *pharyngeal raphe*) which gives attachment to the constrictors. The pharyngeal muscles are usually described as lying external to the fibrous layer. However, the latter is in reality the thickened, deep epimysial covering of the muscles, whilst the thinner external layer of the epimysium constitutes the *buccopharyngeal fascia*.

The *muscular coat* consists of the muscles of the pharynx.



PHARYNGEAL MUSCULATURE

The muscles of the pharynx comprise three *constrictors*, superior, middle and inferior, and a trio of muscles which descend from the styloid process, the cartilaginous torus of the auditory tube and the soft palate. The latter are the *stylo-*, *salpingo-*, and *palatopharyngei* and they descend obliquely into the muscular wall of the pharynx. The palatopharyngeus has already been described (p. 1271).

The inferior constrictor muscle of the pharynx is the thickest of the constrictors and consists of two parts, the cricopharyngeus and the thyropharyngeus. It arises (**8**.84) from the side of the cricoid cartilage in the interval between the origin of the cricothyroid in front, and the articular facet for the inferior cornu of the thyroid cartilage behind (*cricopharyngeus*). It also arises from the oblique line of the lamina of the thyroid cartilage, from a strip of the surface of the lamina behind this line, from a fine tendinous band, which is thrown across the cricothyroid from the inferior thyroid tubercle to the cricoid cartilage, and, by a small slip, from the inferior cornu (*thyropharyngeus*). The fibres spread backwards and medially, and are inserted with the muscle of the opposite side into a fibrous raphe in the posterior median line of the pharynx. The inferior fibres, which are horizontal, are continuous with the circular fibres of the oesophagus and

8.86A The muscles of the pharynx; posterior view. (From Quain's *Anatomy*, 11th ed.)

8.86B The muscles of the left half of the soft palate and adjoining part of the pharyngeal wall. (Dissection by the late Prof. James Whillis, Department of Anatomy, Guy's Hospital Medical School.)

surround the narrowest part of the pharynx; the rest ascend obliquely, and overlap the middle constrictor. During swallowing, the cricopharyngeus acts as the 'sphincteric' part of the muscle (Fuller *et al.* 1959) while the thyropharyngeus acts as the 'propulsive' part; failure of relaxation of the cricopharyngeus may result in a herniation of the pharyngeal mucous membrane posteriorly between the two parts of the muscle (misnamed 'pressure-diverticulum *of the oesophagus*' and sometimes referred to as Killian's dehiscence).

Relations. External to inferior constrictor is the buccopharyngeal fascia. *Behind*, the muscle is in relation with the prevertebral fascia and muscles; *laterally*, with the thyroid gland, the common carotid artery, and the sternothyroid; by its *internal surface*, with the middle constrictor, the stylopharyngeus, the palatopharyngeus and the fibrous coat. The internal laryngeal nerve and the laryngeal branch of the superior thyroid artery run to the thyrohyoid membrane between the upper border of the inferior constrictor and the lower border of the middle constrictor. The external laryngeal nerve runs down on the superficial surface of the muscle, just behind the origin from the thyroid cartilage, and pierces the lower part of the muscle. The recurrent laryngeal nerve and the laryngeal branch of the inferior thyroid artery ascend deep to its lower border, before they enter the larynx.

The middle constrictor muscle of the pharynx is a fan-shaped sheet which is attached anteriorly to the lesser cornu of the hyoid bone and the lower part of the stylohyoid ligament (the *chondropharyngeal* part of the muscle), and to the whole length of the upper border of the greater cornu of the hyoid bone (the *ceratopharyngeal* part). The lower fibres descend deep to the inferior constrictor as far as the inferior end of the pharynx, the middle fibres pass transversely, and the upper fibres ascend and overlap the superior constrictor. It is inserted, with the muscle of the opposite side, into the posterior median fibrous raphe.

Relations. The middle constrictor is separated from the superior constrictor by a small interval, through which pass the glossopharyngeal nerve and the stylopharyngeus, and from the inferior constrictor by the internal laryngeal nerve and laryngeal branch of the superior thyroid artery. *Posteriorly*, it is related to the provertebral fascia, the longus colli and the longus capitis. *Laterally*, it is in relation with the carotid vessels, the pharyngeal plexus of nerves and some lymph nodes. Near its origin it is covered with the hyoglossus, from which it is separated by the lingual artery. Its *internal surface* lies upon the superior constrictor, the stylopharyngeus, the palatopharyngeus and the fibrous coat.

The superior constrictor muscle of the pharynx is a quadrilateral sheet, thinner and paler than the other two. It is attached anteriorly to the pterygoid hamulus, and sometimes to the adjoining part of the posterior margin of the medial pterygoid plate, to the pterygomandibular raphe, to the posterior end of the mylohyoid line on the inner surface of the mandible, and by a few fibres to the side of the tongue (**8**.85). According to the different regions of origin of the muscle (as above), the superior constrictor consists of the following parts: *pterygopharyngeal, buccopharyngeal, mylopharyngeal* and *glossopharyngeal*. The fibres curve backwards into the median raphe, being also prolonged by means of an aponeurosis to the pharyngeal tubercle on the basilar part of the occipital bone. The superior fibres arch beneath the levator veli palatini and auditory tube. An interval exists between the cranial border of the muscle and the base of the skull to give passage to the auditory tube. It is bounded anteriorly by the medial pterygoid plate and is closed by the pharyngobasilar fascia (p. 1311).

A constant band of muscle fibres arises from the anterior and lateral part of the upper surface of the palatine aponeurosis and sweeps backwards, lateral to the levator veli palatini, to blend with the internal surface of the superior constrictor near its upper border (**8**.86B). This band has been termed the *palatopharyngeal sphincter*, producing a rounded ridge on the pharyngeal wall (known as the *ridge of Passavant*), which can be seen when the soft palate is elevated in the living (Whillis 1930). These fibres are much hypertrophied in cases of complete cleft palate. The change from columnar, ciliated 'respiratory' epithelium to tall, stratified squamous epithelium on the superior surface of the soft palate takes place where the palatopharyngeal sphincter is attached to the palate.

Relations. The superior constrictor is in relation by its *external surface* with the prevertebral fascia and muscles, the ascending pharyngeal artery and pharyngeal venous plexus, glossopharyngeal and lingual nerves, the styloglossus, middle constrictor and medial pterygoid, the stylohyoid ligament and the stylopharyngeus. The internal carotid artery, the sympathetic trunk, the hypoglossal nerve, the internal jugular vein and the styloid process are more distant relations. By its *internal surface* it is in relation with the palatopharyngeus, the capsule of the tonsil, and the pharyngobasilar fascia. *Superiorly* it is separated from the base of the skull by a crescentic interval in which the levator veli palatini, the tensor veli palatini and the auditory tube are situated. *Inferiorly* its border is separated from the middle constrictor by the stylopharyngeus and glossopharyngeal nerve. *In front* it is separated from the buccinator by the pterygomandibular raphe.

Nerve supply. The constrictors of the pharynx are supplied by the *pharyngeal plexus* (p. 1079). In addition the inferior constrictor receives branches from the external and recurrent laryngeal nerves. Since the pharynx is largely a derivative of branchial structures (p. 199), its motor and sensory supply, through the trigeminal, glossopharyngeal and vagus nerves, which are all branchial in origin, is to be expected. In addition, the glandular tissue in the pharyngeal mucous membrane and, of course, the nonstriated muscle in the blood vessels of the pharynx entail an autonomic nerve supply which in man reaches the pharynx through the pharyngeal plexus. Postganglionic sympathetic fibres reach the plexus from nerve cells in the superior cervical ganglion via special rami; and the parasympathetic supply, which is preganglionic, issues from the medulla oblongata chiefly in the glossopharyngeal nerve. The latter carries back sensory fibres from the mucous membrane of the oral and laryngeal levels of the pharynx, its nasal part being in the trigeminal region of supply. The vagus nerve carries efferent fibres innervating the striated musculature of the pharynx, but most of those probably emerge from the brainstem in the cranial,

bulbar part of the accessory nerve.

The pharyngeal rami of the glossopharyngeal and vagus nerves and of the superior cervical ganglion communicate in a plexiform manner in the connective tissue external to the pharyngeal constrictors, particularly the intermediate muscle (Hovelacque 1927). From this plexus, which permits intermingling of the autonomic (sympathetic and parasympathetic) and branchial (efferent and afferent) supplies, mixed rami extend cranially and caudally over the exterior of the superior and inferior constrictors. From these rami branches pass into the muscular layer and others through it to the mucous membrane. This is the pattern of innervation common to most primates (Sprague 1944), including mankind. There is evidence that in some lower primates the plexus is absent or much simplified, and may lack its glossopharyngeal or vagal components. In mammals other than primates arrangements are variable, and in many there is no pharyngeal plexus, but precise information is largely lacking—not only as to the source of the main rami supplying the pharynx, but also, and more significantly, their exact brainstem sources and connexions. The marked development of the pharyngeal plexus in man and some other primates may be associated with the elaboration of phonation, but that is perhaps too facile a view, considering the sparseness of factual evidence.

Actions. The constrictors exercise, in general, a sphincteric or peristaltic action in swallowing. For details, *vide infra.*

The stylopharyngeus (**8**.79, 85) is a long, slender muscle which is cylindrical above and flattened below. It arises from the medial side of the base of the styloid process of the temporal bone, descends along the side of the pharynx, passes between the superior and the middle constrictors, and spreads out beneath the mucous membrane. Some of its fibres merge into the constrictors and the lateral glosso-epiglottic fold, while others are inserted with the palatopharyngeus into the posterior border of the thyroid cartilage. The glossopharyngeal nerve winds round the posterior border and the lateral side of the stylopharyngeus and passes through the interval between the superior and the middle constrictors to reach the tongue.

Nerve supply. The stylopharyngeus is supplied by a branch from the glossopharyngeal nerve.

Action. The stylopharyngeus is an elevator of the pharynx in swallowing and speech (*vide infra*).

The salpingopharyngeus (**8**.85) arises from the inferior part of the cartilage of the auditory tube near its pharyngeal opening; it passes downwards and blends with the palatopharyngeus.

Nerve supply. The salpingopharyngeus is supplied by the pharyngeal plexus.

Action. The salpingopharyngeus raises the upper part of the lateral wall of the pharynx, i.e. the part above the attachment of the stylopharyngeus. For its role in swallowing see below.

Vessels and Nerves

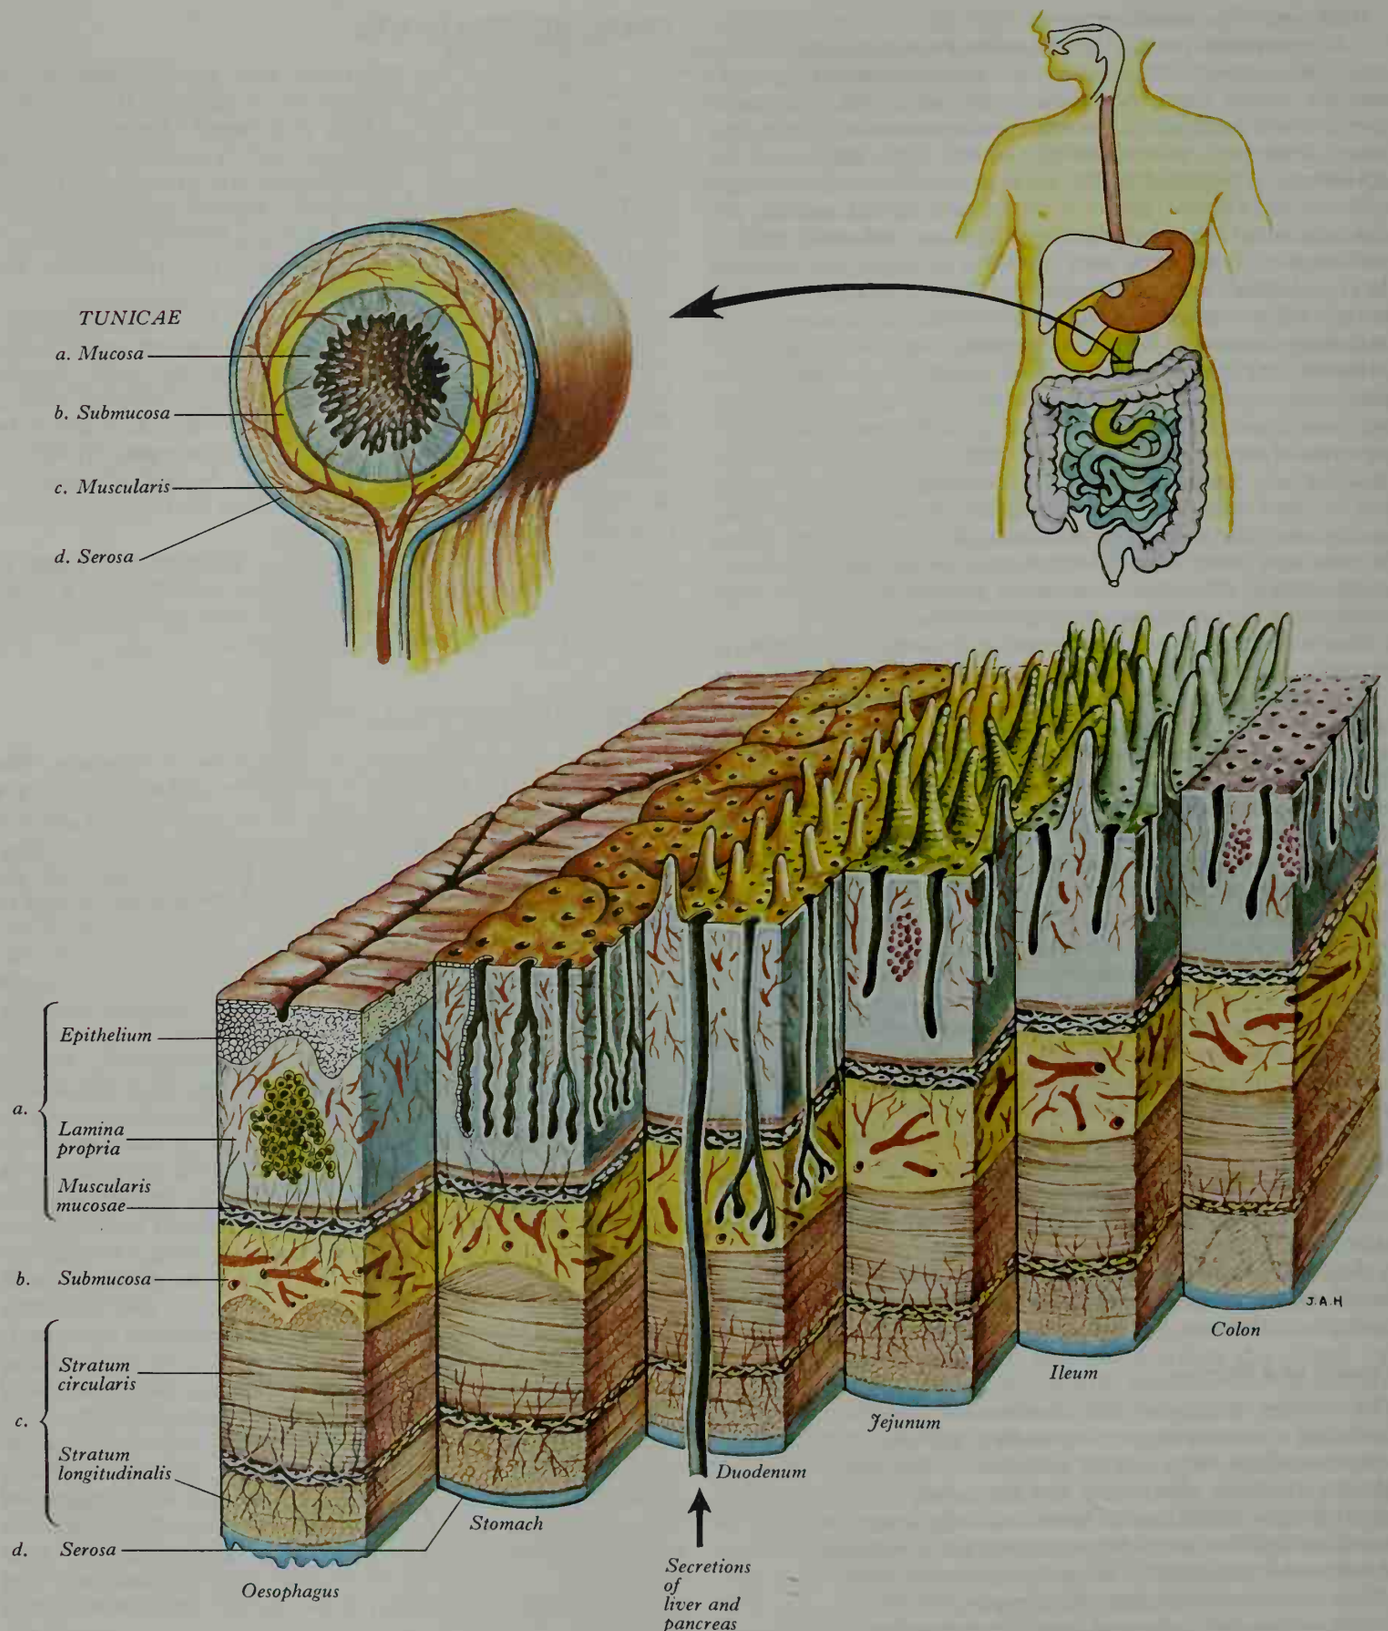
The *arteries* supplying the pharynx are derived from the ascending pharyngeal, the ascending palatine and tonsillar branches of the facial artery, branches of the maxillary artery (greater palatine, pharyngeal and the artery of the pterygoid canal) and the dorsal lingual branches of the lingual artery. The *veins* form a plexus which communicates above with the pterygoid plexus and drains into the internal jugular and facial veins.

The *lymph vessels* are described on pp. 787–789.

The *nerve supply* is derived chiefly from the pharyngeal plexus, which is formed by branches from the glossopharyngeal, vagus and sympathetic. (See also p. 1312.) The principal *motor* element is the cranial part of the accessory nerve, which, through branches of the vagus, supplies all the muscles of the pharynx and soft palate, except stylopharyngeus (supplied by the glossopharyngeal) and the tensor veli palatini (supplied by the mandibular nerve). The main *sensory* nerves are the glossopharyngeal and vagus; much of the mucous membrane of the nasal part of the pharynx is supplied by branches of the maxillary nerve (through the pterygopalatine ganglion); the mucous membrane of the soft palate is supplied by the lesser palatine and glossopharyngeal nerves, as is the tonsil. Proprioceptor nerve endings have not been convincingly demonstrated in the pharynx. (*See* Bossy and Vidić 1967 for a discussion.)

PALATINE MOVEMENTS

The movements of the soft palate play an important part in deglutition, in speech and in the act of blowing, and involve a variable degree of closure of the pharyngeal isthmus (p. 1308), necessitated by these activities. Closure is maximal in blowing out through the mouth, when it is essential to prevent entirely any escape of air through the nose. In deglutition closure of the isthmus prevents the food from passing into the nasopharynx, whilst in speech the closure is maximal in the production of the explosive consonants (e.g. *b*, *p*).



Closure of the isthmus is brought about in the following way. The two levatores veli palatini pull the soft palate upwards and backwards towards the posterior pharyngeal wall. Simultaneously the fibres of the palatopharyngeal sphincter raise a rounded ridge on the posterior pharyngeal wall, which meets the nasal surface of the soft palate over a considerable area. (It is at the upper limit of this area of contact that the mucous membrane on the upper surface of the palate changes from the respiratory to the pharyngeal type.)

The tensor veli palatini is active in deglutition rather than in speech, and by producing a localized depression of the anterior part of the palate (p. 1271) squeezes the bolus against the tongue and so helps its descent in the oral pharynx.

MECHANISM OF DEGLUTITION

The *first stage* of swallowing, or deglutition, is *voluntary*. The anterior part of the tongue is raised and pressed against the hard palate, the movement commencing at the tip of the tongue and spreading backwards rapidly. Thus a bolus formed on the tongue behind the tip is pushed to the posterior part of the mouth. At the end of the first stage, the soft palate closes down on to the back of the tongue to help to form the bolus. The movements of the tongue are effected by the intrinsic muscles, especially the superior longitudinal and transverse. At the same time the hyoid bone is raised and moved forwards by contraction of the geniohyoid, mylohyoid, digastric and stylohyoid. By elevation of the posterior part of the tongue posterosuperiorly by the styloglossi, and approximation of the palatoglossal arches, caused by the contraction of the palatoglossi, the bolus is now passed through the oropharyngeal isthmus into the oral pharynx and the second, or *involuntary*, stage of the act of swallowing begins. In swallowing fluids, the intrinsic tongue muscles are used to squirt the fluid back through the mouth; this is succeeded by contraction of the mylohyoid, which bulges the base of the tongue into the oral pharynx. In swallowing solids, only the latter action is used, except when the mouth is being cleansed of saliva and debris after the bolus has been swallowed (Whillis 1946). Hiiemae *et al.* (1978) have made a highly detailed analysis of the activity of the tongue and hyoid apparatus of muscles in swallowing, using the cat and the opossum as their models. By cine-radiographic and electromyographic techniques they have described cyclical activities in the hyoid muscles (see also p. 581) and have also delineated 'envelopes' of such hyoid activity. They regard the lingual movements as essentially a transport of ingested food, the precise combination of movements of the tongue and hyoid bone depending upon the nature of the ingested material. The extension of these studies to primates is to be awaited with great interest.

In the *second stage*, the soft palate is elevated (by the levator muscles) and tightened (by the tensor muscles). In addition it is closely and firmly approximated to the posterior pharyngeal wall by the contraction of the palatopharyngeal sphincter (p. 1272) and the upper fibres of the superior constrictor. The pharyngeal isthmus is tightly closed and the bolus is prevented from passing upwards. At the same time the larynx is drawn upwards behind the hyoid bone and the pharynx ascends with it. This upward displacement is brought about by the stylopharyngeus, salpingopharyngeus, thyrohyoid and palatopharyngeus muscles. Simultaneously the aryepiglottic folds are approximated and the arytenoid cartilages are drawn upwards and forwards by the contraction of the aryepiglottic, oblique arytenoid and thyroarytenoid muscles. This serves to prevent the bolus from entering

8.87 The general arrangement of the alimentary canal, its mural tunicae, and (below) the general histology at the levels indicated (highly diagrammatic). The transverse colon (above right) has been displaced downwards to reveal the duodenum.

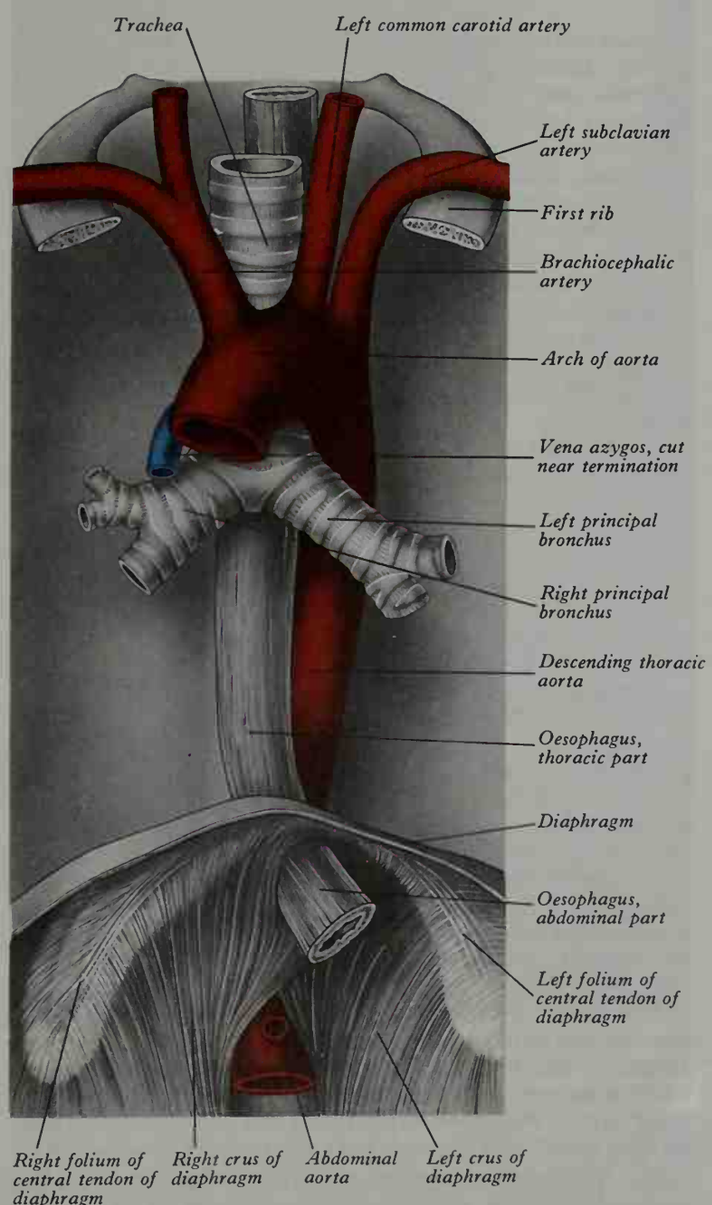
the larynx. Partly under the influence of gravity—when the body is in the erect or sitting posture—and partly urged onwards by the successive contractions of the superior and middle constrictors, the bolus slips over the posterior aspect of the epiglottis, the closed inlet of the larynx and the posterior surfaces of the arytenoid cartilages to gain the lowest part of the pharynx. During this stage its passage is facilitated by the action of the palatopharyngei, which shorten the pharynx and pull it upwards. These two muscles, when contracting, convert the surface of the posterior pharyngeal wall into an inclined plane directed downward and backwards, and on its under surface the bolus descends. The aryepiglottic folds provide lateral food channels leading from the sides of the epiglottis through the piriform fossae to the oesophagus. They are kept more or less tense and upright by the backward pull of the posterior crico-arytenoids on the arytenoid cartilages (to which the folds are attached) and by the muscles in the folds themselves (aryepiglottic and thyro-epiglottic), assisted by the cuneiform cartilages, which act as passive props. In paralysis of these muscles (which are supplied by the recurrent laryngeal nerves), the inlet of the larynx is not

closed during swallowing, the aryepiglottic folds fall medially, and fluids tend to overflow into the larynx.

The *last stage* in the act is effected by the inferior constrictor, which compresses the bolus onwards into the oesophagus (*see* p. 1312).

These stages follow one another in rapid succession, but it is not difficult for the student to satisfy himself, by palpation of the body of the hyoid bone and the laryngeal prominence during the act, that elevation and forward movement of the hyoid bone precede elevation of the larynx and that the amount of upward movement of the thyroid cartilage is considerable. It is important to emphasize that the thyroid cartilage, and hence the whole larynx, ascends also *relative* to the hyoid bone, an action which shortens the larynx, causes structures between the hyoid bone and thyroid cartilage to bulge posteriorly into the larynx above the vestibular folds, and is also a factor in the increase in curvature of the epiglottis, especially its inferior part, thus aiding the stenosis of the aditus to the larynx during swallowing. Fink and Martin (1977) have drawn special attention to this mechanism.

The actual evidence for the foregoing intimate analysis is, of course, not merely the muscular geometry as a basis for hypothecation. Radiological studies, deductions from the effects of known paralyses, electromyographic observations, and, most recently, cine-radiographic technique have all contributed. Swallowing is, however, a highly complex neuromuscular integration, and considerable disagreement over details, which cannot be reflected in this account, exists among the many observers involved. For full critiques and physiological aspects of the extensive literature on this topic consult Bosma (1957); Doty (1968); Hiiemae (1978).



Applied Anatomy. In young children overgrowth of the lymphoid tissue in the nose and nasal part of the pharynx (adenoids), with or without enlargement of the palatine tonsils, may obstruct nasal respiration, making mouth breathing more or less obligatory. As the child has to keep its mouth open in order to breathe, the hard palate and alveolar arch are habitually out of contact with the dorsum of the tongue; lacking its pressure, they develop with an abnormally high arch and forward projection. Thus the hard palate becomes narrowed laterally, and the projecting alveolar processes afford insufficient room for the permanent teeth, which appear crowded, irregularly set, and overhang those in the lower jaw. The facial surfaces of the maxillae become pinched together, with narrowing of the nasal cavities and maxillary air sinuses. The upper lip is drawn up, still further exposing the projecting front upper teeth. The face is lengthened by dropping of the lower jaw; the whole expression of the child ('adenoid facies') is highly characteristic, suggesting vacuity and inattention, the latter being due to the deafness so often associated with nasal obstruction and caused by blocking of the pharyngeal openings of the auditory tubes.

General Alimentary Organization

Although there is some structural variation along the length of the alimentary tract, a common basic plan of organization exists throughout. This is best appreciated by reference to its embryological development (p. 76). Much of the alimentary canal develops initially as a tube of endoderm enveloped in splanchnopleuric mesoderm, the external surface of which borders the intraembryonic coelom. The endodermal lining forms the epithelium of the tract, and also the secretory and the duct-lining cells of the glands which pour their secretions into the gut lumen, including the pancreas and liver. The main mass of splanchnopleuric mesoderm surrounding the endodermal tube forms the connective tissues, muscle layers, blood vessels and lymphatics of the gut wall, whilst its external surface forms the visceral mesothelium. The latter is, of course, absent throughout the neck and thorax, and also where the hindgut approaches and penetrates the pelvic floor. The disposition and developmental changes in the dorsal and ventral mesenteries of the subdiaphragmatic foregut, and of the dorsal mesentery of the midgut and hindgut have been described elsewhere (p. 200). The nervous elements associated with the gut wall invade it from neighbouring masses of neural crest tissue (p. 174). Cranially, striated muscle of branchial arch origin and, caudally, striated muscle of less certain origin contribute to the musculature of the extremities of the gut.

In the mature state, therefore, the gut wall is composed of a series of different layers; these are, from the internal to the external surface of the tube: (1) the *epithelium*; (2) the *lamina propria*; (3) the *muscularis mucosae*, which together with the epithelium and the lamina propria, constitutes the *mucosa*; (4) the *submucosa*; (5) the *muscularis externa*, composed of the muscle layers of the main muscle coat; and (6) the *serosa*, or *visceral peritoneum*, throughout most of the subdiaphragmatic gut; throughout the pharynx and most of the oesophagus, however, a serosa is absent and is replaced by a relatively dense connective tissue *adventitia* or fibrous 'coat', which blends with the fascial planes of surrounding structures (**8**.87). The mesenteries carry blood vessels, autonomic nerves and lymphatic channels to and from the wall of the gut, and at certain points they accompany the ducts of outlying glands.

The epithelium of the gut is the chief region in which interaction between the body and ingested food takes place. Its cytological composition varies in accordance with its particular regional functions; in the pharynx, oesophagus and lower anal canal it is lined with non-keratinizing, stratified, squamous epithelium which protects the underlying tissue and which facilitates the passage of solid material by the lubricant action of its glandular diverticula. In other regions the epithelium is one

8.89A A low-power micrograph of a vertical section through the wall of a human oesophagus taken in the upper thorax. Mallory's triple stain. Visible in this section are: the epithelium (blue-grey on the right), the lamina propria, muscularis mucosae, submucosa with a group of mucous glands, the external muscle with the circular fibres more deeply placed, and the longitudinal fibres placed externally. See text for further description. Magnification about × 6. (Prepared by Dr. W. Owen, Department of Anatomy, Guy's Hospital Medical School.)

cell thick and is composed predominantly of secretory cells, which provide mucus, enzymes and various ions amongst other materials, and of absorptive cells, which are columnar, with striated or brush borders. The total amount of secretion and of absorption is dependent partly on the surface area of the epithelium, which is maximized by the presence of large folds, finger-like projections (villi), crypts and glands at various points along the tract. The glands are placed at varying positions with reference to the surface of the tract, some in the lamina propria, some in the submucosa, and some completely outside the confines of the alimentary tract's wall, these being the liver and pancreas. The secretions of these glands are important in providing the correct environment for the activity of the different digestive enzymes, and the glands are usually under nervous or hormonal control.

The lamina propria is a layer of compact connective tissue, often rich in elastin fibres, which supports the epithelium; it is bounded at its base by the **muscularis mucosae**, a plexus of nonstriated muscle fibres which can alter the local conformation of the mucosa by the contractile activity of its two layers, the inner of which is circular and the outer longitudinal in direction. **The submucosa** is rich in blood vessels, lymphatics and nerves; variations in its thickness create the macroscopic folds and ridges of the internal aspect of the gut, particularly in the small intestine.

The muscularis externa consists in most regions of two distinct layers, the inner circular and the outer longitudinal. The antagonistic activities of these two components create a series of peristaltic waves which are responsible for the movement of solids within the lumen of the tract. In the stomach, where muscular movements are more complex than in the majority of the tract, an oblique layer is present in some parts of the gastric wall, within the usual two external muscle coats. The muscularis externa is composed chiefly of nonstriated muscle, except where the striated muscle of the upper part of the oesophagus blends with the layers and where the striated fibres of the anal sphincters enter into close association with the tract. The different layers of the external muscle are separated by connective tissue planes in which lie vascular and nervous plexuses. Some controversy (Carey 1921; Elsen and Arey 1966) has existed over the precise direction of the fibres in the external muscle layers, one suggestion being that the inner circular muscle was a tight helix and the longitudinal layer an open spiral (Carey 1921). Other observations (Elsen and Arey 1966), however, on a number of different mammals, including man, indicated that, although some deviations from the precisely circular and longitudinal directions may exist locally within the intestine, fibres do not in general follow spiral pathways. In the small intestine of man, it appears that adjacent 'rings' of circular muscle are often connected to each other by oblique slips of muscle fibres allowing for some interchange between muscle groups (Schofield 1968).

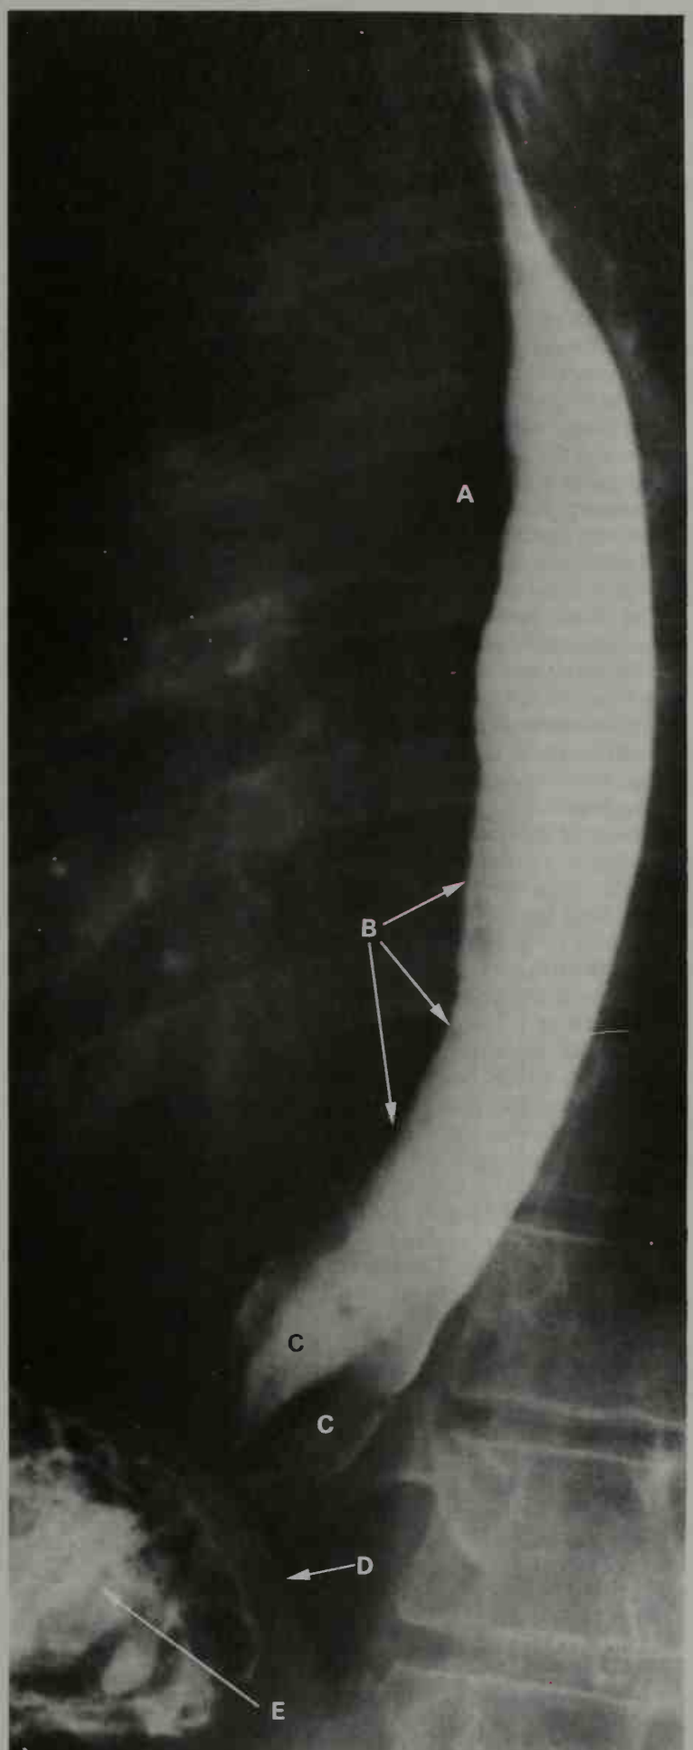
The nerve plexuses of the alimentary tract, mentioned above, comprise a plexus between the inner and outer layers of external muscle (the *myenteric* or *Auerbach's plexus*), another on the submucosal surface of the external muscle (the *submucosal* or *Meissner's plexus*), and a third at the level of the muscularis mucosae. All three plexuses are connected by fine nerve fibres. The first two plexuses contain scattered ganglion cells of the autonomic system, whereas the mucosal plexus appears to be derived from the submucosal nerve net. The epithelium of the alimentary tract is also innervated from the mucosal plexus, and several types of sensory cells have been postulated to occur on the basis of experimental evidence. The structural counterparts to the physiologically identified receptors have so far evaded observational verification, in most cases, although there is no shortage of suggestions (*see* **8**.125 and p. 1366).

The Oesophagus

The oesophagus (**8**.88) is a muscular tube, about 25 cm (10 in.) long, connecting the pharynx to the stomach. It begins in the neck at the caudal border of the cricoid cartilage, opposite the sixth cervical vertebra, where it is continuous with the pharynx. It descends largely anterior to the vertebral column, through the superior and posterior parts of the mediastinum, pierces the

Weigert and Van Gieson, with alcian blue. (Prepared by Mr. David Ristow; photographed by Miss Marina Morris, Department of Anatomy, Guy's Hospital Medical School.)

diaphragm level with the tenth thoracic vertebra, and ends at the cardiac orifice of the stomach at the level of the eleventh thoracic vertebra. The general direction of the oesophagus is vertical; but it presents two shallow curves. At its commencement it is median; but it inclines slightly to the left side as far as the root of the neck, gradually passes again to the median plane, at the level of the fifth thoracic vertebra, and again, at the seventh, deviates to the left and then turns anteriorly to the oesophageal opening in the diaphragm. The oesophagus also presents anteroposterior flexures corresponding to the curvatures of the cervical and thoracic parts of the vertebral column. It is the narrowest region of the alimentary tract except for the vermiform appendix, and is constricted (*a*) at its commencement, 15 cm (6 in.) from the incisor teeth, (*b*) where it is crossed by the aortic arch, 22·5 cm (9 in.) from the incisor teeth, (*c*) where it is crossed by the left principal bronchus, 27·5 cm (11 in.) from the incisors, and (*d*) where it pierces the diaphragm, 40 cm (16 in.) from the incisors. The sites of these constrictions are important clinically in connexion with the passage of instruments along the oesophagus.



The cervical part of the oesophagus has the following relations. *Anteriorly* lies the trachea, to the posterior membranous wall of which it is attached by loose connective tissue; the recurrent laryngeal nerves ascend, one on each side, in, or slightly in front of, the groove between the trachea and oesophagus. *Posteriorly*, it adjoins the vertebral column, the longus colli and the prevertebral layer of the deep cervical fascia. *Laterally*, on each side, lie the corresponding common carotid artery and the posterior part of the lobe of the thyroid gland; in the lower part of the neck, where the oesophagus projects to the left side, it has a closer relation to the carotid sheath and the thyroid gland than on the right side. The thoracic duct ascends for a short distance along the left side of the oesophagus.

The thoracic part of the oesophagus (**8**.17, 18, 24, 88) is at first situated in the superior mediastinum between the trachea and the vertebral column, a little to the left of the median plane. It passes behind and to the right of the aortic arch and descends in the posterior mediastinum along the right side of the descending thoracic aorta. Below, as it inclines to the left, it crosses in front of the aorta, and enters the abdomen through the diaphragm at the level of the tenth thoracic vertebra. It is in relation, *anteriorly* (from above downwards), with the trachea, the right pulmonary artery, the left principal bronchus, the pericardium (separating it from the left atrium), and the diaphragm; *posteriorly* are the vertebral column, the longus colli muscles, the right posterior (aortic) intercostal arteries, the thoracic duct, the azygos vein and the terminal parts of the hemiazygos and accessory hemiazygos veins, and inferiorly, near the diaphragm, the front of the aorta. In the posterior mediastinum an elongated recess of the right pleural sac intervenes between the oesophagus and the vena azygos and vertebral column. On its *left* side, in the superior mediastinum the terminal part of the aortic arch, the left subclavian artery, the thoracic duct, and left pleura are immediate relations, while the left recurrent laryngeal nerve runs upwards in, or just in front of the groove between it and the trachea; in the posterior mediastinum it is in relation with the descending thoracic aorta and the left pleura. On its *right* side it is related to the right pleura, the azygos vein intervening as it arches forwards above the right principal bronchus to join the superior vena cava. Below the roots of the lungs the vagus nerves descend in close contact with it, the right nerve chiefly behind, and the left chiefly in front of it; the two nerves unite to form a plexus around the tube (pp. 1079, 1089).

In the lower part of the posterior mediastinum the thoracic duct lies behind and to the right of the oesophagus; higher up, it is placed behind it, and crossing to the left about the level of the fifth thoracic vertebra, is continued upwards on its left side.

On the right side of the oesophagus, just above the diaphragm, a small serous sac (the *infracardiac bursa*) is sometimes found; it represents the upper detached part of the right pneumato-enteric recess (p. 205).

The abdominal part of the oesophagus, having emerged from the right crus of the diaphragm (p. 549) slightly to the left of the median plane at the level of the tenth thoracic vertebra, lies in the oesophageal groove on the posterior surface of the left lobe of

8.90 An oblique radiograph of the thorax during the oesophageal transit of part of a 'meal' of barium sulphate paste. At (A) the translucency of the air-containing right principal bronchus is visible. The concave ventral aspect of the oesophagus (B) is topographically related to the pericardium covering the left atrium of the heart. Longitudinal mucosal folds are visible (C) immediately proximal to the soft tissue shadow of the diaphragm (D). Some barium sulphate is already admixed with the gastric contents (E). The oesophagus in the lower thorax curves ventrally away from the vertebral column to reach the oesophageal orifice in the diaphragm.

the liver. It is shaped like a truncated cone, 1·25 cm long, curving sharply to the left (**8**.88), the base of the cone being continuous with the cardiac orifice of the stomach; its right border continues evenly into the lesser curvature of the stomach while its left border is separated from the fundus of the stomach by the cardiac notch (**8**.105). It is covered by peritoneum in front and on its left side; it is contained in the upper left part of the lesser omentum, the peritoneum reflected from its posterior surface to the diaphragm being part of the gastrophrenic ligament (p. 1326). The oesophageal branches of the left gastric vessels pass to the oesophagus in this peritoneal ligament. Behind the oesophagus are the left crus of the diaphragm and the left inferior phrenic artery. The vagus nerves have variable relations to the oesophagus as it passes through the diaphragm (Doubilet *et al.* 1948). Sometimes one trunk (consisting mainly of left vagal fibres) lies on the front, and one (consisting mainly of right vagal fibres) on the back of the oesophagus, but each vagus may consist of two or three trunks at this level.

Structure (**8**.89). The histological structure of the oesophagus follows the same general pattern as the rest of the alimentary tract, outlined above, being formed of four layers: external or fibrous, muscular, submucous or areolar, and internal or mucous.

The *fibrous layer* consists of an external adventitia of irregular, dense connective tissue, containing many elastin fibres. Its fibres also penetrate and surround the fasciculi of muscle in the deeper layers.

The *muscular layer* (muscularis externa) is composed of the usual two strata, here particularly thick—an outer longitudinal and an inner circular stratum.

The *longitudinal fibres* form a complete investment for nearly the whole of the oesophagus, but at the upper part of the back of the tube, at a point between 3 cm and 4 cm below the cricoid cartilage, they diverge from the median plane and form two longitudinal fasciculi which incline upwards and forwards to the front of the tube. Here they pass deep to the caudal border of the inferior constrictor to end in a tendon attached to the upper part of the ridge on the posterior surface of the lamina of the cricoid cartilage (**8**.13). The V-shaped interval between the diverging longitudinal fasciculi is filled by the circular fibres of the oesophagus, thinly covered below by some decussating longitudinal fibres, and above by the overlapping lower edge of the inferior constrictor. For the main part the longitudinal muscular coat of the oesophagus is thicker than the circular muscle coat.

Accessory slips of non-striated muscle tissue sometimes pass between the oesophagus and the left pleura, or between the oesophagus and the root of the left principal bronchus, trachea, pericardium, or aorta. These muscular slips are sometimes considered to fix the oesophagus to neighbouring structures.

The *circular fibres* are continuous superiorly, on the posterior surface, with the inferior constrictor; anteriorly, the uppermost are inserted into the lateral margins of the tendon of the two longitudinal fasciculi. Inferiorly, the circular muscle fibres are continuous with the oblique fibres of the stomach.

In man, striated muscle is generally limited to the upper two-thirds of the oesophagus; the lower third contains nonstriated muscle only. In the upper quarter, both layers are striated; in the second quarter bundles of nonstriated muscle appear, first on the internal aspect of the muscle layers, and these gradually replace the striated muscle more caudally.

Radiological studies show that swallowed food is momentarily held up in the lower, gastric end of the oesophagus, prior to entry into the stomach (**8**.90). It is hence certain that some form of sphincteric mechanism, capable of contraction and relaxation, must be present at the oesophagogastric junction. The failure of many observers to identify any notable aggregations of muscle to account, with certainty, for the control of entry into or regurgitation from the stomach, has lead to a somewhat meaningless phrase—'a physiological cardiac sphincter'. The frequency of pathological disturbance of this sphincteric control has exacerbated the controversy, for a full discussion of which consult Bombeck *et al.* (1944); Botha (1962); DiDio and Anderson (1968); Code (1968). A wide variety of factors have been adduced to account for the undoubted sphincteric effects at the junction of oesophagus and cardia of the stomach. There are circularly disposed muscle fibres in both organs adjoining the junction, and these are potentially reinforced by the splitting of the right crus of the diaphragm around the oesophagus (p. 549). Some have recorded evidence against the latter view (Atkinson *et al.* 1957). The phrenico-oesophageal ligament, a layer of connective tissue extending from the inferior surface of the diaphragm through the oesophageal orifice to blend with the submucosa and interfascicular septa of the musculature of the termination of the oesophagus, has also been invoked as an accessory factor. The obliquity of the gastro-oesophageal junction, the effects of spiral and longitudinal muscle (Stelzner and Lierse 1967), and various mucosal folds (Creamer 1955), have all been considered to exert a valvular effect. It is hence noticeable that a number of *structures* may possess either alone, or collectively, the potentiality of '*physiological*' sphincteric control at this site of controversy. However, the actual mechanism is still uncertain. (*See* also p. 1336.)

The *submucosa* connects loosely the mucous and muscular coats. It contains the larger blood vessels and nerves, as well as mucous glands.

The *mucous layer* is thick, reddish in colour above, and pale below. It is disposed in longitudinal folds, which disappear on distension of the tube. It consists of: (1) a layer of non-keratinizing stratified squamous epithelium, lining the tube; (2) a layer of connective tissue, papillae from which project into the epithelium; and (3) the muscularis mucosae, a layer of nonstriated muscle. At the commencement of the oesophagus the muscularis mucosae is absent, or only represented by a few scattered bundles; lower down it forms a considerable stratum. At intermediate levels the muscle bundles are mainly longitudinal in direction, but they become more plexiform as the gastro-oesophageal junction is approached. At the gastro-oesophageal junction the stratified squamous epithelium of the oesophagus is abruptly succeeded by the simple columnar epithelium of the stomach. The junction is visible to the naked eye in fresh preparations as a crenated line, the greyish-pink, smooth, oesophageal contrasting with the red, mamillated, gastric mucosa.

The *oesophageal glands* are small, compound racemose glands of the mucous type; they are lodged in the submucous tissue outside the muscularis mucosae, and each opens into the tube by a long duct which pierces the muscularis mucosae. In the abdominal oesophagus, the glands resemble those in the cardiac part of the stomach and are between the muscularis mucosae and lumen (Johns 1952).

Vessels and Nerves

The *arteries* supplying the oesophagus are derived from the inferior thyroid branch of the thyrocervical trunk, from the descending thoracic aorta, from the bronchial arteries, from the left gastric branch of the coeliac artery, and from the left inferior phrenic branch of the abdominal aorta. They have for the most part a longitudinal direction. The *veins* from the cervical part of the oesophagus drain into the inferior thyroid veins and those from the thoracic part into the azygos, hemiazygos and accessory hemiazygos veins. The abdominal part drains partly into the azygos vein and partly into the left gastric vein. The latter vein being a tributary of the portal vein, the abdominal part of the oesophagus is one of the sites where anastomoses between the portal and systemic veins occur (p. 765). In cases of obstruction of the portal circulation (e.g. in cirrhosis of the liver), these veins may become varicose and may burst into the lower part of the oesophagus, causing vomiting of blood and even fatal haemorrhage. The *lymph vessels* are described on pp. 765, 800.

The *nerves* are derived from the vagus and sympathetic. The cervical part of the oesophagus receives branches from the recurrent laryngeal nerves and from the cervical sympathetic trunks (by means of the plexus around the inferior thyroid artery). The thoracic part has branches from the vagal trunks and oesophageal plexus, and from the sympathetic trunks and greater splanchnic nerves. The abdominal part (Mitchell 1938) is supplied by the vagal trunks (anterior and posterior gastric nerves), the thoracic sympathetic trunks, the greater (and occasionally the lesser) splanchnic nerves, and the plexus around the left gastric and inferior phrenic arteries. The nerves form a

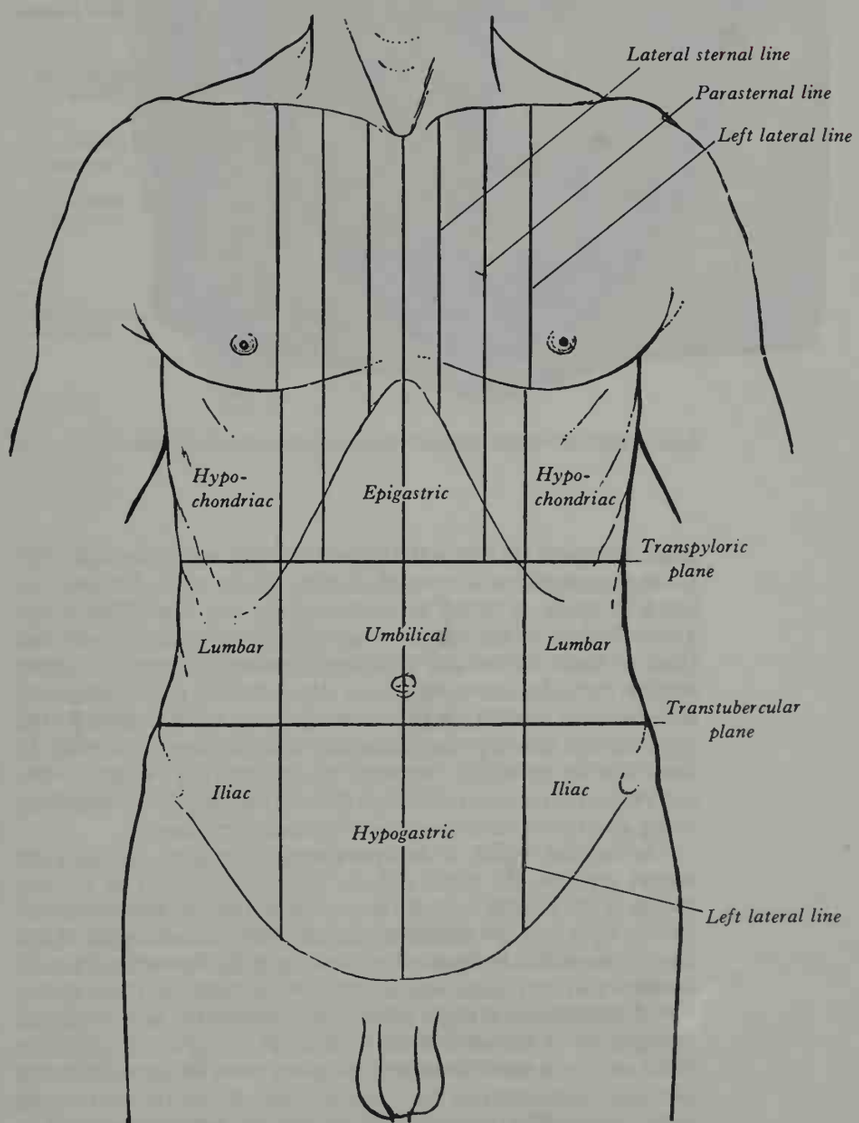
plexus containing groups of ganglion cells between the two layers of the muscular coat, and a second plexus in the submucous tissue. (See also Semenova 1962.) The literature concerning the 'myenteric' plexus of the oesophagus has been reviewed by Rodrigo *et al.* (1975), who have described intraganglionic nerve endings which they suggest may be afferent in nature.

Radiology (**8**.90). In oblique lateral views after a barium meal the main part of the thoracic portion of the oesophagus is seen in the 'retrocardiac space' behind the heart and diaphragm. The entire thoracic part is seen to be situated a little distance from the vertebral column, its lower part inclining forwards still further from the column. Its anterior wall is indented by the arch of the aorta, the left bronchus, and the left atrium, successively from above downwards. A thin layer of the barium meal may outline the longitudinal grooves of the mucous membrane, producing a characteristically striated shadow.

THE ABDOMEN

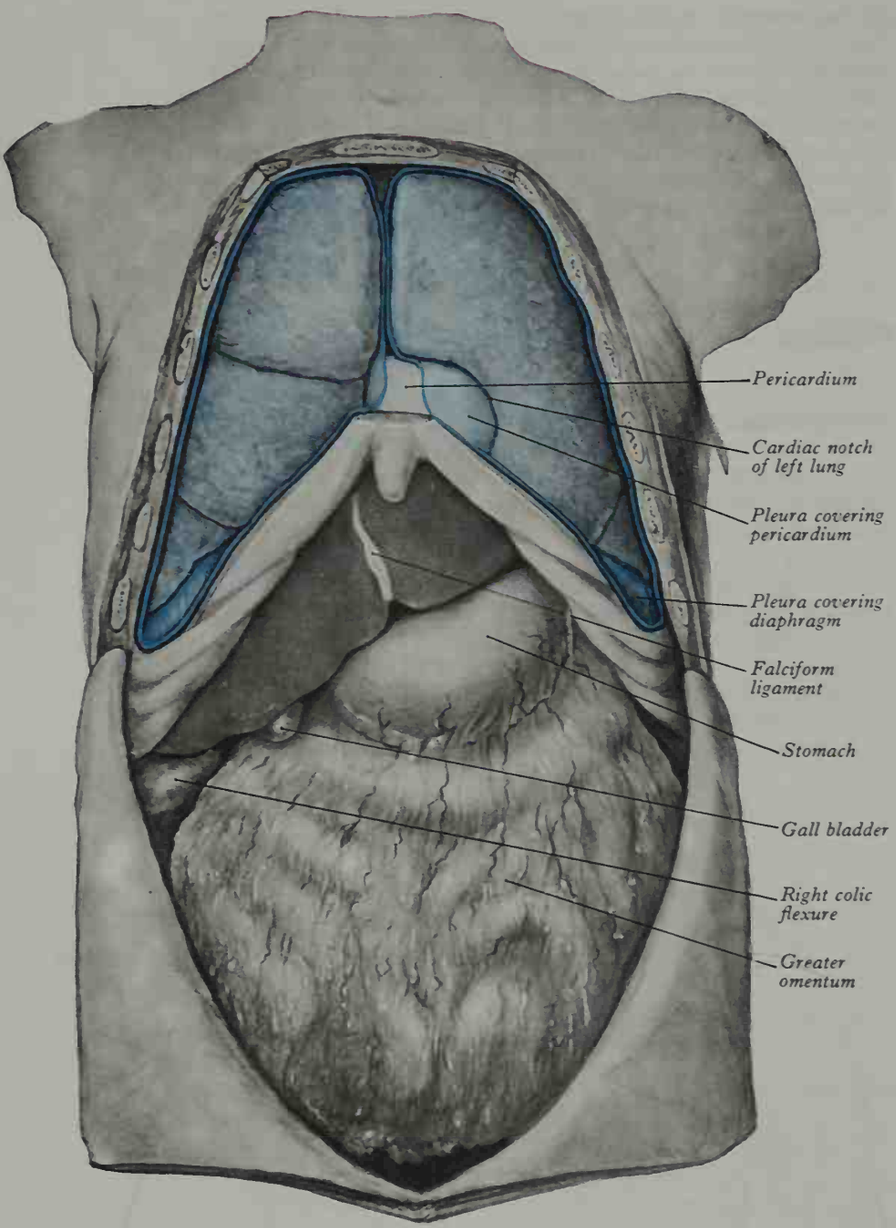
The abdomen is the region of the trunk below the diaphragm (**8**.92). It comprises an upper part, the *abdomen proper*, and a lower part, the *lesser pelvis*. These are continuous at the plane of the inlet of the lesser pelvis, which is bounded by the promontory of the sacrum, the arcuate lines of the innominate bones, the pubic crests and the upper border of the symphysis pubis. The abdomen is, to a large extent, bounded by muscles; consequently its shape and size can alter under different conditions, such as varying degrees of distension of the contained hollow organs and the phases of respiration. Further, the tone of these muscles is an important factor in maintaining the abdominal and pelvic viscera in position (pp. 558 and 561).

The *abdomen proper* is bounded *in front* by the rectus abdominis muscles, the pyramidales and the aponeurotic parts of the flat abdominal muscles (obliquus externus abdominis, obliquus internus abdominis and the transversus abdominis); *at the side*, by the fleshy parts of these flat abdominal muscles, the iliacus muscles and the iliac bones; *behind*, by the lumbar part of the vertebral column, the crura of the diaphragm, the psoas and quadratus lumborum muscles and the posterior parts of the iliac bones; *above*, by the diaphragm; while *below*, it is continuous with the pelvis through the superior aperture of the lesser pelvis (p. 385). As the diaphragm, which forms the dome-like roof of the abdominal cavity, arches upwards, a considerable part of the cavity extends superiorly and is internal to the bony framework of the thorax (*see* pp. 550–551 for variations in the position of the diaphragm during respiration, etc.). The abdomen proper contains the greater part of the digestive tube, as well as the liver, pancreas, spleen, kidneys, parts of the ureters, suprarenal glands and numerous blood vessels, lymph vessels, lymph nodes and nerves.



The *lesser pelvis* is roughly infundibular, like an inverted, truncated cone, and extends dorso-inferiorly from the lower end of the abdominal cavity (**8**.95, **3**.181). It is bounded *antero-laterally* by the parts of the hip bones below the pubic crests and arcuate lines, and by the obturator internus muscles; *supero-dorsally*, by the sacrum, coccyx and the piriformis and coccygeus muscles; and *inferiorly*, by the levatores ani, which with their covering fasciae form the pelvic diaphragm (pp. 559–561), and by the transversus perinei profundus and sphincter urethrae, which together with *their* fascial coverings constitute the urogenital diaphragm. The lesser pelvis contains the urinary bladder, terminal parts of the ureters, the sigmoid colon, rectum and a few coils of small intestine, and the internal genitalia, together with blood vessels, lymph vessels, lymph nodes and nerves.

The muscles bounding the abdomen proper and the pelvis are, like muscles in general, ensheathed in fascia; the layer of fascia covering the deep surface of the muscles immediately adjacent to the abdominal and pelvic cavities is named differently in the various regions. For example, that which adjoins the internal surface of the transversus abdominis is the *transversalis fascia* (p. 559), that inferior to the diaphragm is the *diaphragmatic fascia*, that covering the psoas and iliac is the *iliac fascia* (p. 593), that covering the anterior surface of the quadratus lumborum is the *anterior layer of the thoracolumbar fascia* (p. 542), and that covering the muscles in the pelvis is the *pelvic fascia* (p. 560).



Most of the organs in the abdominal and pelvic cavities are largely covered with a serous membrane, termed the *peritoneum* (pp. 1321–1333).

ABDOMINAL REGIONS

For purposes of location of the viscera, especially in clinical usage, the abdomen is divided into nine regions by imaginary planes, two horizontal and two sagittal, passing through the cavity, the edges of the planes being indicated by lines projected upon the surface of the body (**8**.91). The upper horizontal plane, or *transpyloric plane* (of Addison), is indicated by a line encircling the body at a level midway between the suprasternal notch and the symphysis pubis (roughly midway between the umbilicus and the inferior end of the body—not the xiphoid process—of the sternum, or a hand's breadth below the xiphisternal joint); it intersects the front of the body of the first lumbar vertebra near its lower border and

8.91 Reference lines on the anterior aspect of the thorax and abdomen for use in delineating surface projections.

8.92 Anterior aspect of the thoracic and abdominal viscera.

meets the costal margin at the tip of the ninth costal cartilage. The lower horizontal plane is indicated by a line carried round the trunk at the level of the tubercles on the iliac crests (**8**.91, pp. 378–380) and is termed the *transtubercular plane*; it cuts the front of the body of the fifth lumbar vertebra near its upper border. By means of these planes the abdomen is cut into three zones; each of these is further subdivided into three regions by the *right* and *left lateral planes*, which are indicated on the surface by lines drawn vertically through points halfway between the anterior superior iliac spines and the symphysis pubis (these lines being also called 'midclavicular' or 'mammary' lines).

The median region of the upper zone is the *epigastric*, and the lateral regions, the *right* and *left hypochondriac*. The median region of the middle zone is the *umbilical*, and the lateral regions are the *right* and *left lumbar* or *lateral*. The median region of the lower zone is the *hypogastric* or *pubic*, and the lateral regions are the *right* and *left iliac* or *inguinal* (**8**.91). (*See* Addison 1899–1901.)

A third horizontal plane is frequently utilized in describing the topography of the abdominal viscera. It is drawn through the body on a level with the most dependent parts of the tenth costal cartilages and is termed the *subcostal plane*. It cuts the front of the body of the third lumbar vertebra near its upper border. It is frequently utilized instead of the transpyloric plane for the purpose of dividing the abdomen into the regions named above.

The *umbilicus* is variable in position; in the young adult it usually lies on a level with the disc between the third and fourth lumbar vertebrae. As age advances, and in conditions of deficient tone of the abdominal muscles, it sinks to a lower position. It is also lower in the child because of the under-developed condition of the pelvic region.

On the posterior surface of the body, a transverse line joining the highest parts of the two iliac crests cuts through the spinous process of the fourth lumbar vertebra in the midline; it is known as the *supracristal plane*. This landmark is used for the purpose of identifying individual vertebral spinous processes.

When the anterior abdominal wall is removed (**8**.92), the viscera are partly exposed as follows: above and to the right side the liver is visible, situated chiefly under the shelter of the right ribs and their cartilages, but extending across the median plane, where it reaches down to the transpyloric plane. The stomach is exposed in the angle between the left costal margin and the lower border of the liver. From its lower border an apron-like fold of peritoneum, termed the *greater omentum*, descends for a varying distance, anterior to the other viscera to a greater or lesser extent. Below the greater omentum, however, some of the coils of the small intestine can generally be seen, while in the right iliac region the caecum and, in the left iliac region, the lower portion of the descending colon are partly exposed (*see* p. 1330). The urinary bladder occupies the anterior part of the pelvis, and if distended, projects above the symphysis pubis; the rectum is placed in the concavity of the sacrum, but is usually hidden by coils of the small intestine. The sigmoid colon may be seen lying between the rectum and the bladder.

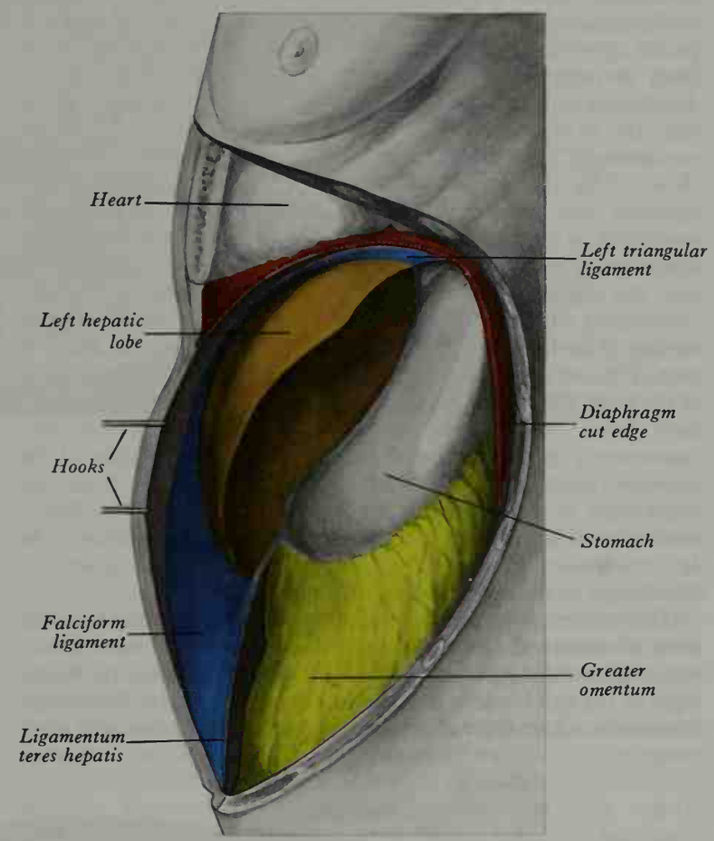
When the stomach is followed from left to right, it is seen to be continuous with the first part of the small intestine (duodenum), the point of continuity being marked by a thickened ring (of muscle), which indicates the position of the pyloric sphincter. The duodenum passes towards the under surface of the liver, and then, curving downwards, is lost to sight. If, however, the greater omentum, together with the transverse colon which lies beneath it, be turned upwards over the chest, the horizontal part of the duodenum can be traced across the vertebral column towards the left side, where it ascends to the second lumbar vertebra to become continuous with the coils of the jejunum and ileum, which constitute the remainder of the small intestine. These measure about six metres in length (see also p. 1342), and if followed downwards the ileum is seen to end in the right iliac fossa by opening into the large intestine at the junction of the caecum and ascending colon. From the caecum the large intestine takes a looped course, passing at first upwards on the right side, then across the median plane below the liver and stomach, and then downwards on the left side, forming respectively the ascending, transverse, and descending parts of the colon. In the pelvis the colon assumes the form of a loop, termed the sigmoid colon, and ends in the rectum.

The spleen lies behind the stomach in the left hypochondriac region, and may be exposed in part by pulling the stomach over towards the right side.

The glistening appearance of the deep surface of the abdominal wall and of the surfaces of the exposed viscera is due to the fact that the former is lined, and the latter are largely covered, with a serous membrane, termed the *peritoneum*.

The relations of the organs described in the following pages refer to the body in the recumbent position. But it must be noted that the position of the viscera is affected not only by posture but by respiratory movements and by the condition of the hollow organs as regards quantity of contents. In addition there is a wide range of variation associated with bodily build, i.e. the shape of the chest, abdomen and pelvis; also the organs may vary in the same individual at different times depending, for example, on their physiological activity and their degree of mobility. Thus, in the absence of radiological examination, the surface outlines of the viscera, particularly the hollow organs, described in the text and illustrated in the figures, must be regarded as variable within wide limits.

With regard to their different types of physique individuals have been classified into two extreme groups, namely, *hypersthenic* (for pyknic) and *asthenic* (or leptosomatic), with inter-



mediate grades, *sthenic* and *hyposthenic* (Mills 1917, 1922). In the hypersthenic type, with massive physique, the thorax is wide and short and the subcostal angle is very obtuse, so that the heart and lungs are wide transversely; the abdomen is widest in its upper part and the stomach is less elongated in a vertical direction with the pylorus relatively high, while the transverse colon is more truly transverse. In the asthenic type, with frail and slender physique, the thorax is long and narrow and the subcostal angle is acute, so that the heart and lungs are long and narrow; the abdomen is widest in its lower part, the stomach is long with the pylorus relatively low, while the colon is long with the transverse colon descending in a V-shaped manner to the pelvis. The varieties of human physique (somatotypes) have also been classified as endomorphic (massive bodybuild), mesomorphic (intermediate) and ectomorphic (slender), with intermediate grades, each type having predominant psychological characteristics (Sheldon *et al.* 1940; Sheldon and Stevens 1942). (Consult current monographs of physical anthropology for details.)

THE PERITONEUM

The peritoneum (Brizon *et al.* 1956) is the largest and most complexly arranged serous membrane in the body, and consists, in the male, of a closed sac, a part of which lines the abdominal wall, whilst the remainder is reflected over the contained viscera. In the female the lateral ends of the uterine tubes open into the peritoneal cavity. The part which lines the abdominal wall (or parieties) is named the *parietal* portion of the peritoneum; that which is reflected over the contained viscera constitutes the *visceral* portion of the peritoneum. The *free surface* of the membrane is smooth, covered with a layer of flattened *mesothelium* and kept moist and smooth by a thin film of serous fluid. Hence the viscera can glide on the wall of the cavity or on one another with complete freedom—within the limits dictated by their attachments to the walls of the abdominal cavity, or to other structures, such as vascular supplies. Some organs are themselves sessile, but are covered by peritoneum wherever they are in contact with mobile viscera.

The peritoneal cavity is, of course, a *coelom*—a discontinuity in the mesoderm with its own special surface epithelium (mesothelium) which maintains the surface. Loss of this epithelium entails adherence of the underlying tissues and a consequent interference with function which may be serious and even lethal (p. 1332), providing also convincing evidence of at least one essential contribution of such serosal epithelia—the separation of viscera sufficiently to allow them unimpeded activity. As a biological arrangement the coelomic principle is sufficiently basic to divide all animals into the *Coelomata* and the *Acoelomata*.

Many different functions are served by coelomic spaces in various invertebrates and vertebrates (Jones 1913; Romer 1970). Thus, excretory organs such as nephridia drain from a general body coelom, and the nephric systems of vertebrates are in part derived from it. As animals evolve to a greater size, a coiled gut becomes essential. It is difficult to envisage how such coiling could evolve phylogenetically or develop ontogenetically without the emergence of a coelomic cavity. In elementary chordates such as *Amphioxus*, the gametes are extruded from the gonads into a coelom, and in some early vertebrates the same arrangement exists in both male and female, persisting in the female in all forms, including mankind. The special ducts which evolve to connect the kidneys and testes to the cloaca and its later derivatives are in part formed from the coelomic epithelium, which is also closely associated with the formation of the gonads themselves (p. 210).

8.93 A dissection to expose the left side of the falciform fold or ligament of the liver.

General Structure

A considerable amount of areolar connective tissue intervenes between the parietal peritoneum and the abdominal walls, with the fascial lining of which it blends. It is known as the *extraperitoneal tissue*. It varies in quantity and contains a varying amount of fat in different regions. While this tissue loosely connects the parietal peritoneum to the abdominal and pelvic walls in general and so allows the peritoneum to be relatively easily stripped from them, it is denser on the inferior surface of the diaphragm and behind the linea alba, so that the parietal peritoneum is more firmly adherent to these parts. It is especially loosely arranged in some places to allow alteration in the size of certain organs; for example, in the front part of the pelvis and lower part of the anterior abdominal wall where it allows the urinary bladder to distend in an upward direction behind the anterior abdominal wall, from which it strips off the peritoneum as it ascends. It is usually heavily laden with fat on the posterior abdominal wall in relation to the kidneys. The visceral peritoneum, on the other hand, is firmly united to the viscera which it covers, and cannot be readily stripped off them. In fact, the connective tissue layer (*tela subserosa*) of the visceral peritoneum is directly continuous with the fibrous tissue stroma of the viscera; thus from the point of view of pathological conditions of an organ, the visceral peritoneum must be considered to be part of the viscus itself.

THE PERITONEAL CAVITY

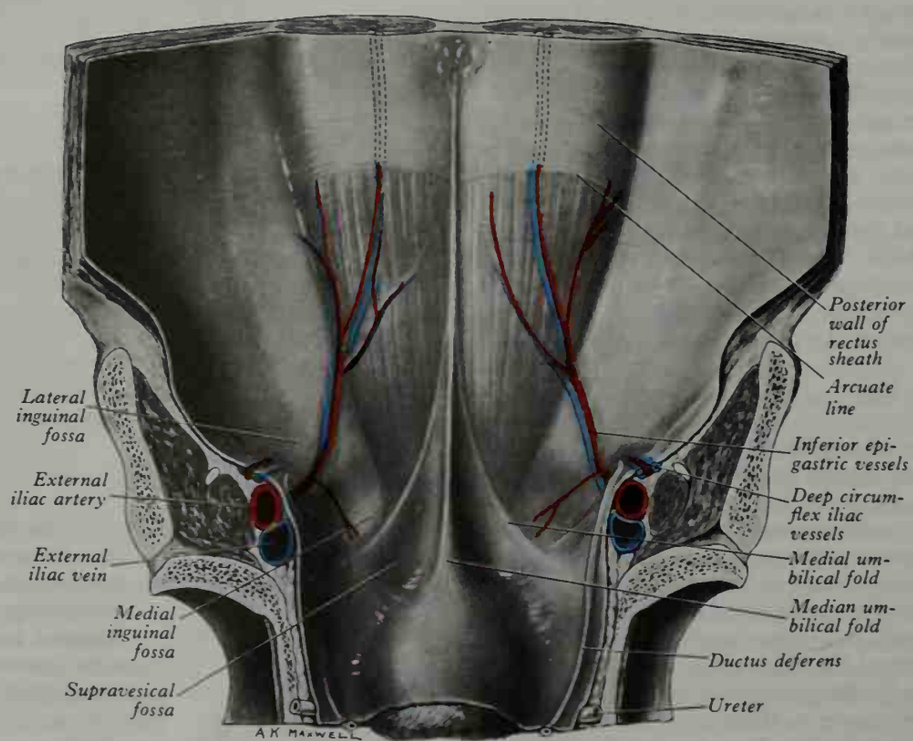
The parietal and visceral layers of the peritoneum are in actual contact; the potential space between them is the *peritoneal cavity*. The latter consists of (1) a main region, termed the *greater sac* (or *cavum peritonei*), and (2) a diverticulum from this, the *omental bursa* or *lesser sac*, which is situated behind the stomach and adjoining structures; the neck or communication between the greater sac and the lesser sac is the *epiploic foramen* (or *aditus to the lesser sac*).

The disposition of the complexly arranged peritoneum is best understood by first studying the development of the alimentary canal (pp. 197–207), followed by examination of the various

regions of the peritoneal cavity in a cadaver which has not been made unnaturally rigid by preservative fluids.

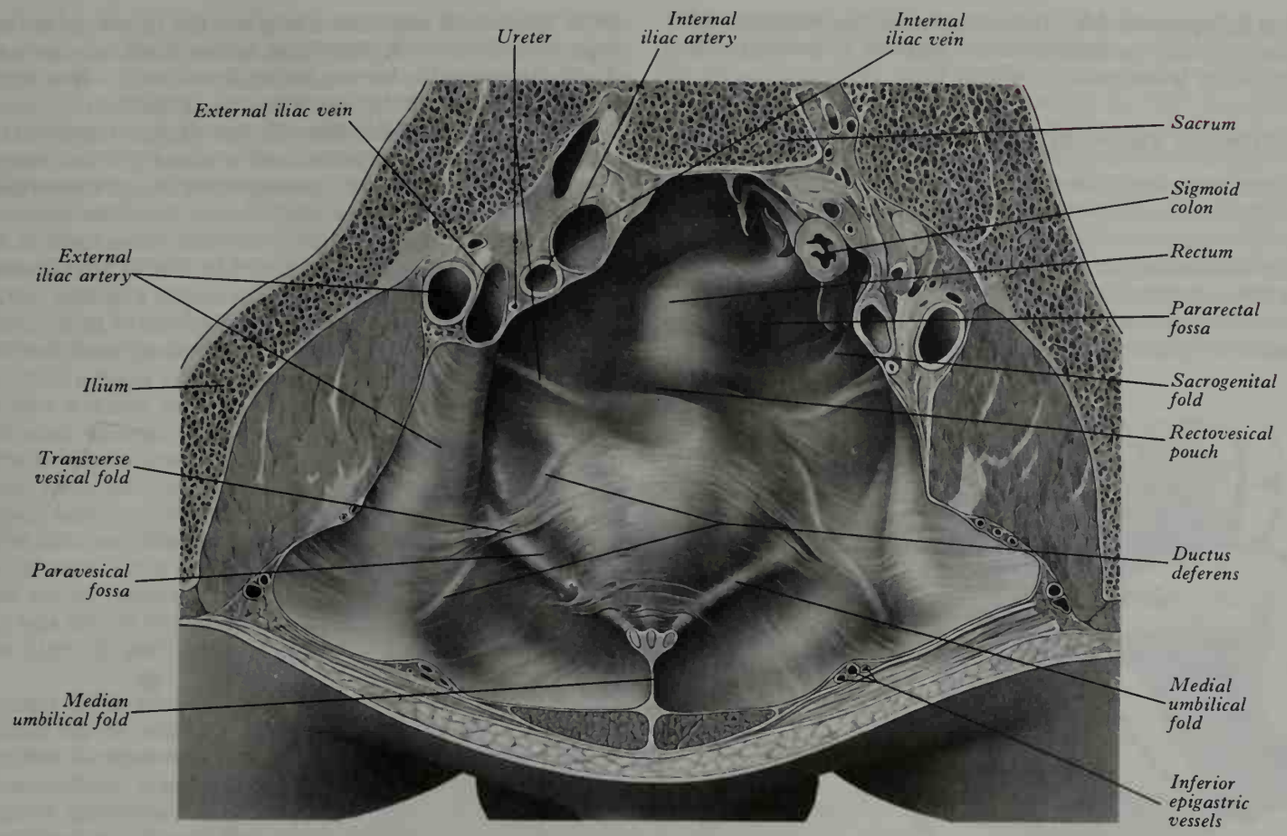
To trace the peritoneum from one viscus to another, and from the viscera to the parieties, it is helpful to follow its continuity in the vertical and horizontal directions, and it is simpler to describe the greater sac and the lesser sac separately.

VERTICAL DISPOSITION OF THE PERITONEUM



It is convenient to commence tracing the arrangement of the greater peritoneal sac in the vertical plane (**8**.97) from the anterior abdominal wall at the level of the umbilicus. A fibrous cord, the *ligamentum teres* or *obliterated left umbilical vein* (p. 665), ascends from the umbilicus to the inferior surface of the liver; it commences at the umbilicus, inclines slightly to the right of the midline and recedes slightly from the anterior abdominal wall as it passes upwards; it raises a triangular fold of parietal peritoneum from the anterior abdominal wall and inferior surface of the diaphragm in this upward course—the *falciform ligament of the liver* (p. 1376 and **8**.93). The latter consists of two layers of peritoneum, right and left, with intervening connective tissue (**8**.99). The inferior, juxta-umbilical region of the falciform ligament has a posterior free border, extending from the umbilicus to the inferior border of the liver and containing the ligamentum teres (obliterated left umbilical vein). Superior to this the ligament extends from the diaphragm to become continuous with the visceral peritoneum on the anterosuperior surface of the liver (**8**.93). At the site of reflexion from the anterior part of the inferior surface of the diaphragm to the upper surface of the liver, the two layers of the falciform ligament diverge from each other (**8**.135), the right layer passing more or less transversely to the right and forming the *superior layer of the coronary ligament of the liver* (which thus passes from the diaphragm to the upper surface of the right lobe of the liver), while the left layer passes to the left to form the *anterior layer of the left triangular ligament* of the liver (which passes from the diaphragm to the upper surface of the left lobe).

The visceral peritoneum on the supero-anterior surface of the liver is continued round the sharp lower border to the inferior (visceral) surface where it has the following arrangements. To the right of the gall bladder it covers the inferior surface of the right lobe and is reflected from the posterior part of this lobe to the right suprarenal gland and the upper end of the right kidney, forming the *inferior layer of the coronary ligament*; the peritoneum frequently passes directly from the inferior surface of the liver to the front of the right kidney, forming a fold termed the *hepatorenal ligament*. From the right kidney the peritoneum passes downwards to the front of the superior part of the duodenum and of the right colic flexure; it also passes medially in front of a short segment of the inferior vena cava (between the duodenum and the liver), where it is continuous with the posterior wall of the omental bursa (**8**.98). Between the two layers of the coronary ligament there is a large, triangular area on the back of the right lobe devoid of peritoneal covering; this is termed the *bare area* of the liver and here the liver is attached to the diaphragm by areolar tissue.



Towards the right margin of the liver the superior and inferior layers of the coronary ligament gradually approach each other and ultimately fuse to form a small triangular fold, connecting the right lobe of the liver to the diaphragm and called the *right triangular ligament* of the liver (**8**.135). The latter forms the apex of the bare area, the base being formed by the *groove for the inferior vena cava*.

The visceral peritoneum covers the inferior surface and sides of the gall bladder, the inferior surface of the quadrate lobe of the liver as far back as the anterior margin of the porta hepatis, and the inferior surface of the left lobe; from the posterior surface of the left lobe it is reflected to the diaphragm as the *posterior layer of the left triangular ligament*. The peritoneum along the anterior margin of the porta hepatis is continuous at the right extremity of the porta with the peritoneum of the omental bursa, the latter being reflected from the posterior margin of the porta (**8**.135). The visceral peritoneum passes into the depth of the fissure for the ligamentum venosum (**8**.135), between the caudate and left lobes of the liver, in two layers, anterior and posterior. The anterior layer is continuous with the peritoneum reflected from the anterior margin of the porta hepatis (**8**.135). From this L-shaped line formed by the left margin of the fissure for the ligamentum venosum and the anterior margin of the porta hepatis, the peritoneum is reflected to the lesser curvature of the stomach and about the first 2 cm of the duodenum, forming the anterior layer of the *lesser omentum*.

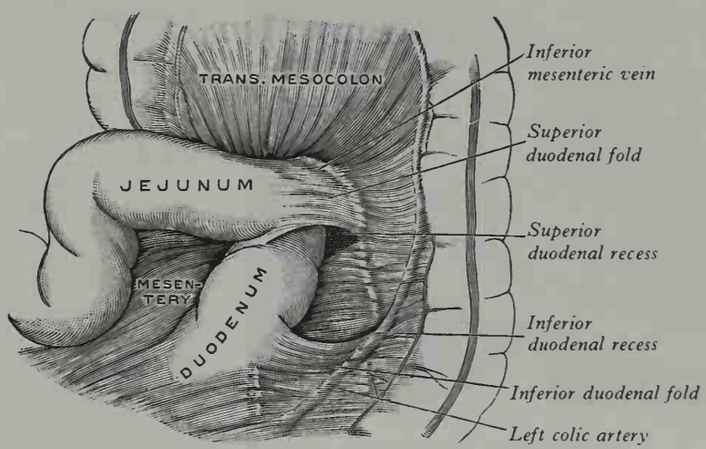
The part of the lesser omentum connecting the liver to the stomach is called the *hepatogastric ligament*, while the part passing

8.94 The infra-umbilical part of the anterior abdominal wall of a male subject. Posterior surface, with the peritoneum *in situ*.

8.95 The peritoneum of the male pelvis. Anterosuperior view. The median umbilical fold contains both the unpaired median and the paired medial umbilical ligaments in the plane of section in this subject.

from the liver to the duodenum is named the *hepatoduodenal ligament*. The anterior layer of the lesser omentum, if traced to the right, is found to pass in front of the hepatic artery proper, bile duct and portal vein, and then to turn round the right side of these structures to become continuous behind them with the posterior layer of the lesser omentum; the latter here forms the anterior wall of the omental bursa. Thus the lesser omentum has a free right border, in which lie the hepatic artery proper, bile duct and portal vein, and behind which is the *epiploic foramen* (**8**.99). The anterior layer of the lesser omentum is continuous below with the visceral peritoneum that covers the front of the stomach and the first 2 cm of the duodenum. This layer of peritoneum then descends from the greater curvature of the stomach and the neighbouring part of the duodenum to form the most anterior layer of a large free fold, called the *greater omentum*. Reaching the free lower margin of this fold, it turns upwards, forming the most posterior layer of the greater omentum; the latter runs to the anterosuperior aspect of the transverse colon (opposite the *taenia omentalis*), to which it is adherent but from which it can be stripped off. It then passes backwards, adherent to but separable from the upper layer of the transverse mesocolon, to the anterior surface of the head and the anterior border of the body of the pancreas; it leaves the latter as the upper layer of the transverse mesocolon (**8**.97). This passes to the posterior surface of the transverse colon (opposite the *taenia mesocolica*), covers the upper, anterior and lower surfaces of that part of the gut, and passes from its posterior surface to the front of the head and the anterior border of the body of the pancreas as the inferior layer of the transverse mesocolon. Thence it is continued over the lower part of the anterior surface of the head and over the inferior surface of the body of the pancreas on to the front of the horizontal and ascending parts of the duodenum. From the latter it passes downwards on the posterior abdominal wall; it is also in part carried forward on the superior mesenteric vessels to the jejenum and ileum as the *right layer of the mesentery*. It invests this part of the gut and then passes to the posterior abdominal wall as the *left layer of the mesentery*; it then descends over structures like the abdominal aorta, inferior vena cava, the ureter and the psoas major into the lesser pelvis. It is reflected from the posterior pelvic wall, as the anterior layer of the *sigmoid mesocolon*, invests the sigmoid colon and returns to the pelvic wall as the posterior layer of the sigmoid mesocolon. It then descends, covering the front and sides of the upper third of the rectum and the front of the middle third of the rectum.

In the male, it leaves the front of the rectum (at the junction of its middle and lower thirds) and passes forwards on to the upper ends of the seminal vesicles and the upper surface of the urinary bladder. Between the rectum and the bladder it dips slightly downwards forming a recess, the *rectovesical pouch*, the bottom of which is a little below the level of the upper ends of the seminal vesicles and about 7·5 cm from the anal orifice. From the apex of the bladder it is carried along the median and medial umbilical ligaments (**8**.94) to the anterior abdominal wall up to the level of the umbilicus (from which a start was made). When the bladder is distended the peritoneum is stripped away from the lower part of the anterior abdominal wall, so that a considerable part of the anterior surface of the bladder lies directly against the abdominal wall without the intervention of peritoneum (p. 1405). An instrument can therefore be passed through the abdominal wall into the distended bladder without passing through the peritoneal cavity.



In the female, the peritoneum passes from the front of the rectum on to the posterior fornix of the vagina and thence on to the back of the cervix and body of the uterus, forming the *recto-uterine fold*. This fold dips downwards to form the *recto-uterine pouch* (of Douglas), the bottom of which is about 5·5 cm from the anal orifice. The peritoneum continues over the fundus of the uterus and descends on its anterior (vesical) surface as far as the junction of the body and cervix, from which site it is reflected forwards on to the upper surface of the bladder, forming a shallow recess, the *vesico-uterine pouch*. The layers of peritoneum on the anterior and posterior surfaces of the uterus are reflected laterally, from the lateral margins of the uterus, to the side walls of the pelvis, forming on each side an expanded fold, termed the *broad ligament of the uterus*; the latter thus consists of two layers, antero-inferior and posterosuperior, which are continuous above to form the free upper border of the broad ligament; between the two

layers at the upper border is the uterine tube. The reflexion of the peritoneum from the bladder to the anterior abdominal wall is similar to that in the male.

HORIZONTAL DISPOSITION OF THE PERITONEUM

Below the transverse colon the arrangement is simple, and it may be considered in three regions: pelvic, lower abdominal, and upper abdominal.

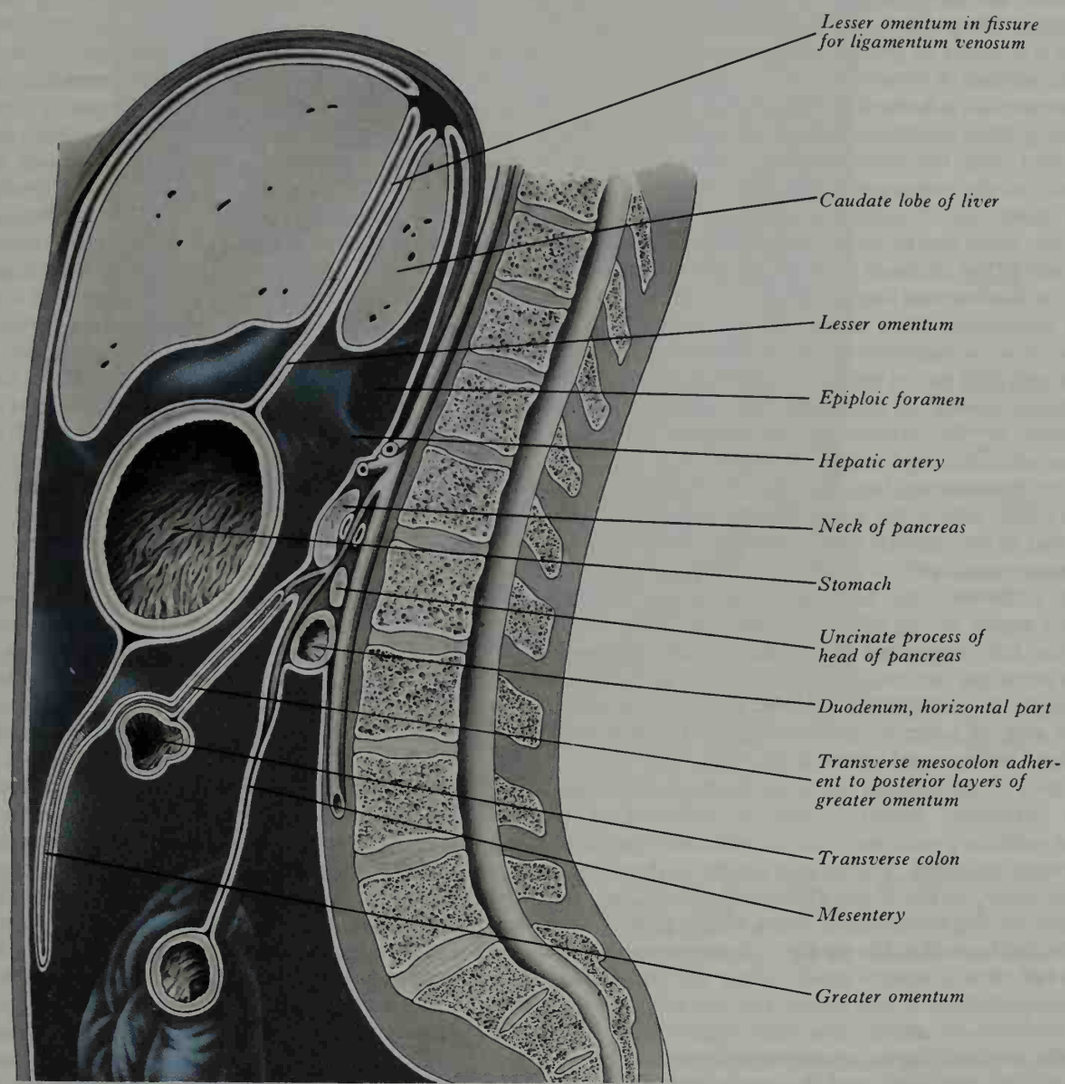
(1) **In the lesser pelvis.** The peritoneum here follows closely the surfaces of the pelvic viscera and the inequalities of the pelvic walls, and presents important differences in the two sexes. (*a*) **In the male** (**8**.95) it almost encircles the sigmoid colon, from which

8.96 The superior and inferior duodenal recesses. The transverse colon and jejunum have been displaced. (After Jonnesco. From Poirier and Charpy's *Traité d'Anatomie humaine*. Masson et Cie.)

it is reflected to the posterior wall of the pelvis as the *sigmoid mesocolon*. It leaves the sides and, finally, the front of the rectum, and is continued over the upper parts of the seminal vesicles to the superior surface of the bladder; on each side of the rectum it forms a *pararectal fossa*, which varies in size with the distension of the rectum. Anterior to the rectum the peritoneum forms the *recto-vesical pouch*, which is limited laterally by peritoneal folds extending from the sides of the bladder posteriorly, on either side of the rectum, to the anterior aspect of the sacrum. These folds are known, from their position, as the *sacrogenital folds*; each is lateral to the corresponding pararectal fossa. The peritoneum of the anterior pelvic wall covers the superior surface of the bladder, and on each side of this viscus forms a *paravesical fossa*, which is limited laterally by a ridge of peritoneum elevated by the ductus deferens. The size of this fossa is dependent on the state of distension of the bladder, and when the bladder is empty, a variable *transverse vesical* fold of peritoneum bisects the fossa. Under the same conditions, the anterior ends of the sacrogenital folds may sometimes be joined by a fold which demarcates an anterior part of the recto-vesical pouch, termed the middle fossa (**8**.95). On the peritoneum between the paravesical and pararectal fossae the only elevations are those produced by the ureters and the internal iliac vessels. (*b*) **In the female**, pararectal and paravesical fossae similar to those in the male are present; the lateral limit of the paravesical fossa is the peritoneum investing the round ligament of the uterus. The rectovesical pouch is, however, divided by the uterus and vagina into a small, anterior, vesico-uterine and a deep, posterior, recto-uterine pouch (**8**.183). The folds forming the margins of the latter are the *recto-uterine folds* (p. 1432); they correspond to the sacrogenital folds of the male, and pass backwards from the sides of the cervix uteri, on each side of the rectum, to the front of the sacrum. The *broad ligaments* extend from the sides of the uterus to the lateral walls of the pelvis; the uterine tubes are contained in their free margins, and the ovaries are attached to their posterior layers. Below, the broad ligaments are continuous with the peritoneum on the lateral walls of the pelvis. In the angle between the elevations produced by the obliterated umbilical artery and the ureter on the lateral pelvic wall, there is a shallow fossa, known as the *ovarian fossa*, in which the ovary lies in the nulliparous female. It is situated behind the lateral attachment of the broad ligament.

(2) **In the lower abdomen.** The peritoneum lining the lower part of the anterior abdominal wall is raised into five ridges or folds which converge as they pass upwards (**8**.94). One of these is placed in the median plane and extends from the apex of the urinary bladder to the umbilicus. It contains the urachus (p. 1405) and is termed the *median umbilical fold*. To its lateral side the obliterated umbilical artery forms the *medial umbilical fold*, as it ascends from the pelvis towards the umbilicus. The depressions between these folds form the two *supravesical fossae*. Further to the lateral side, the inferior epigastric artery raises a fold, called the *lateral umbilical fold*, below the point at which it enters the sheath of the rectus muscle. The *medial inguinal fossa* is the depression situated between the lateral and medial umbilical folds; the *lateral inguinal fossa*, which overlies the deep inguinal ring, lies to the lateral side of the lateral umbilical fold and indicates the site where the processus vaginalis extended into the anterior abdominal wall during the descent of the testis. A fourth depression is placed below and slightly medial to the lateral inguinal fossa and is separated from it by the medial end of the inguinal ligament. It overlies the femoral ring (p. 725) and is termed the *femoral fossa*.

Traced from the linea alba, below the level of the transverse colon, and followed in a horizontal direction to the right, the peritoneum covers the inner surface of the abdominal wall almost as far as the lateral border of the quadratus lumborum; it is reflected over the sides and front of the ascending colon and encloses the caecum and vermiform appendix; it may then be traced over the duodenum, psoas major, and inferior vena cava towards the median plane, whence it passes along the superior mesenteric vessels to invest the small intestine, and back again to the large vessels in front of the vertebral column, forming the *mesentery* (**8**.97, 98), the layers of which enclose the jejunum, ileum, the superior mesenteric blood vessels, nerves, lacteals and lymph nodes. It is then continued across the abdominal aorta and the left psoas major; it covers the sides and front of the descending colon, and, reaching the abdominal wall, is carried on it to the median plane.



(3) **In the upper abdomen** (**8**.98, 99A). Above the transverse colon, the peritoneum of the greater sac is more complexly arranged. Starting in front of the part of the inferior vena cava lying immediately above the superior part of the duodenum, the peritoneum of the greater sac is here continuous to the left, behind the epiploic foramen, with the peritoneum forming the posterior wall of the omental bursa (**8**.99A). From the front of the inferior vena cava, it passes to the right over the front of the right suprarenal gland and upper part of the right kidney to the anterolateral abdominal wall. From the anterior median line a double fold passes backwards and to the right, to become continuous with the peritoneum investing the liver, and forms the *falciform ligament*. Continuing to the left, the peritoneum lines the anterolateral abdominal wall and covers the lateral part of the front of the left kidney, and is thence reflected to the posterior border of the hilum of the spleen as the posterior or lateral layer of the *lienorenal* (or *phrenicolienal*) *ligament* (**8**.99A). It can then be traced over the surfaces of the spleen to the front of its hilum, and thence to the cardiac end of the greater curvature of the stomach as the left layer of the *gastrosplenic ligament*. It covers the anterosuperior surface of the stomach and commencement of the duodenum, and ascends from the lesser curvature of the stomach to the liver as the anterior layer of the lesser omentum. The right free border of the latter has been previously described (p. 1323), and at this border the anterior layer of the lesser omentum (formed by peritoneum of the greater sac) becomes continuous with the posterior layer of the lesser omentum (formed by the peritoneum of the omental bursa).

THE OMENTAL BURSA (LESSER SAC)

The omental bursa (or lesser sac of the peritoneum), is a large potential recess of irregular form behind the stomach and

extending beyond its limits. Its name is due to the concept that it forms a bursa (p. 522) facilitating movement of the *posterior aspect* of the stomach. It is not, however, closed, and the fact that its communication with the greater sac is so limited is due rather to embryological factors than to functional demands. The stomach expands or contracts and moves about just as freely in vertebrates in which no special narrow-necked diverticulum exists. (It is also perhaps stating the obvious, that movements of the *anterior aspect* of the stomach place similar functional demands on greater sac peritonealized surfaces.) The anterior and posterior walls of the omental bursa are extensive and they are limited by variable inferior, right, left and superior borders. The recess is shut off from the greater sac except in the upper part of its right border,

The epiploic foramen (aditus to the lesser sac) is a short, vertically flattened passage, about 3 cm long, which leads out from the upper part of the right border of the omental bursa into the greater sac. Its *anterior wall* is formed by the right margin of the lesser omentum, which contains between its two layers in this situation the bile duct, the portal vein and the hepatic artery proper (**8**.99A). Traced upwards, the two layers separate and the posterior layer covers the caudate process of the liver, forming the *roof* of the epiploic foramen (**8**.100), and then descends in front of the inferior vena cava, forming the *posterior wall* of the foramen. At, or a little below, the upper border of the superior part of the duodenum, this layer passes forwards from the front of the inferior vena cava and above the head of the pancreas to become

8.97 A sagittal section through the abdomen, approximately in the median plane. Compare with **8**.98. The section cuts the posterior abdominal wall along the line YY in **8**.98. The peritoneum is shown in blue except along its cut edges, which are left white.

where a communication is established through a vertical, slit-like opening. In its upper part the posterior wall of the lesser sac is formed by a single layer of peritoneum, closely applied to the posterior abdominal wall (**8**.97), but, below the pancreas, the sac is carried into the interior of the greater omentum and its posterior wall is formed by the posterior two layers of that structure, which, above the transverse colon, are blended with the transverse mesocolon (**8**.97). It is usual to state this part of the peritoneum to consist of four layers; but while such layers may be appreciated, it must be understood that the true, epithelial peritoneum is lost, except where a surface persists. Where two originally separate 'folds' of peritoneum adhere and blend into a single structure, the opposed epithelia disappear, although sub-epithelial layers of supporting connective tissue may still be recognizable.

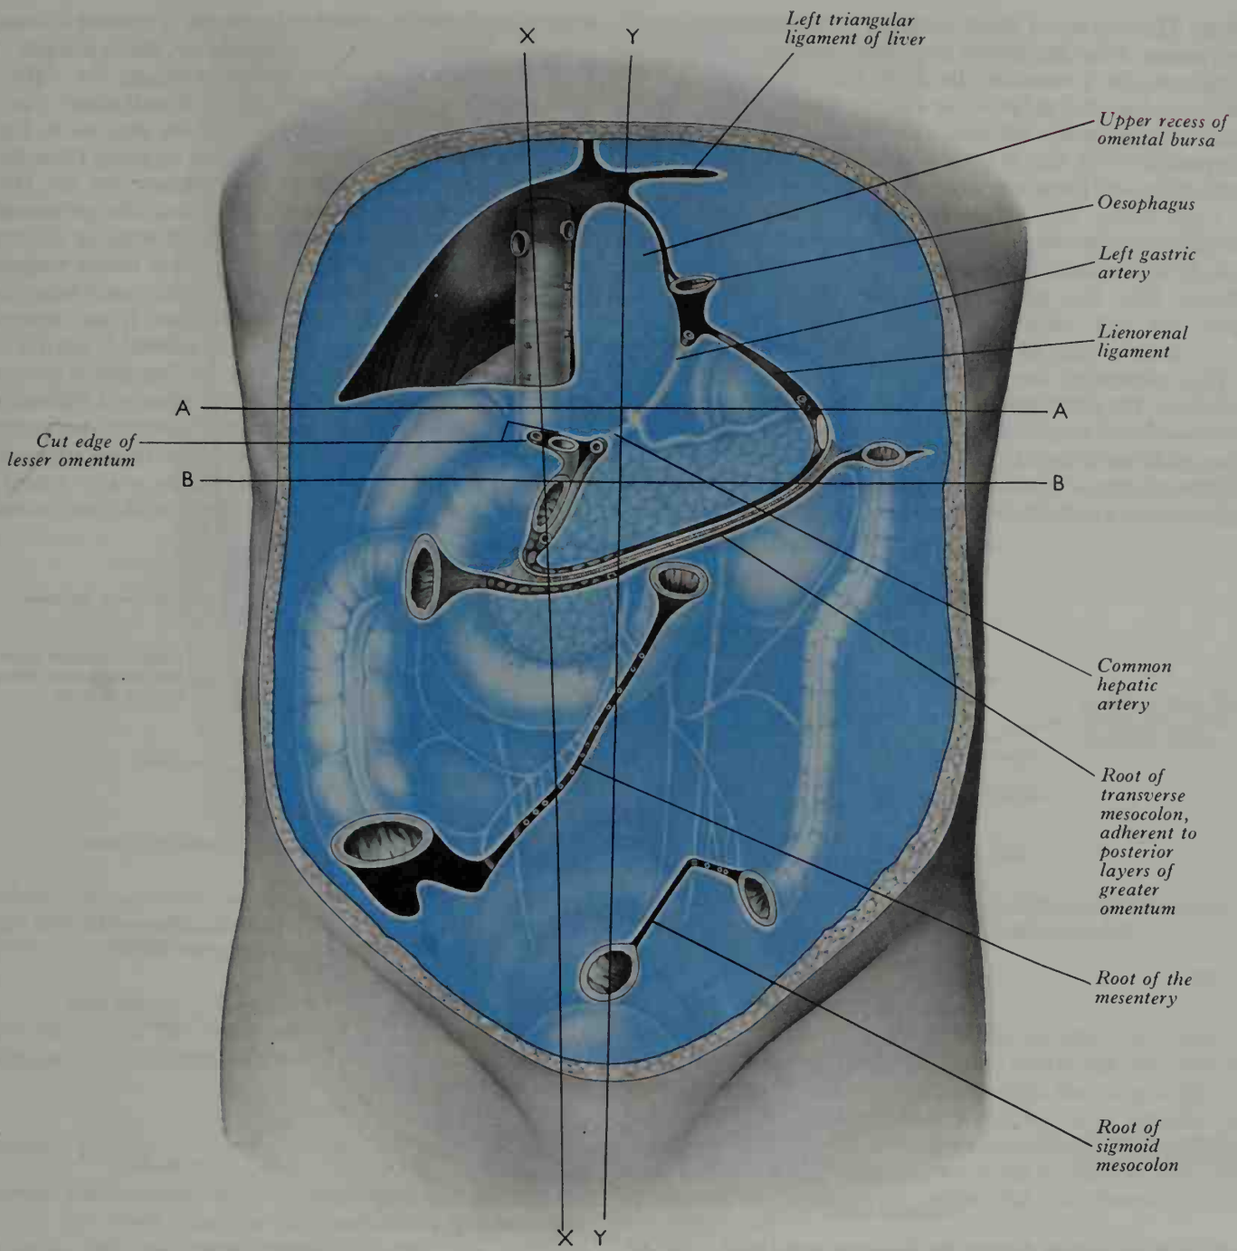
continuous with the posterior layer of the lesser omentum, and in this situation, it forms the *floor* of the epiploic foramen. The medial end of the floor is continuous inferiorly with the right border of the lower part of the lesser sac (**8**.98), and it is by passing forwards below the medial end of the floor that the hepatic artery is able to insinuate itself between the two layers of the lesser omentum (**8**.99A). The narrow passage lying to the left of the epiploic foramen, below the caudate process of the liver and above the superior part of the duodenum, is called the *vestibule* of the omental bursa. Traced laterally, to the right, all boundaries of the epiploic foramen are directly continuous with the peritoneum of the greater sac. The roof is continuous with the peritoneal covering of the inferior surface of the right hepatic lobe (**8**.135); the posterior wall with the peritoneum on the right suprarenal gland (**8**.98); the anterior wall with the anterior layer of

the lesser omentum round the portal vein and the bile duct (**8**.99A); the floor with the peritoneum covering the lower part of the right suprarenal gland and the adjacent parts of the duodenum and right kidney (**8**.98). The anterior and posterior walls of the epiploic foramen are normally in contact with each other.

The omental bursa and its boundaries can now be considered in detail. The *anterior wall* is formed (1) by the peritoneum which covers the postero-inferior aspect of the stomach and about the first 2 cm of the duodenum. Traced downwards this layer becomes the posterior of the anterior two layers of (2) the greater omentum; traced upwards and to the right, it leaves the stomach along the lesser curvature and the duodenum at its upper border, and becomes the posterior layer of (3) the lesser omentum. The omental bursa is usually described as passing upwards *behind* the caudate lobe of the liver, but this description is scarcely accurate, for the caudate lobe projects into the omental bursa from its right border and is covered by peritoneum on its anterior as well as on its posterior surface (**8**.97, 135).

The *posterior wall* is formed by the anterior of the posterior two layers of the greater omentum. Above, the posterior of these two layers is fused with, but separable from, the peritoneum on the upper aspect of the transverse colon and the upper layer of the transverse mesocolon. Surgical separation of the omentum from the transverse colon and its mesocolon thus provides access to the posterior wall of the stomach through the posterior wall (greater omentum) of the omental bursa. Dissection where the omentum meets the transverse colon opens up the embryological plane ('bloodless plane') of adhesion of the omentum to the colon and its mesocolon, and thus passes between the omental vessels (from the gastro-epiploic vessels) in the greater omentum and the middle colic vessels in the transverse mesocolon (Freder 1905; Lardennois and Okinczyc 1913; Grégoire 1922; Ogilvie 1935). There are no anastomoses between the omental and colic vessels across this plane. Above the anterior border of the pancreas, the posterior wall of the omental bursa lines the posterior abdominal wall, covering a small part of the front of the head, and the whole of the front of the neck and body of the pancreas, a small part of the anterior aspect of the left kidney and most of the anterior aspect of the left suprarenal gland, the commencement of the abdominal aorta and the coeliac artery, and a considerable area of the diaphragm. In addition, the inferior phrenic, the splenic, the left gastric and, to a much smaller extent, the hepatic arteries course behind the omental bursa (**8**.98, 99A).

The borders of the omental bursa are formed by the lines along which its peritoneal posterior wall is reflected to become continuous with the peritoneal anterior wall, and they are subject to considerable variation. The *inferior border* is, developmentally (p. 205), the lower border of the greater omentum, but, as a rule, partial fusion of the constituent layers of the greater omentum occurs after birth, so that the cavity of the omental bursa in the adult does not usually extend much below the transverse colon. (As an accompaniment of this fusion, the two internally opposed epithelial surfaces, of course, lose their epithelium.) The *upper border* of the omental bursa is narrow and extends between the right side of the oesophagus and the upper end of the fissure for the ligamentum venosum of the liver (**8**.135). In this interval the peritoneal posterior wall of the omental bursa is reflected forwards from the diaphragm and becomes continuous with the posterior layer of the lesser omentum.



The *right border* of the omental bursa corresponds, below, to the right free border of the greater omentum. Above the upper end of the latter it is formed by the reflexion of the peritoneum from the neck and head of the pancreas on to the inferior aspect of the superior part of the duodenum (**8**.99B). The line of this reflexion passes upwards and to the left along the medial side of the gastroduodenal artery. Near the upper border of the duodenum the right border becomes continuous with the floor of the epiploic foramen round the hepatic artery proper (**8**.98). Above the opening, which interrupts its continuity, the right border is formed by the reflexion of the peritoneum from the diaphragm to the right margin of the caudate lobe of the liver where it follows the left edge of the inferior vena cava (**8**.98).

The *left border* of the omental bursa corresponds, below, to the left margin of the greater omentum. Above the root of the transverse mesocolon (**8**.98) the left border is broader. It is formed by the *lienorenal* and the *gastrosplenic ligaments* (**8**.99A), which together represent a part of the original dorsal mesogastrium (p. 200). The lienorenal ligament extends from the front of the left kidney to the hilum of the spleen (*lien*) as a bilaminar fold, in which the splenic vessels and tail of the pancreas (**8**.98, 99A) are enclosed. From the hilum of the spleen these two layers are continued forwards to the greater curvature of the stomach as the gastrosplenic ligament. The inner (or right) layer of the lienorenal ligament is directly continued into the inner (or right) layer of the gastrosplenic ligament; but the outer (or left) layer of the lienorenal ligament, on reaching the back of the hilum of the spleen, is continuous with the visceral peritoneum of the spleen. The latter is then reflected from the front of the hilum of the spleen as the outer (or left) layer of the gastrosplenic ligament. The spleen thus projects to the left into the greater sac (**8**.99A). The part of the omental bursa projecting towards the spleen, between the lienorenal and gastrosplenic ligaments, is known as the *splenic recess* of the omental bursa. At their superior ends the lienorenal and the gastrosplenic ligaments merge into a short fold, the *gastrophrenic ligament*, which passes from the diaphragm, behind, to the posterior aspect of the fundus of the stomach, in front. The two layers of this ligament diverge as they approach the oesophagus and a part of the posterior surface of the stomach is devoid of a peritoneal covering. In this situation the upper end of the left border becomes continuous with the left extremity of the roof and the left gastric artery turns forwards to gain the lesser omentum. (A considerable number of peritoneal *folds* are misleadingly termed 'ligaments'. They have little in common either in structure or function with skeletal ligaments, being often the neurovascular pedicles of organs which are inevitably covered by peritoneum. In a few instances they may also have a supportive function, but the actual evidence for this is usually tenuous. The lienorenal 'ligament' might be more suitably termed *splenorenal*.)

The omental bursa is encroached upon by two crescentic folds of peritoneum which are drawn into the sac by the hepatic and left gastric arteries. The *left gastropancreatic fold* is formed by the left gastric artery as it passes from the posterior abdominal wall to reach the lesser curvature of the stomach; the *right gastropancreatic fold*, at a lower level, is formed by the hepatic artery as it passes forwards from the posterior abdominal wall to the lesser omentum (**8**.98). The folds show considerable variation in their depths but, when well marked, they constrict the lesser sac and enclose a *foramen bursae omenti majoris*. The *superior recess* of the omental bursa lies above the foramen and communicates through it with the *inferior recess*, which represents the pancreatico-enteric recess of the embryo (p. 205). The superior recess thus lies behind the lesser omentum and the liver, while the inferior recess lies behind the stomach and in the greater omentum.

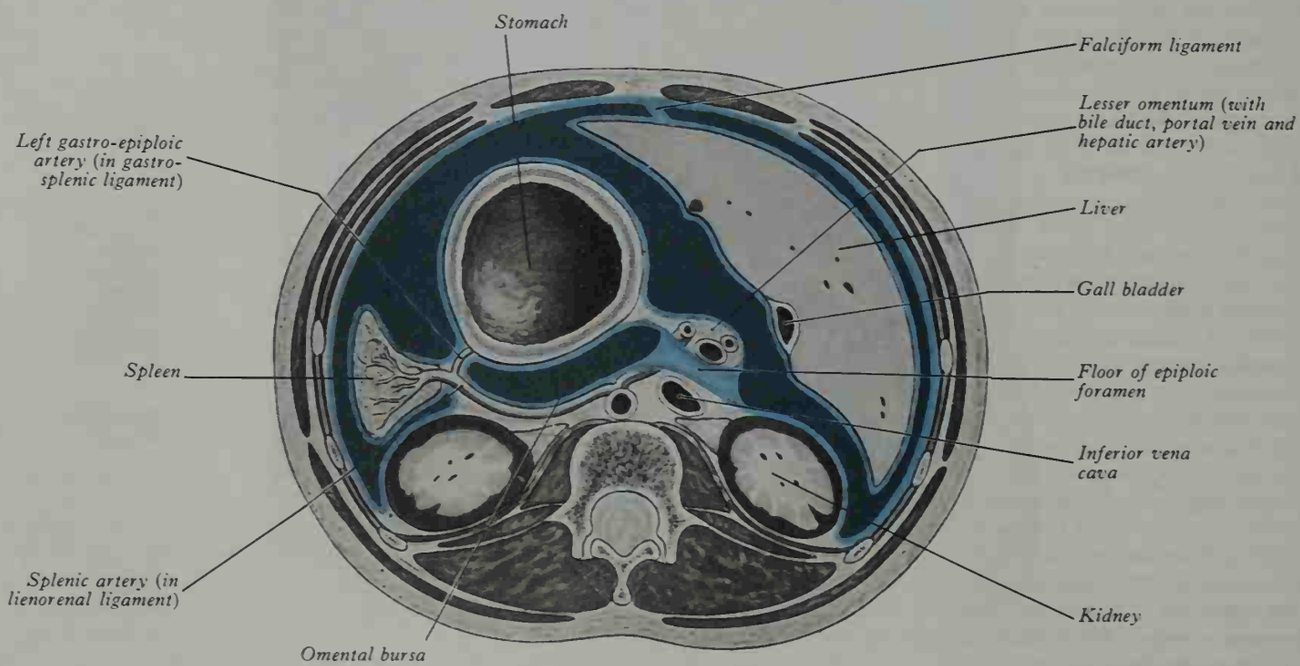
During a considerable part of fetal life the transverse colon is suspended from the posterior abdominal wall by a mesentery of its own, the posterior two layers of the greater omentum passing at this stage in front of the colon (**2**.135). This condition occasionally persists throughout life, but as a rule adhesion occurs between the mesentery of the transverse colon and the posterior layer of the greater omentum; even so, these layers of peritoneum are separable in the adult (more readily in the living subject than in the formalinized cadaver) (*see* pp. 1327, 1328), though, of course, the epithelial elements have disappeared from the fused layers, leaving only the subjacent connective tissue. In the adult the omental bursa intervenes between the stomach and the structures on which that viscus lies and which form the 'stomach bed' (p. 1334); it performs therefore the functions of a serous bursa for the stomach, facilitating the movements of the latter over the neighbouring structures.

A number of peritoneal folds extend between various organs or connect them to the abdominal and pelvic walls; they enclose the vessels and nerves proceeding to the viscera and, although they are clearly not designed to sustain any weight, they may help to retain certain of the viscera in contact with one another. They are named ligaments, omenta and mesenteries. (The inappropriate nature of the term 'ligament' in this context has been alluded to above. An 'omentum' is a cover and the word may have been used to denote an apron. Hence, the term is suitable for the greater

8.98 The posterior abdominal wall, showing the lines of peritoneal reflexion, after removal of the liver, spleen, stomach, jejunum, ileum, caecum, transverse colon and sigmoid colon. The various sessile (retroperitoneal) organs are seen shining through the posterior parietal peritoneum. Note the ascending and descending colon, duodenum, kidneys, suprarenals, pancreas and inferior vena cava. Line YY represents the plane of **8**.97. Line AA represents the plane of **8**.99 A. Line XX represents the plane of **8**.100. Line BB represents the plane of **8**.99 B.

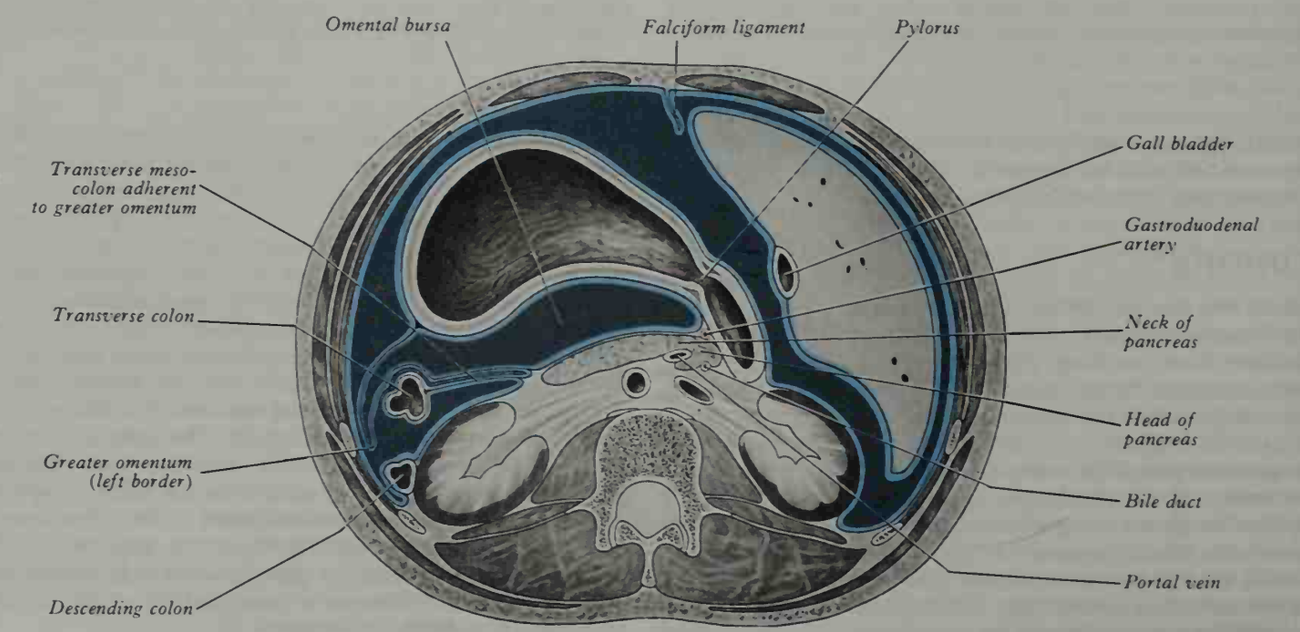
omentum, but has been used by extension for other peritoneal folds connected with the stomach.) The peritoneal 'ligaments' will be described with their respective organs.

THE OMENTA



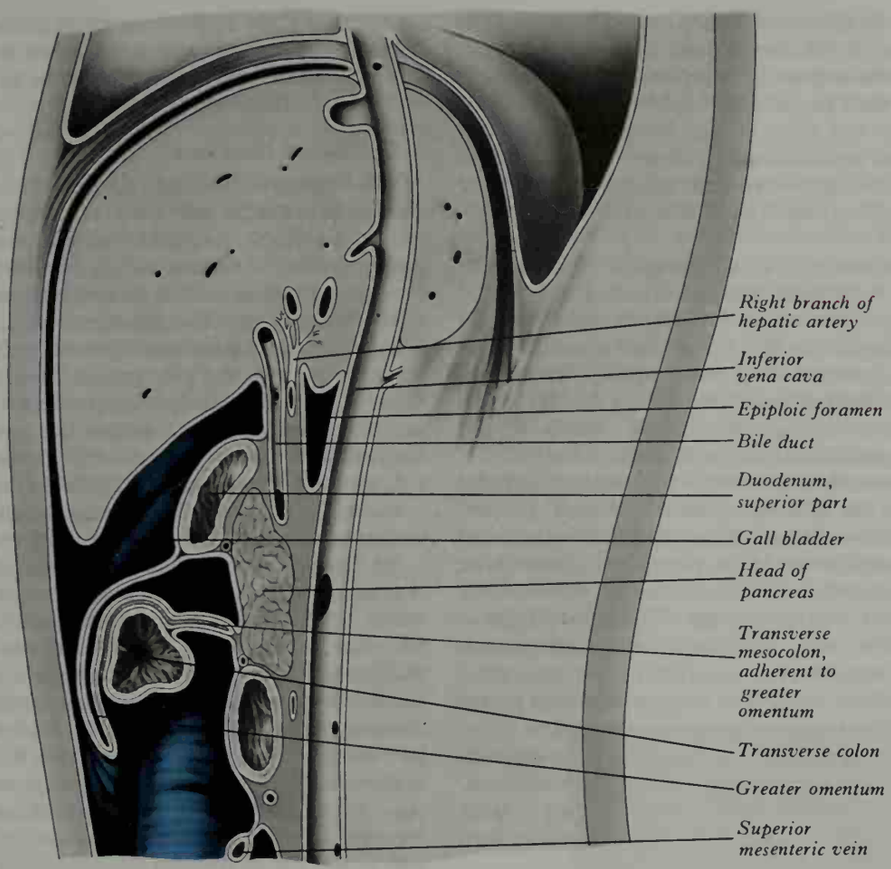
There are two omenta, the lesser and the greater.

The lesser omentum is the fold of peritoneum which extends to the liver from the lesser curvature of the stomach and the commencement of the duodenum. It is continuous with the two layers which cover the anterosuperior and postero-inferior surfaces of the stomach and about the first 2 cm of the duodenum. From the lower part of the lesser curvature of the stomach and the upper border of the duodenum, these two layers ascend as a double fold to the porta hepatis; from the upper part of the lesser curvature, the two layers pass to be attached to the bottom of the fissure for the ligamentum venosum. The hepatic attachment of the lesser omentum is, therefore, ⅃-shaped, the horizontal limb corresponding to the margins of the porta hepatis, and the vertical limb to the floor of the fissure for the ligamentum venosum. At the superior limit of the latter, the lesser omentum reaches the diaphragm, where the two layers separate to embrace the abdominal part of the oesophagus. At the right border of the omentum the two layers are continuous, and form a free margin which constitutes the anterior boundary of the epiploic foramen. The portion of the lesser omentum extending between the liver and stomach is named the *hepatogastric ligament*, and that between the liver and duodenum the *hepatoduodenal ligament*. Close to its right free margin the two layers of the lesser omentum enclose the hepatic artery proper, portal vein and bile duct, a few lymph nodes and lymph vessels, and the hepatic plexus of nerves—all these structures being enclosed in a fibrous capsule, termed the *perivascular fibrous capsule*. The right and left gastric arteries, the corresponding veins, branches from the gastric (vagus) nerves (p. 1081), and some of the left gastric lymph nodes and their vessels, lie between the layers of the lesser omentum, where these are attached to the stomach. The left part of the lesser omentum is thinner than the right part and may be fenestrated. This variation in thickness is dependent upon the amount of connective tissue and, especially fat.



The greater omentum is the largest peritoneal fold. It consists of a double sheet, folded on itself so that it is made up of

four layers. The two layers which descend from the stomach and commencement of the duodenum pass downwards in front of the small intestine for a variable distance; they then turn upon themselves, and ascend as far as the anterosuperior aspect of the transverse colon (opposite the taenia omentalis). They adhere to, but are separable from, the peritoneum on the upper surface of the transverse colon and the upper layer of the transverse mesocolon (*see* pp. 1326, 1329). The left border of the greater omentum is continuous above with the gastrosplenic ligament; its right border extends as far as the commencement of the duodenum. (It must be emphasized that the greater omentum and gastrosplenic 'ligaments' are not merely continuous; they are the same structure, separated only by descriptive convenience and terminology. This continuity has been further obscured by *changes* in terminology; the gastrosplenic *ligament* was formerly regarded as an *omentum*, but it is now officially the gastro-*lienal* ligament—a somewhat inadvisable use of the stem 'lien', the spleen, in a region where almost all else is 'splenic'.) The greater omentum is usually thin, and presents a cribriform appearance, but it always contains some adipose tissue, which in fat people is present in considerable quantity. Between its anterior two layers, about a finger's breadth from the greater curvature of the stomach, the right and left gastro-epiploic vessels anastomose with each other. Variations in the distribution and anastomoses of the arteries in the greater omentum have been recently recorded by Jiang Dian-fu (1978).



Apart from functioning as a storehouse for fat, the greater omentum may limit spread of infection in the peritoneal cavity. When the abdomen is carefully opened without disturbing the organs, the greater omentum is frequently found wrapped about the organs in the upper part of the abdomen; only occasionally is it evenly dependent anterior to the intestines. It has a lesser capacity for absorption than the peritoneum in general. That it is not a vital physiological organ is indicated by the fact that it is occasionally congenitally absent and that it may be removed without apparent ill effect. The greater omentum contains numerous fixed macrophages, which can be mobilized as free macrophages. These cells may accumulate in places into dense, oval or round patches, visible to the naked eye as '*milky-spots*' on the omentum. Similar

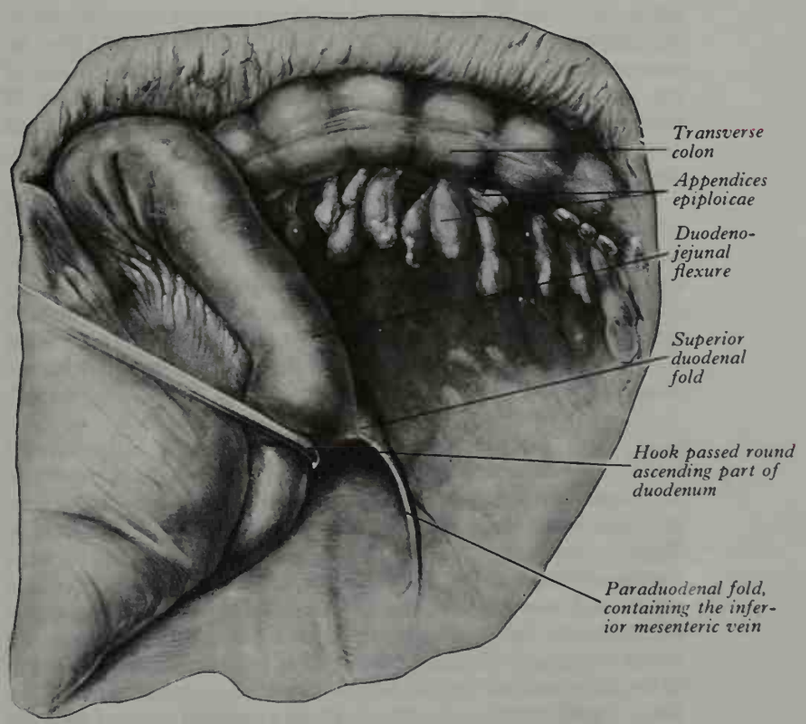
8.99B A transverse section through the abdomen, at the level of the line BB in **8.98**, viewed from above. Colours as in **8.99A**.



8.100 A section through the upper part of the abdominal cavity, along the line XX in **8.98**. The boundaries of the epiploic foramen are shown, and a small recess of the omental bursa is displayed in front of the head of the pancreas. Note that the transverse colon and its mesocolon are adherent to the posterior two layers of the greater omentum.

spots may be found on other serous membranes (pleura, pericardium and, on occasion, in association with the leptomeninges).

THE MESENTERIES

The peritoneal folds collectively known as *mesenteries* include the mesentery of the small intestine (the mesentery proper), the mesoappendix, the transverse mesocolon and the sigmoid mesocolon. An ascending and a descending mesocolon are sometimes present and the gall-bladder occasionally has a mesentery.

The mesentery (of the small intestine) is a broad, fan-shaped fold of peritoneum connecting the coils of jejunum and ileum to the posterior abdominal wall. The border attached to the posterior wall of the abdomen is called the *root of the mesentery*; it is about 15 cm (6 in.) long and is directed obliquely downwards to the right from the duodenojejunal flexure (at the left of the second lumbar vertebra) to the upper part of the right sacro-iliac joint. (Schmidt, 1974, measured the mesenteric 'root' in 44 cadavers, finding a mean length of 13·9 cm, with extremes of 7·4 and 19·3 cm.) In this course it passes successively in front of the horizontal part of the duodenum (where the superior mesenteric vessels enter the mesentery), the abdominal aorta, the inferior vena cava and the right ureter and right psoas major. The intestinal border of the mesentery is about 6 m (20 ft) long and is thrown into numerous pleats or frills. (Its length is, however, subject to much variation, *see* p. 1342.) The pleating diminishes towards the posterior abdominal wall where the root is attached along almost a straight line. The central part of the mesentery is the longest (measured from its root to its intestinal border) and attains a maximum of about 20 cm (8 in.); it becomes shorter towards each end. The mesentery consists of two layers of the peritoneum of the greater sac—right and left—between which lie the jejunal and ileal branches of the superior mesenteric artery, with their accompanying veins, nerve plexuses and lymph vessels (here called *lacteals*), the mesenteric lymph nodes, connective tissue and fat. The fat is most abundant in the lower part of the mesentery and here extends from the root to the intestinal border; in the upper part, the mesentery contains less fat and this tends to accumulate near the root and to leave oval or circular fat-free, translucent areas in the mesentery adjoining the upper part of the jejunum. At the intestinal border of the mesentery, the two layers of peritoneum separate to enclose the gut, forming its visceral

8.101 The paraduodenal recess.

peritoneal coat. At the root of the mesentery, the right layer of the peritoneum is reflected, in its lower part, over the posterior abdominal wall to cover the ascending colon, and in its upper part, to become continuous with the inferior layer of the transverse mesocolon; whereas the left layer passes to the left over the posterior abdominal wall and descending colon. (It is helpful to bear this arrangement in mind when determining which is the proximal and which the distal part of a coil of small intestine while still *in situ*.)

The mesoappendix (**8**.102) is a triangular fold of the peritoneum around the vermiform appendix, and is attached to the back of the lower end of the mesentery, close to the ileocaecal junction. It usually extends to the tip of the appendix, but sometimes it fails to reach the distal third or so, and is here represented by a low peritoneal ridge containing fat. Its layers enclose the blood vessels, nerves and lymph vessels of the vermiform appendix, together with a lymph node (p. 795).

The transverse mesocolon is a broad fold which connects the transverse colon to the posterior abdominal wall. Its two layers pass from the anterior surface of the head and the anterior border of the body of the pancreas to the posterior surface of the transverse colon (opposite the *taenia mesocolica*), where they separate to surround that part of the gut. The upper layer is adherent to, but separable from, the greater omentum (*see* pp. 1326, 1328 and **8**.97). Posteriorly, the lower layer of the transverse mesocolon covers the inferior surface of the pancreas and passes thence on to the front of the horizontal and ascending parts of the duodenum. Between the layers of the transverse mesocolon are the blood vessels, nerves and lymphatics of the transverse colon. The middle colic artery descends to the right, leaving a large avascular area of the fold to its left, and a similar but smaller area to its right.

The sigmoid mesocolon is a fold of peritoneum which attaches the sigmoid colon to the pelvic wall. Its line of attachment has the form of an inverted V, the apex of which is near the division of the left common iliac artery (**8**.98); the left limb descends medial to the left psoas major; the right limb descends into the pelvis and ends in the median plane at the level of the third sacral vertebra. The sigmoid and superior rectal vessels run between the layers of the sigmoid mesocolon and the left ureter descends into the pelvis behind its apex.

Usually the peritoneum covers only the front and sides of the ascending and descending parts of the colon, but sometimes these are surrounded by peritoneum and attached to the posterior abdominal wall by an ascending and a descending mesocolon respectively (p. 1355). A fold of peritoneum, termed the *phrenicocolic ligament*, is continued from the left colic flexure to the diaphragm opposite the tenth and eleventh ribs; it has an anterior free border and passes inferolateral to the lateral end of the spleen; it is sometimes given the misleading name of *sustentaculum lienis* or, more explicitly, 'the splenic shelf'—both implying a supportive role which is as hypothetical as it is in the case of most peritoneal folds or 'ligaments'.

The *appendices epiploicae* are small appendages of the peritoneum filled with adipose connective tissue and situated along the colon; they are best marked on the transverse (**8**.101) and sigmoid parts of the colon, absent from the rectum and rudimentary on the caecum and appendix. Many contain a small arteriole which enters them from the wall of the gut. In the case of the colon, they are most numerous along the line of the *taenia libera* (p. 1362).

PERITONEAL RECESSES

In certain parts of the abdomen, peritoneal folds may sometimes be found which bound fossae or recesses of the peritoneal cavity. These recesses are of surgical importance since they may become the site of 'internal' herniae, that is, a piece of intestine may enter a recess and may be constricted (strangulated) by the peritoneal fold guarding the entrance to the recess. Since the entrance to the recess may need to be cut to relieve strangulation and allow the gut to be drawn out of the recess, it is necessary to note whether the fold is significantly vascularized. From a surgical point of view the omental bursa can be considered to belong to this category, with its opening at the epiploic foramen, bounded in front by the free border of the lesser omentum. Other recesses, of much smaller size, are sometimes found in relation to the duodenum, caecum and sigmoid mesocolon.

1. Duodenal Recesses

(*a*) The *superior duodenal recess* (**8**.96) is present in about 50 per cent of subjects; it may exist alone but usually occurs together with the inferior duodenal recess. It lies on the left side of the upper portion of the ascending part of the duodenum, opposite the second lumbar vertebra, and is situated behind a crescentic fold of peritoneum, the *superior duodenal fold* (or *duodenojejunal fold*), which has a semilunar free lower margin and which merges, on the left, with the peritoneum covering the front of the left kidney. The inferior mesenteric vein lies behind the point of junction between the left end of the superior duodenal fold and the posterior parietal peritoneum. The recess is about 2 cm deep and admits a fingertip; its orifice looks downwards and is situated in the angle formed by the left renal vein as it crosses in front of the abdominal aorta.

(*b*) The *inferior duodenal recess* (**8**.96) is present in about 75 per cent of subjects, usually in association with a superior duodenal recess, with which it may share a single oval orifice. It lies on the left side of the lower portion of the ascending part of the duodenum, opposite the third lumbar vertebra, and is situated behind a non-vascular, triangular peritoneal fold, the *inferior duodenal fold* (or *duodenomesocolic fold*), which has a sharp upper free margin. The recess is about 3 cm deep and admits the tips of one or two fingers; its orifice looks upwards, facing that of the superior duodenal recess. The inferior duodenal recess may sometimes extend behind the ascending part of the duodenum and to the left in front of the ascending branch of the left colic artery and the inferior mesenteric vein; in these circumstances this large fossa is liable to become the site of an internal hernia.

(*c*) The *paraduodenal recess* (**8**.101) may occur together with the superior and inferior duodenal recesses. It is found more frequently in the fetus and the newborn child than in the adult, in whom it occurs in about 2 per cent of subjects. It lies a little to the left of the ascending part of the duodenum, behind a falciform peritoneal fold (*paraduodenal fold*), the right free edge of which contains the inferior mesenteric vein accompanied by the ascending branch of the left colic artery, the fold forming a mesentery for these vessels. The free margin of the fold lies in front of the wide orifice of the recess, which is directed towards the right.

(*d*) The *retroduodenal recess* is only occasionally present. It is the largest of the duodenal recesses and lies behind the horizontal and ascending parts of the duodenum, in front of the abdominal aorta. It extends upwards nearly as far as the duodenojejunal junction, being about 8 to 10 cm deep, and is bounded on both sides by peritoneal folds (the duodenoparietal folds); its orifice looks downwards and to the left.

(*e*) The *duodenojejunal* or *mesocolic recess* is present in about 20 per cent of subjects and is rarely or never accompanied by any other variety of duodenal recess. It is about 3 cm deep and lies on the left side of the abdominal aorta, between the duodenojejunal junction and the root of the transverse mesocolon; it is bounded above by the pancreas, on the left by the left kidney, and below by the left renal vein. Its orifice is circular, bounded by two peritoneal folds and looks downwards and to the right.

(*f*) The *mesentericoparietal recess* (of Waldeyer) is found more frequently in the fetus and the newborn child than in the adult, in whom it occurs in about 1 per cent of subjects. It lies just below the horizontal part of the duodenum and invaginates the upper part of the mesentery towards the right. Its orifice is large and looks towards the left; it is guarded in front by a fold of the mesentery raised by the superior mesenteric artery.

2. Caecal Recesses

(*a*) The *superior ileocaecal recess* (**8**.102) is usually present, and best developed, in children, but it may become reduced in size and is often absent in the aged, especially in the obese. It is formed by a peritoneal fold (the *vascular fold of the caecum*) which arches over the branch of the ileocolic artery (and its accompanying vein) that

supplies the ileocaecal junction on its anterior surface (anterior caecal artery). The recess is a narrow chink and is bounded, in front, by the vascular fold of the caecum, behind, by the mesentery of the ileum, below, by the terminal part of the ileum and, on the right, by the ileocaecal junction. Its orifice opens downwards and to the left.

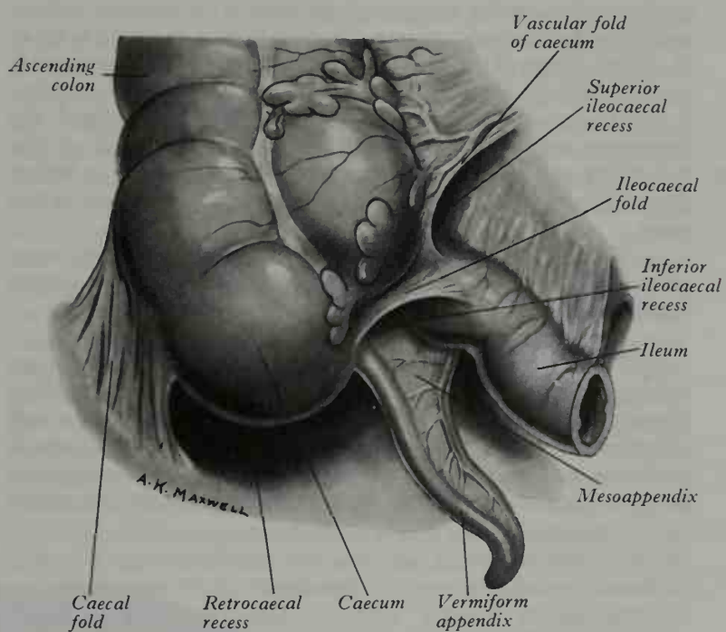
(*b*) The *inferior ileocaecal recess* (**8**.102) is well marked in the young subject but is frequently obliterated by fat in advanced age. It is produced by a peritoneal fold, the *ileocaecal fold*, which extends from the anterior and inferior surfaces of the terminal part of the ileum to the front of the mesoappendix (or to the appendix or the caecum). The ileocaecal fold is also known as the '*bloodless fold of Treves*', but it sometimes contains blood vessels; if inflamed, and especially if the appendix and its mesentery lie behind the caecum, the fold may be mistaken for the mesoappendix. (Regarding the source of vessels in this fold, *see* Cabanie and Javelle 1966.) The inferior ileocaecal recess is bounded, in front, by the ileocaecal fold; above, by the posterior surface of the ileum and its mesentery; to the right by the caecum, and, behind, by the upper part of the mesoappendix. Its orifice opens towards the left and downwards.

(*c*) The *retrocaecal recess* (**8**.102) lies behind the caecum; it varies much in size and extent and may occasionally extend upwards for some distance behind the ascending colon and be deep enough to admit an entire finger. It is bounded, in front, by the caecum (and sometimes the lower part of the ascending colon); behind, by the parietal peritoneum and, on each side, by the *caecal folds* (parietocolic folds) of peritoneum passing from the caecum to the posterior abdominal wall. The vermiform appendix frequently lies in this recess (pp. 1352, 1353).

3. The Intersigmoid Recess

This is constantly present in the fetus and during infancy, but may disappear as age advances. It lies behind the apex of the V-shaped parietal attachment of the root of the sigmoid mesocolon and forms a funnel-shaped recess which is directed upwards; its orifice opens downwards. The recess varies in size from a mere dimple to a fossa which will admit the little finger, and its posterior wall, formed by the peritoneum on the posterior abdominal wall, covers the left ureter as it crosses the bifurcation of the left common iliac artery. Occasionally the recess lies within the layers of the sigmoid mesocolon nearer the gut than the root of the mesocolon. The presence of the recess is due to imperfect blending of the mesocolon with the posterior parietal peritoneum.

ANOMALOUS PERITONEAL FOLDS



In addition to the folds described above in connexion with the peritoneal recesses, certain other peritoneal folds, bands, or ligaments are sometimes found in the abdomen. They are of interest in that some of them are considered to cause obstruction to the passage of its contents along the gut by exerting traction on, and producing angulation of, sections of the intestine. Others are thought to be of importance in limiting the spread of peritoneal effusions to certain localities in the abdomen. Their exact mode of origin is doubtful and they have been variously attributed to errors in development, to previous inflammation (peritonitis) and to mechanical traction by the gut, possibly associated with the evolution of the upright posture in man, though the latter factor is improbable. These anatomically anomalous folds must be distinguished from pathological adhesions which are definitely due to peritonitis, and it must be borne in mind that, when coils of intestine are pulled out of their normal position by the observer, they may be artificially kinked by the traction thus exerted upon their mesenteries, with resultant simulation of bands, whereas none actually existed with the gut *in situ*. Further, these anomalous folds only become of clinical importance if it be proved, in a given case, that they interfere with the normal function of the gut, and mere discovery of their presence should not cause a search for another—the real—cause of the symptoms to be neglected. The principal anomalous folds which are encountered are as follows:

(*a*) Occasionally the lesser omentum is prolonged to the right of the usual site of the epiploic foramen in the form of a peritoneal fold which may pass from the gall bladder to the superior part of the duodenum (*cystoduodenal ligament*), or in front of the latter to the greater omentum or right colic flexure, or from the under surface of the right lobe of the liver to the right colic flexure (*hepatocolic ligament*).

(*b*) The duodenojejunal junction is sometimes joined to the transverse mesocolon by a peritoneal band.

(*c*) The greater omentum may be attached to the front of the ascending colon or extend over it to the lateral abdominal wall. A thin sheet of peritoneum (*Jackson's membrane*), containing fine blood vessels, may pass from the front of the ascending colon and caecum to the lateral part of the posterior abdominal wall; it may be continuous, on the left, with the greater omentum. Occasionally a peritoneal band passes from the right side of the ascending colon to the lateral abdominal wall at about the level of the iliac crest; it has been called the 'sustentaculum hepatis', but it is only closely related to the liver in fetal and early post-natal life, when that organ is relatively larger than in the adult. Other folds passing from the ascending colon to the posterolateral abdominal wall may divide the right lateral paracolic gutter (the groove between the right side of the ascending colon and the posterior abdominal wall) into several small recesses.

(*d*) The ascending colon, and less frequently the descending colon, may have a mesentery.

8.102 The peritoneal folds and recesses in the caecal region.

(*e*) The proximal and distal ends of the sigmoid colon may be bound close to each other by a fibrous band.

(*f*) Frequently a fan-shaped peritoneal fold (the *presplenic fold*) extends from the anterior surface of the gastrosplenic ligament (near the greater curvature of the stomach), below the lateral end of the spleen, to blend with the phrenicocolic ligament. It may be adherent to the spleen or to the diaphragm, and it contains branches from the splenic or left gastro-epiploic artery. The omental bursa may be prolonged into the fold. The fold is better marked in the fetus than in the adult, in whom it often appears to be merely a part of the phrenicocolic ligament. It may be of importance in limiting peritoneal effusions in the left supracolic space (*vide infra*), and, if adherent to the spleen or diaphragm, it may form a vascular obstruction in the surgical removal of the spleen.

(*g*) A fibrous band, described as passing from the terminal part of the ileum to the posterior abdominal wall, and a similar one passing from the proximal part of the sigmoid colon to the posterior abdominal wall, were formerly thought to be the cause of partial obstruction by producing kinking of these parts of the gut, but such a view does not receive much support at the present time.

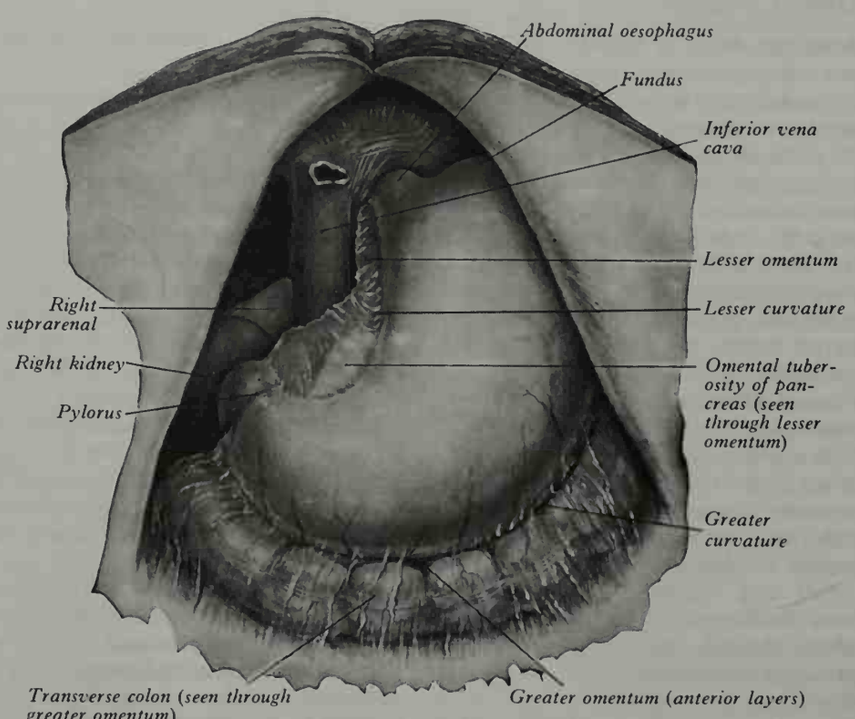
SPECIAL PERITONEAL REGIONS

From the point of view of the spread of pathological collections of fluid, the peritoneal cavity presents a number of potential spaces or recesses which are normally in communication with each other, but which may become sealed off from one another by pathological adhesions between the neighbouring peritoneum and viscera. These spaces are as follows:

(1) The *supracolic space* (or *subphrenic region*) lies between the diaphragm above, and the transverse colon and its mesocolon below. It is subdivided into (*a*) the *right subphrenic space*, which lies between the diaphragm and the anterior, superior and right lateral surfaces of the right lobe of the liver, bounded to the left by the falciform ligament, and behind by the upper layer of the coronary ligament; (*b*) the *left subphrenic space*, which lies between the diaphragm, the anterior and superior surfaces of the left lobe of the liver, the anterosuperior surface of the stomach, and the diaphragmatic surface of the spleen; it is bounded to the right by the falciform ligament, and behind by the anterior layer of the left triangular ligament; (*c*) the *right subhepatic space* (also known as the *hepatorenal recess*, or *Morison's pouch*), which is bounded, above and in front, by the inferior surface of the right lobe of the liver and by the gall bladder; below and behind, by the right suprarenal gland, the upper part of the right kidney, the descending part of the duodenum, the right colic flexure, the transverse mesocolon and part of the head of the pancreas; above and behind, it extends between the right kidney and liver as far as the inferior layer of the coronary ligament and the right triangular ligament; (*d*) the *left subhepatic space*, which is the omental bursa.

(2) The *right infracolic space* lies below and behind the transverse colon and mesocolon and to the right side of the mesentery, owing to the obliquity of which the space is widest above. The vermiform appendix often lies in the lower part of this space.

(3) The *left infracolic space* lies below and behind the transverse colon and mesocolon and to the left of the mesentery; it is widest below and in free communication with the pelvis.



(4) The *pelvic cavity*.

(5) The *paracolic gutters* are the longitudinal channels alongside the ascending and descending colon (which are normally sessile), where their visceral peritoneum dips dorsally on the medial and lateral aspects of the gut, to become continuous with the parietal peritoneum of the dorsolateral abdominal wall. Thus *medial* and *lateral* paracolic gutters exist both on the *right* (ascending colon) and on the *left* (descending colon) sides of the abdomen. Of particular surgical significance is the *right lateral paracolic gutter*. Superiorly it skirts the superolateral aspect of the hepatic flexure of the colon to become continuous with the hepatorenal pouch (of Morison), and beyond this, through its aditus, with the cavity of the omental bursa and its superior recess. Inferiorly, skirting the lateral margin of the caecum and passing unimpeded over the brim of the lesser pelvis, the right lateral paracolic gutter is continuous with the *recto-vesical* (male) or *recto-uterine* (female) *pouch* (of Douglas). Intimately related to the right lateral gutter, and its superior extension, are the vermiform appendix, the right kidney, the gall bladder, the lesser curvature of the stomach, and the first and second parts of the duodenum—all common sites of acute abdominal disease. Slow percolation of infected fluid along this channel, from one site to another, may result in uncharacteristic symptoms and signs, with consequent errors in diagnosis. Further, with the patient supine, infected fluid in the right lateral gutter, tends to *ascend* and may enter, and accumulate in, the superior recess of the omental bursa, with potentially grave consequences, because of its deep inaccessible site, and its close relation to the pleural and pericardial cavities. Conversely, with the patient nursed in the semi-sitting posture, such fluid *descends* either to the relatively accessible recto-vesical pouch or to the recto-uterine pouch which may be approached surgically through the rectum or vagina.

(6) Two extraperitoneal 'spaces' in the subphrenic region are defined, which may likewise become the site of localized infection. They are: (*a*) the *right extraperitoneal space*, which lies between the two layers of the coronary ligament, the 'bare area' of the liver, and the diaphragm; and (*b*) the *left extraperitoneal space*, which comprises the extraperitoneal connective tissue around the left suprarenal gland and the upper pole of the left kidney.

PERITONEAL ABSORPTION

With regard to the question of the absorption of fluid effusions from the peritoneal cavity, substances in complete solution (solutes) are probably absorbed directly into the blood capillaries, whereas particulate matter in suspension probably passes into the lymph vessels, with the aid of phagocytes (granular leucocytes and monocytes). After abdominal or pelvic operations, it has been customary to prop up the patient in bed so that any inflammatory intraperitoneal effusion will gravitate into the pelvis. One presumed reason for adopting this position was that the

8.103 The stomach *in situ*, after removal of the liver.

peritoneum in the subphrenic region has a greater absorptive capacity than the other regions; hence inflammatory products, if they gained access to this region, would more rapidly pass into the general circulation. It was held by some that in the subphrenic region there were gaps (peritoneal stomata) between the mesothelial cells lining the peritoneum and similar gaps (endothelial stigmata) between the endothelial cells lining the lymph vessels subjacent to the peritoneum, and that these gaps greatly facilitated absorption. It is now generally believed that these gaps are artefacts produced during the histological technique employed to demonstrate them, that absorption is more or less equally rapid in all parts of the peritoneum, and that the greater absorption in the upper part of the abdomen is to be correlated partly with the larger area of the peritoneal surface in the subphrenic region and partly with the fact that respiratory movements expedite absorption in this zone.

PERITONEAL STRUCTURE

The peritoneum consists of a single layer of flattened mesothelial cells which covers a layer of loose connective tissue. In most areas the mesothelium forms a continuous surface. Adjacent mesothelial cells are joined by junctional complexes, which probably allow the passage of macrophages to and from the underlying connective tissue, in the same manner as endothelial cell junctions allow leucocytes to pass from the bloodstream. In other areas, however, as in the greater omentum, the peritoneum may be discontinuous, presenting a series of fenestrations which may be visible to the unaided eye. At such points the mesothelial surface layer is continuous over the trabeculae of connective tissue which interlace around the margins of the fenestrae.

The sub-mesothelial connective tissue carries the cells usually found in loose connective tissues, but the population of macrophages, lymphocytes, and in some regions adipocytes, are particularly numerous. Aggregations of lymphocytes occur in some regions and form macroscopic 'milky spots' under the mesothelium. It has been claimed that the mesothelial cells possess a phagocytic capacity, and that they may leave the surface to form free macrophages. They may also transform into fibroblasts, and fusion between layers of fibroblasts of mesothelial origin may lead to macroscopic adhesions between the peritoneal surfaces of adjacent structures; if extensive, these may have serious clinical consequences, interfering with intestinal motility, or even leading to complete obstruction of the gut.

The mesothelium is similar in many respects to the endothelial lining of blood vessels, in that it forms a dialysing membrane across which fluids and small molecules of various solutes may pass. Numerous pinocytotic vesicles are present near the cell surfaces, the remaining cytoplasm being relatively poorly provided with organelles, indicating a low level of metabolic activity (Tesi and Forssmann 1970). Normally, small volumes of fluid are transferred across the peritoneal surfaces. Therapeutically, however, considerable volumes of fluid may be administered via the intraperitoneal route, whilst conversely, certain blood-borne substances such as urea can be dialysed from the bloodstream into fluid artificially circulated through the peritoneal cavity.

PERITONEAL FLUID

The fluid layer which covers the peritoneal surfaces, as already stated, contains water, electrolytes and other solutes derived from the interstitial fluid of the neighbouring tissue and from the plasma of adjacent blood vessels. It also contains proteins and a variety of cell types (Carr 1967). The latter vary in their numbers, structure and type in different pathological conditions, and they are hence of diagnostic importance. Normally the cells consist of desquamated flat mesothelial elements derived from the peritoneal surfaces, and of wandering macrophages, mast cells, fibroblasts, lymphocytes and small numbers of other leucocytes. Some of these cells, particularly the macrophages, can migrate freely between the peritoneal cavity and the surrounding connective tissue; particulate material injected intraperitoneally may therefore be ingested by these cells and transported to various other sites in the body. The lymphocytes in the fluid provide both cellular and humoral immunological defence mechanisms.

PERITONEAL VESSELS AND NERVES

The parietal and visceral layers of the peritoneum are respectively developed from the somatopleural and splanchnopleural layers of the lateral plate mesoderm (p. 118). Correlated with their embryological origin is the fact that the parietal peritoneum derives its arterial supply from the somatic (body wall) arteries supplying the abdominal and pelvic walls; its veins join the systemic veins in the neighbouring parts of the body wall, its lymphatics also join those in the body wall and thus drain into parietal lymph nodes, and its nerve supply is derived from the spinal nerves which also supply the muscles and skin of the parietes. The visceral peritoneum, however, which is to be considered as an integral part of the viscera themselves, derives its arterial supply from the arteries supplying the appropriate viscera, its veins and lymphatics join the visceral veins and lymph vessels, and its nerve supply is derived from the autonomic nerves innervating the viscera. The difference in the sensibility of the two layers of the peritoneum is thus to be correlated with their different innervation. Whereas pain is elicited by the application of tactile, thermal or chemical stimuli to the parietal peritoneum (in the conscious patient), these stimuli are ineffectual when applied to the visceral peritoneum (or to the viscera themselves). For example, the liver, stomach or intestine can be cut, pinched, clamped or burned in the conscious subject without evoking pain, the insensibility of the alimentary canal to these forms of stimulation extending from about the middle of the oesophagus down to the junction of the endodermal and ectodermal parts of the anal canal. On the other hand, a stimulus which evokes pain when applied to viscera or visceral peritoneum is tension, such as that accompanying over-distension of the hollow viscera or traction on the mesenteries, which stretches the nerve plexuses in the walls of the organs or the nerves in the mesenteries. Other effective stimuli are spasm of visceral muscle, and ischaemia (deprivation of blood supply). The somatic nerves which supply the parietal peritoneum also supply the corresponding segmental area of skin and trunk muscles, and in cases where the parietal peritoneum is irritated, the muscles are reflexly contracted, thus causing rigidity of the abdominal wall in that region. The parietal peritoneum of the under surface of the diaphragm is supplied centrally by both phrenic nerves and peripherally by the lower six intercostal and the subcostal nerves. Irritation of the peripheral part of the diaphragmatic peritoneum may result in pain, in tenderness and muscular rigidity in the area of distribution of the lower intercostal nerves. On the other hand, irritation of the peritoneum over the central portion of the diaphragm may result in pain in the area of distribution of the cutaneous branches of the third, fourth and fifth cervical nerves over the shoulder region and can lead to diagnostic errors.

The Stomach

The stomach (ventriculus or gaster) is the most dilated part of the alimentary canal, and is situated between the end of the oesophagus and the beginning of the small intestine. It lies in the epigastric, umbilical, and left hypochondriac regions of the abdomen, and occupies a recess bounded by the upper abdominal viscera, and completed in front and on the left side by the anterior abdominal wall and the diaphragm. Its shape and position are modified by changes within itself and the surrounding viscera, and no one form or position is typical. Its mean capacity varies with age, being about 30 ml at birth, increasing gradually to about 1000 ml at puberty, and commonly reaching to about 1500 ml in the adult.

The stomach has two openings, and is described as if it had two borders or curvatures, and two surfaces. In reality, of course, its external surface is a continuum, and it is not divided by any readily perceptible 'borders'. Since, however, the peritoneal surface is interrupted by the attachments of the greater and lesser omenta, along profiles which define the gastric shadow in

radiographs, these 'borders' or curvatures may be conveniently regarded as separating the surfaces. (Similar arbitrary borders are assigned to the heart, see p. 639.)

THE GASTRIC ORIFICES

The opening by which the oesophagus communicates with the stomach is the *cardiac orifice*, and is situated on the left of the median plane, behind the seventh costal cartilage 2·5 cm (1 in.) from its junction with the sternum, and at the level of the eleventh thoracic vertebra. It is placed about 10 cm (4 in.) from the anterior abdominal wall and is 40 cm (16 in.) from the incisor teeth. The short abdominal part of the oesophagus is like a truncated cone and curves sharply left, the base of the cone being continuous with the cardiac orifice of the stomach. The right side of the oesophagus is continuous with the lesser curvature of the stomach, while the left side joins the greater curvature at an acute angle, termed the *cardiac notch*. The part of the stomach to the left of and above the cardiac orifice is called the *fundus*—a curiously inappropriate term, but it is the *bottom* of the stomach, if entered surgically from below.

The opening into the duodenum is the *pyloric orifice*, and its position is usually indicated (**8**.103) by a circular groove on the surface of the organ, termed the *pyloric constriction*, which indicates the position of the pyloric sphincter. In the living subject, at operation, it can be identified by the prepyloric vein, which runs vertically across its anterior surface. The pyloric orifice lies about 1·2 cm (0·5 in.) to the right of the median plane near the level of the lower border of the first lumbar vertebra (transpyloric plane), when the body is in the supine position and the stomach is empty.

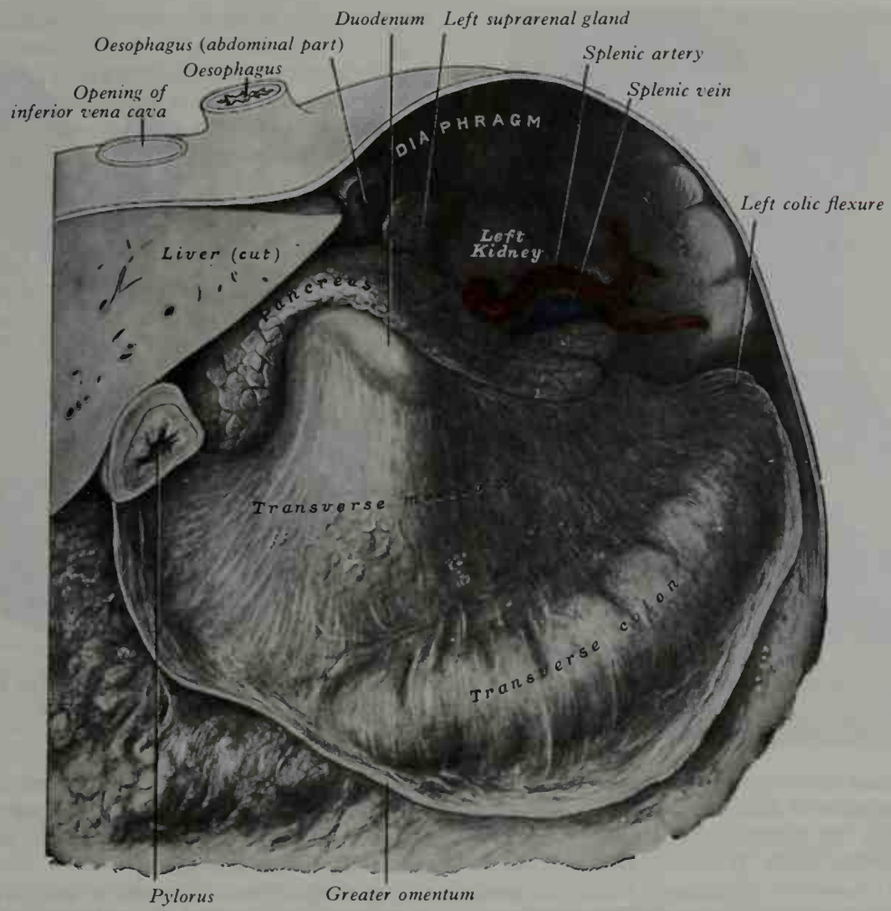
THE GASTRIC CURVATURES

The lesser curvature, extending between the cardiac and pyloric orifices, forms the right (or posterosuperior border) of the stomach. It descends as a continuation of the right margin of the oesophagus in front of the decussating fibres of the right crus of the diaphragm, and then, turning to the right, it curves below the omental tuberosity of the pancreas and ends at the pylorus (**8**.103, 105). The most dependent part of the curve may form a notch, named the *angular incisure*, which varies somewhat in position with the state of distension of the viscus; it may be used to separate the stomach into right and left parts. The lesser curvature gives attachment to the lesser omentum, the two layers of which contain the right and left gastric vessels, adjacent to the lesser curvature.

The greater curvature is directed antero-inferiorly, and is four or five times as long as the lesser curvature. Starting from the cardiac orifice at the cardiac notch, it forms an arch backwards, upwards, and to the left; the highest point of the convexity (of the *fundus*) is on a level with the left fifth intercostal space and lies just below the left nipple, though this level, like that of the diaphragm, varies with the phases of respiration (*see* pp. 550–551). From this level it may be followed downwards and forwards, with a slight convexity to the left almost as low as the cartilage of the tenth rib, when the body is in the supine position; it then turns to the right, to end at the pylorus. Directly opposite the angular incisure of the lesser curvature the greater curvature presents a bulge, which is the left extremity of the *pyloric part* of the stomach; this is limited on the right by a slight groove, which indicates the subdivision of the pyloric part into a pyloric antrum and a pyloric canal. The latter is only 2 to 3 cm in length and terminates at the pyloric constriction. At its commencement the greater curvature is covered by peritoneum continuous with that on the front of the stomach. On the left side of the fundus and the adjoining part of the body, the greater curvature gives attachment to the gastrosplenic ligament, while to its lower region are attached the two layers of the greater omentum, separated from each other by the gastro-epiploic vessels. The gastrosplenic ligament and the greater omentum (together with the gastrophrenic and lienorenal ligaments, *see* pp. 1324, 1326) are directly continuous, being parts of the original dorsal mesentery of the stomach (dorsal mesogastrium) (p. 205). The separate names merely indicate regions of the same peritoneal fold.

THE GASTRIC SURFACES

When the stomach is empty and its walls contracted, its surfaces are almost superior and inferior, but when it is distended they become anterior and posterior respectively. They may therefore be described as anterosuperior and posterio-inferior.



Anterosuperior surface. The left part of this surface is posterior to the left costal margin. It is in contact with the diaphragm, which separates it from the left pleura, the base of the left lung, the pericardium, and the sixth, seventh, eighth and ninth ribs and intercostal spaces of the left side. It is related to the costal attachment of the upper fibres of origin of the transversus abdominis, which intervene between it and the seventh, eighth and ninth costal cartilages. The upper and left part of this surface becomes posterolateral and is in contact with the gastric surface of the spleen. The right half is in relation with the left and quadrate lobes of the liver and with the anterior abdominal wall. When the stomach is empty, the transverse colon may lie on the front of this surface. The whole surface is covered with peritoneum, and a part of the greater sac of the peritoneum intervenes between it and the above structures.

Postero-inferior surface. This is related to the diaphragm, the left suprarenal gland, the upper part of the front of the left kidney, the splenic artery, the anterior surface of the pancreas, the left colic flexure, and the upper layer of the transverse mesocolon. These structures form the shallow *stomach bed*, (**8**.104), but the stomach is separable from them, and can slide over them, due to the intervening omental bursa (lesser sac). The gastric surface of the spleen is also generally described as part of the stomach bed, but as stated above it is separated from the stomach by a part of the greater sac. Further, the greater omentum and the transverse mesocolon separate the stomach from the duodenojejunal flexure and small intestine. The postero-inferior surface is covered with peritoneum, except near the cardiac orifice, where there is a small, somewhat triangular area, in direct contact with the left crus of the diaphragm, and sometimes with the left suprarenal gland. The left gastric vessels reach the lesser curvature of the stomach at the right extremity of this area (in the left gastropancreatic fold, p. 1326), and from its left side a short peritoneal fold, termed the *gastrophrenic ligament*, which is continuous below with the lienorenal and gastrosplenic ligaments, passes to the inferior surface of the diaphragm.

A plane passing through the angular incisure on the lesser curvature and the left limit of the opposed bulge on the greater curvature divides the stomach into a large, left portion or *body* and a small, right, or *pyloric part*.

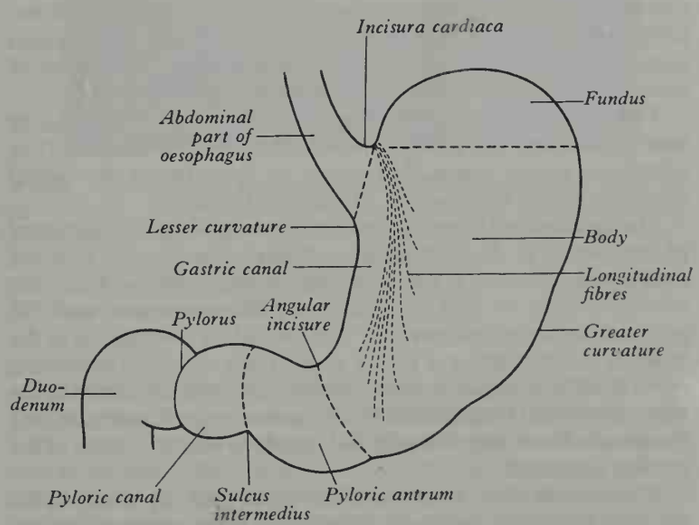
Radiology

By means of X-rays the form and position of the stomach can be studied in the living subject after swallowing a suitable 'meal' containing barium sulphate (**8**.108). During the process of digestion, it is divided by a muscular constriction into a large, dilated, left region, and a narrow, contracted, tubular, right portion. The constriction is in the body of the stomach, and does not follow any of the anatomical landmarks; indeed, it shifts gradually towards the left as digestion progresses. The position of the stomach varies with the posture, with the amount of the stomach contents and with the condition of the intestines on which it rests. It is also influenced by the tone of the abdominal muscle and of the musculature of the organ itself, and by the type of body build of the individual. In the commonest type of stomach, the empty organ is somewhat J-shaped and, in the erect posture, the pylorus descends to the level of the second or the upper part of the third lumbar vertebra, and the most dependent part of the stomach is below the level of the umbilicus. The fundus is usually distended with gas. Variation in the amount of its contents affects mainly the body of the stomach, the pyloric portion remaining in a more or less contracted condition during the process of digestion. As the stomach fills it tends to expand forwards and downwards in the direction of least resistance, but when this is interfered with by a distended condition of the colon or intestines the fundus presses upwards on the liver and diaphragm and gives rise to the feelings of oppression and palpitation complained of in such cases. When hardened *in situ*

8.104 The stomach bed: a dissection in which the stomach has been removed to show its posterior relations.

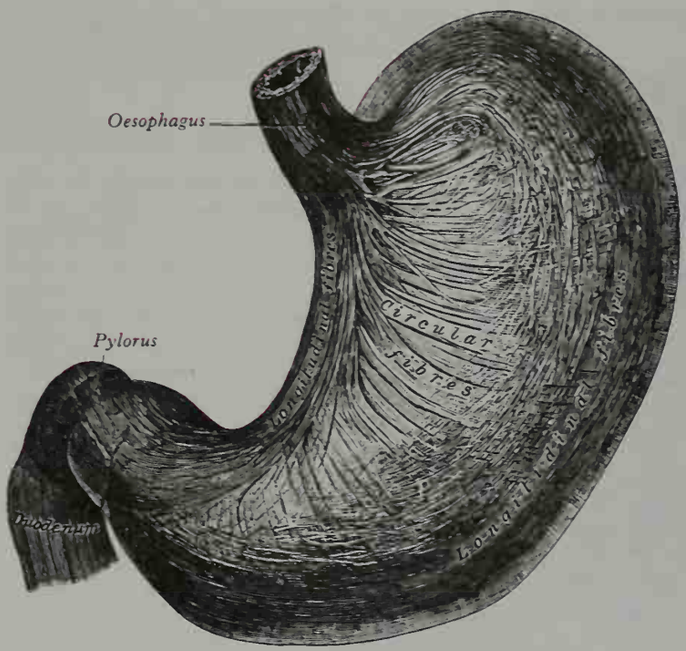
the contracted stomach is crescentic, the fundus looking directly backwards. The surfaces are superior and inferior, the upper having, however, a gradual downward slope to the right. The greater curvature is in front of and at a slightly higher level than the lesser.

The position of the full stomach depends, as already indicated, on the state of the intestines: when the latter are empty the fundus expands vertically and also forwards, the pylorus is displaced towards the right, and the whole organ assumes an oblique position, so that its surfaces are directed more forwards and backwards. The lowest part of the stomach is at the pyloric antrum, which reaches below the umbilicus. Where the intestines interfere with the downward expansion of the fundus the stomach retains the horizontal position which is characteristic of the contracted viscus. Less commonly the stomach may lie almost transversely, even in the erect posture; this is known as the '*steer-horn*' type of stomach. Intermediate types of stomach, between the J-shaped and 'steer-horn' varieties, also occur (Barclay 1936).



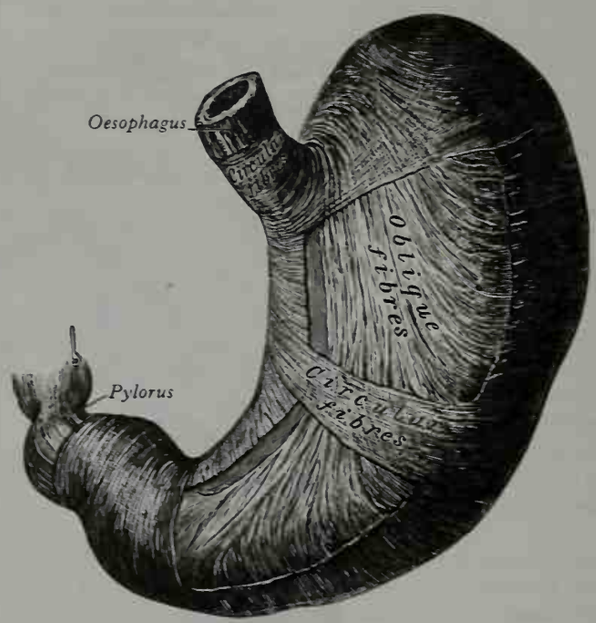
Interior of the Stomach

When examined after death, the stomach is usually fixed at some stage of the digestive process. A common form is that shown in (**8**.109). When the viscus is laid open by a section through the plane of its two curvatures, it is seen to consist of two segments: (*a*) a large globular portion on the left; and (*b*) a narrow tubular part on the right. The transition between the two regions is gradual, and this division is purely arbitrary. The cardiac incisure lies to the left of the abdominal part of the oesophagus: the projection of this notch into the cavity of the stomach increases as the organ distends, and has been supposed to act as a valve preventing regurgitation into the oesophagus. The elevation corresponding to the angular incisure is seen at the beginning, and the circular thickening of the pyloric sphincter at the end, of the pyloric region.



Modelling of the gastric epithelium in the human fetus (Lewis 1912) has shown that a channel (the *gastric canal*) extends along the lesser curvature from the cardiac orifice to the angular incisure (**8**.105). It was also demonstrated radiologically that such a canal exists in the adult (Jefferson 1915); in most cases examined whilst in the act of swallowing radio-opaque fluid it was found that the fluid was at first confined to the part of the stomach adjacent to the lesser curvature, and concluded that the oblique muscular coat of the stomach is so arranged that by its contraction it will cause a temporary separation of a canal along the lesser curvature.

The pyloric sphincter is a muscular ring formed by a marked thickening of the circular layer of the muscular coat. Some of the longitudinal fibres turn in and interlace with the fibres of the sphincter. (*See* DiDio and Anderson 1968.)



A *cardiac sphincter* is sometimes described at the oesophageal end of the stomach, formed from the circular fibres of the gastric

8.105 The parts of the stomach.

8.106 The longitudinal and circular gastric muscular fibres. Antero-superior aspect. (Spalteholz.)

8.107 The oblique muscular fibres of the stomach, shown by partial dissection of its wall. Anterosuperior aspect.

wall. Although radiological observation strongly suggests the presence of some force capable of delaying entry of oesophageal contents into the stomach, the histological evidence for this is uncertain and requires further study. It is often asserted that the muscle fibres of the right crus of the diaphragm, which decussate obliquely around the termination of the oesophagus, may exert a compressive or kinking effect at this level; but this is an anatomical speculation rather than a physiological fact. Bowden and El-Ramli (1967) have described the structure of this part of the diaphragm (see also p. 549), and they concluded that while the right crus invariably embraces the termination of the oesophagus, the relationship does not suggest an effective sphincter, although they agreed that in some positions of the trunk a kinking effect might occur. Others have suggested that the sphincter may be formed by circular muscle of the oesophageal wall (pp. 550, 1318).

GASTRIC STRUCTURE

The wall of the stomach consists of the four usual layers: serous, muscular, submucous and mucous, together with their vessels and nerves.

The serosa, or visceral peritoneum, covers the entire surface of the organ, excepting (*a*) along the greater and lesser curvatures at the lines of attachment of the greater and lesser omenta, where the two layers of peritoneum leave a small space in which vessels and nerves lie, and (*b*) a small area on the postero-inferior surface of the stomach, close to the cardiac orifice, where the stomach is in contact with the inferior surface of the diaphragm at the site of reflexion of the gastrophrenic and left gastropancreatic folds.

The muscularis externa (**8**.106, 107) is situated immediately beneath the serous covering, with which it is closely connected by subserous areolar tissue. It consists of three layers of visceral muscular fibres: longitudinal, circular and oblique.

The *longitudinal fibres* are the most superficial and are arranged in two sets. The first set consists of fibres continuous with the longitudinal fibres of the oesophagus; they radiate from the cardiac orifice, are best developed near the curvatures and end proximal to the pyloric portion. The second set commences in the body of the stomach and passes to the right, its fibres becoming more thickly arranged as they approach the pylorus. Some of the more superficial longitudinal fibres pass on to the duodenum, but the deeper fibres turn inwards and interlace with the fibres of the pyloric sphincter.

The *circular fibres* form a uniform layer over the whole of the stomach internal to the longitudinal fibres. At the pylorus they are most abundant, and are there aggregated into an annular mass, the *pyloric sphincter*. The circular fibres of the gastric wall are continuous with those of the oesophagus, but they are sharply marked off from the circular fibres of the duodenum by a connective tissue septum.

The *oblique fibres*, internal to the circular layer, are limited chiefly to the body of the stomach and are most developed near the cardiac orifice. They sweep downwards from the cardiac notch and run more or less parallel with the lesser curvature. On the right they present a free and well-defined margin (**8**.107); on the left they blend with the circular fibres.

The peristaltic contraction of the musculature of the pyloric antrum thoroughly mixes the stomach contents in this region, returning some to the body of the stomach and propelling some into the duodenum. The pyloric sphincter contracts intermittently during contraction of the antral musculature, but, when the stomach is at rest, it is relaxed, leaving the pylorus open (Atkinson *et al.* 1957; Spira 1957). The exact mechanism of control of the transfer of stomach contents through the pylorus into the duodenum is still not fully clarified. For an authoritative summary consult Hunt and Knox (1968).

The submucosa consists of loose, areolar tissue, connecting the mucous and muscular layers.

The mucous membrane is thick and its surface is smooth, soft and velvety. In the fresh state it is of a pinkish tinge at the pyloric end, and of a red or reddish-brown colour over the rest of its surface. During the contracted state of the organ it is thrown into numerous folds or rugae which for the most part have a longitudinal direction, and are best marked towards the pyloric end of the stomach, and along the greater curvature (**8**.109). These folds are obliterated when the organ is distended.

STRUCTURE OF GASTRIC MUCOSA

When examined with a lens, the luminal surface of the mucous membrane (**8**.109) has a honeycomb appearance, because it is covered with small depressions or alveoli, of a polygonal or slit-like form, about 0·2 mm in diameter. These are the *gastric pits* and at the bottom of each are the orifices of the gastric glands. The surface of the mucous membrane including the gastric pits is covered with a single layer of columnar secretory epithelial cells, the *surface mucous cells*, which liberate mucus from their apices on to the surface of the stomach. This acts as a lubricant and also protects the gastric lining against its own secretions of acid and enzymes. This type of epithelium commences very abruptly at the cardiac orifice, where there is a sudden transition from the stratified epithelium of the oesophagus. The *gastric glands*

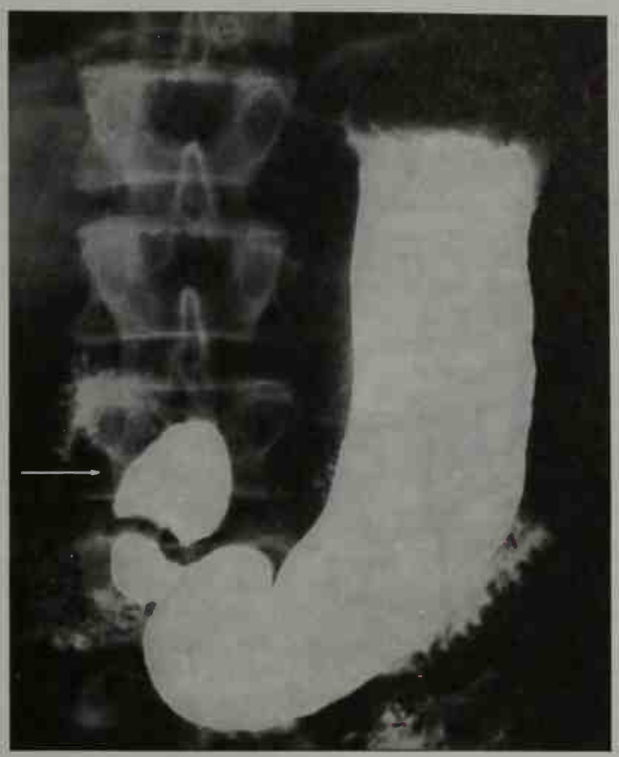
comprise: (1) cardiac glands; (2) main glands of the body and fundus; and (3) pyloric glands.

The cardiac glands (**8**.110A) are infrequent and confined to a small area near the cardiac orifice; some are simple tubular glands whilst others are compound racemose in type. Mucus-secreting cells predominate whilst oxyntic and zymogenic cells are infrequent.

The main gastric glands of the body and fundus, of which from three to seven open into each gastric pit, are cytologically the most highly differentiated of the gastric glands (**8**.110B, C). At least four distinct cell types have been distinguished:

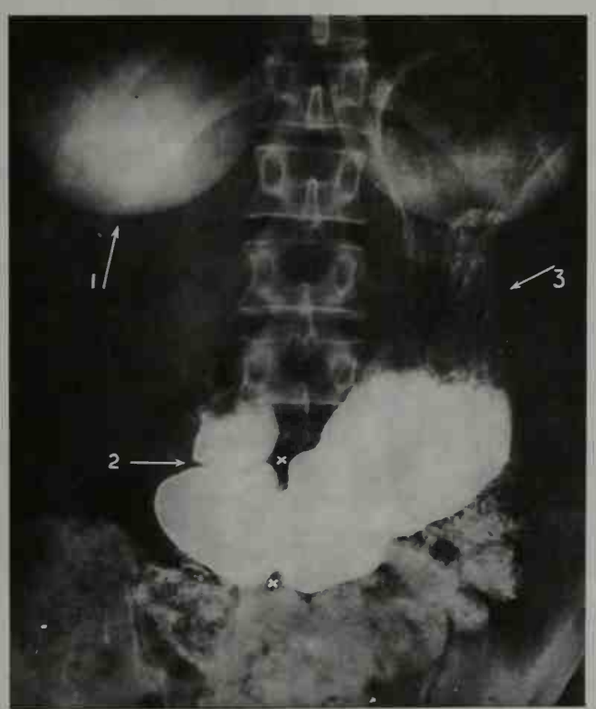
(1) The *chief* (*peptic* or *zymogenic*) *cells* are present particularly in the basal parts of the glands. These are cuboidal, typical protein-synthesizing cells, containing prominent secretory bodies, much rough endoplasmic reticulum, a prominent Golgi complex, and by light microscopy they are strongly basophilic because of their contained RNA. These cells are the source of the digestive enzymes of the stomach (**8**.109).

(2) The *oxyntic* (*parietal*) *cells*, large, rounded and eosinophilic, are most numerous on the side walls and near the duct of the gland. They occur only at intervals, and with the light microscope appear to be applied to the external surface of the other cell types, or partly intercalated between their external aspects. They bulge into the adjacent lamina propria, producing a moniliform or beaded appearance. They are connected with the lumen of the gland by fine processes that pass between the adjacent cells. Ultrastructural studies have shown that the oxyntic cells possess tortuous intracellular canaliculi, the surfaces of which are covered with microvilli, and which open directly into the lumen of the gland on the apices of the fine processes which pass centrally between the adjacent cells as mentioned above. Each cell possesses a large, round, centrally-placed nucleus, and the surrounding cytoplasm carries only sparse endoplasmic reticulum and no secretory granules, but a very large number of closely packed mitochondria. Minute smooth-walled membranous tubules converge on, and open into, the intracellular canaliculi (**8**.109).



(3) *Mucous 'neck' cells* are disseminated between the other types of cell and are particularly numerous around the necks of the glands. They are typical mucus-secreting cells, but their secretions are distinct histochemically from those of the surface mucous cells.

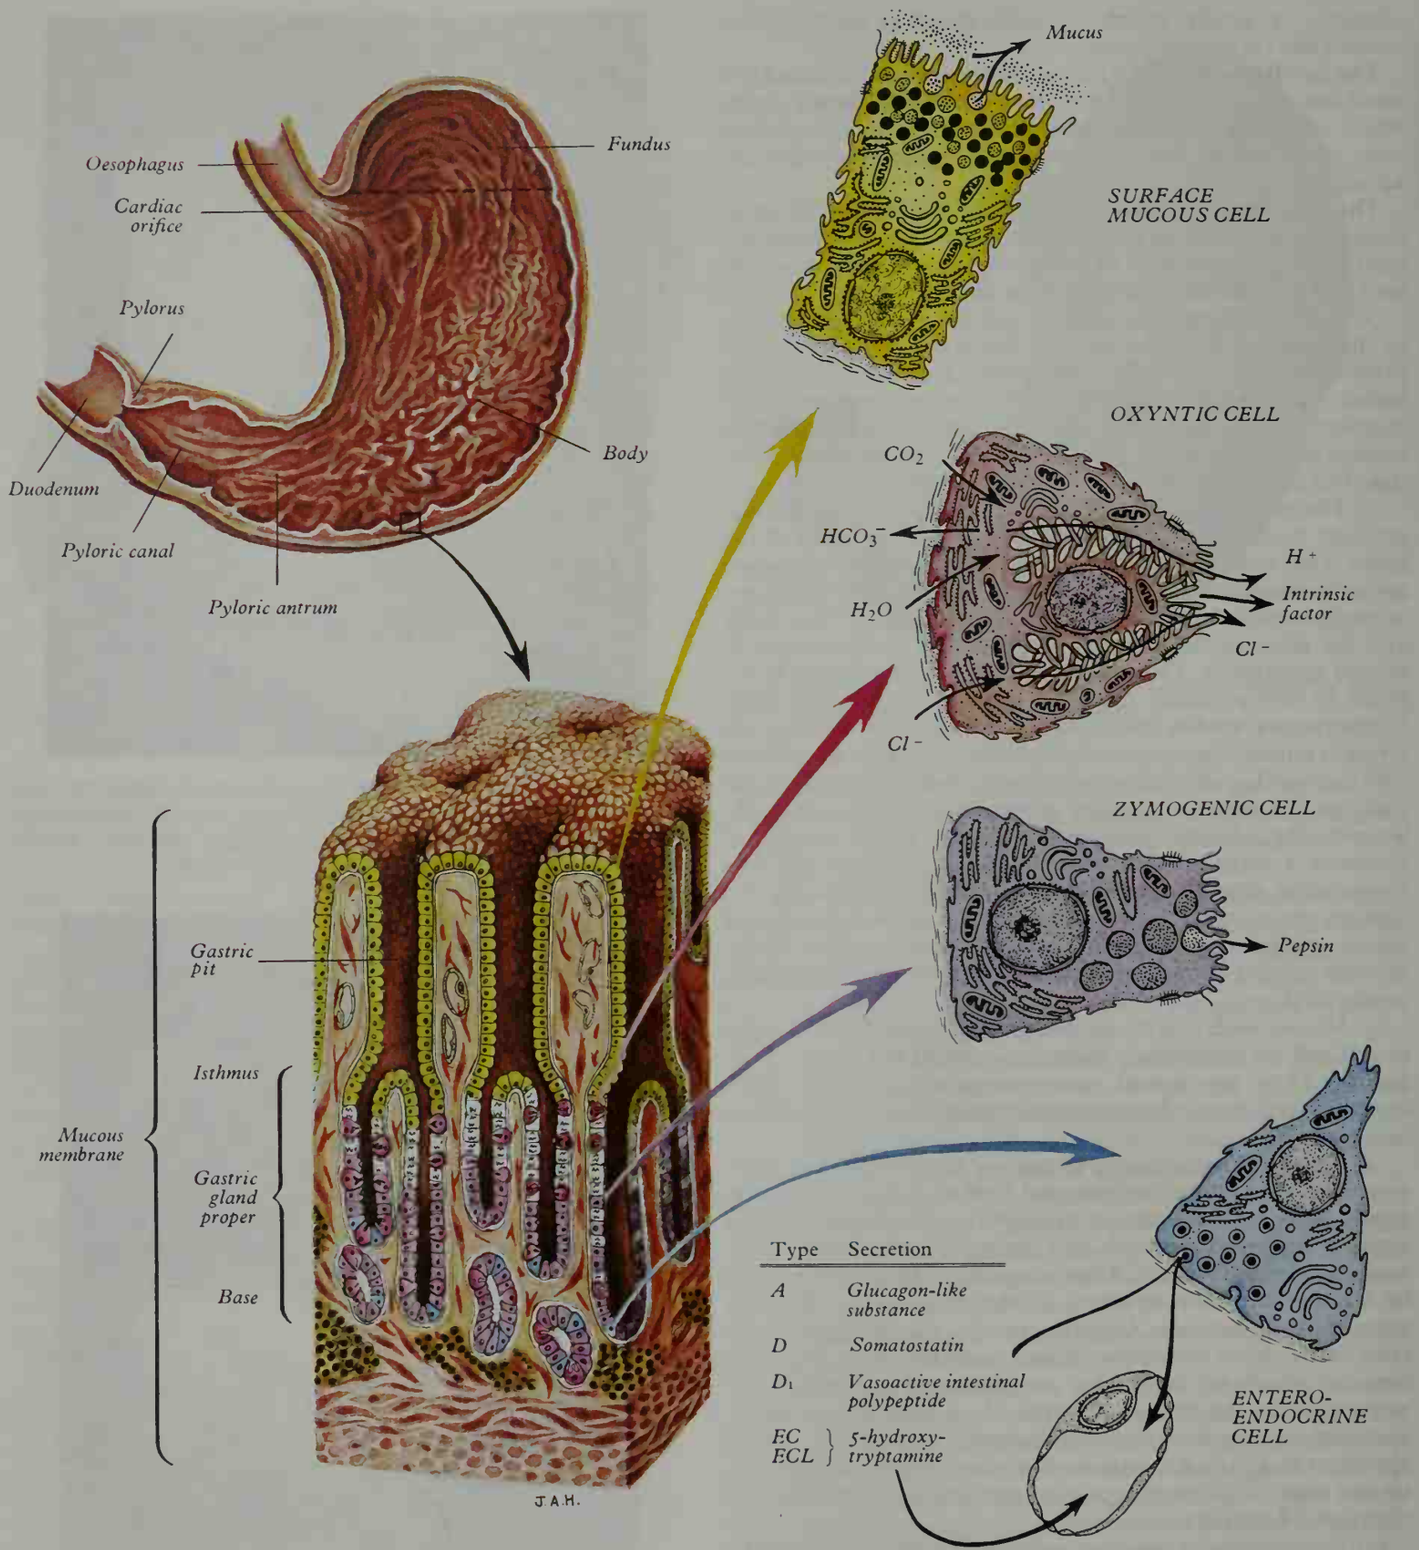
(4) *Argentaffin cells* occur in all types of gastric gland but more commonly in those of the body and fundus than in the pyloric glands. They are more usual in the deeper parts of the gland, lying between the zymogenic cells and the basal lamina; they rarely reach the glandular lumen. Their irregular nuclei are surrounded by a granular cytoplasm which is impregnated strongly with silver-staining methods. Ultrastructurally, the cytoplasm contains many dense membrane-bound vacuoles of varying size, some of which are large (0·3 μm diameter) and which are responsible for the staining reaction. These cells are part of the gastroenteropancreatic endocrine system, described in detail elsewhere (p. 1364), and are now subdivided into a variety of types on the basis of differences in their detailed ultrastructure and secretions (**8**.109, 129).



(5) *Undifferentiated columnar cells* are also present in smaller numbers, and these appear to be the origin of new cells to replace the existing ones as they are lost. Surface mucous cells last for about three days, and mucous neck cells for about one week. Other cell types appear to live considerably longer.

The pyloric glands each consist of two or three short convoluted tubes opening into a conical pit, which occupies about two-thirds of the depth of the mucous membrane (**8**.110D). The epithelial cells are predominantly mucous in type, oxyntic cells being sparse. The enteric hormone *gastrin* has been isolated from these glands in man. Gastrin is released by mechanical stimuli, and acts to increase stomach motility and the secretory activity of chief and oxyntic cells (see also p. 1365).

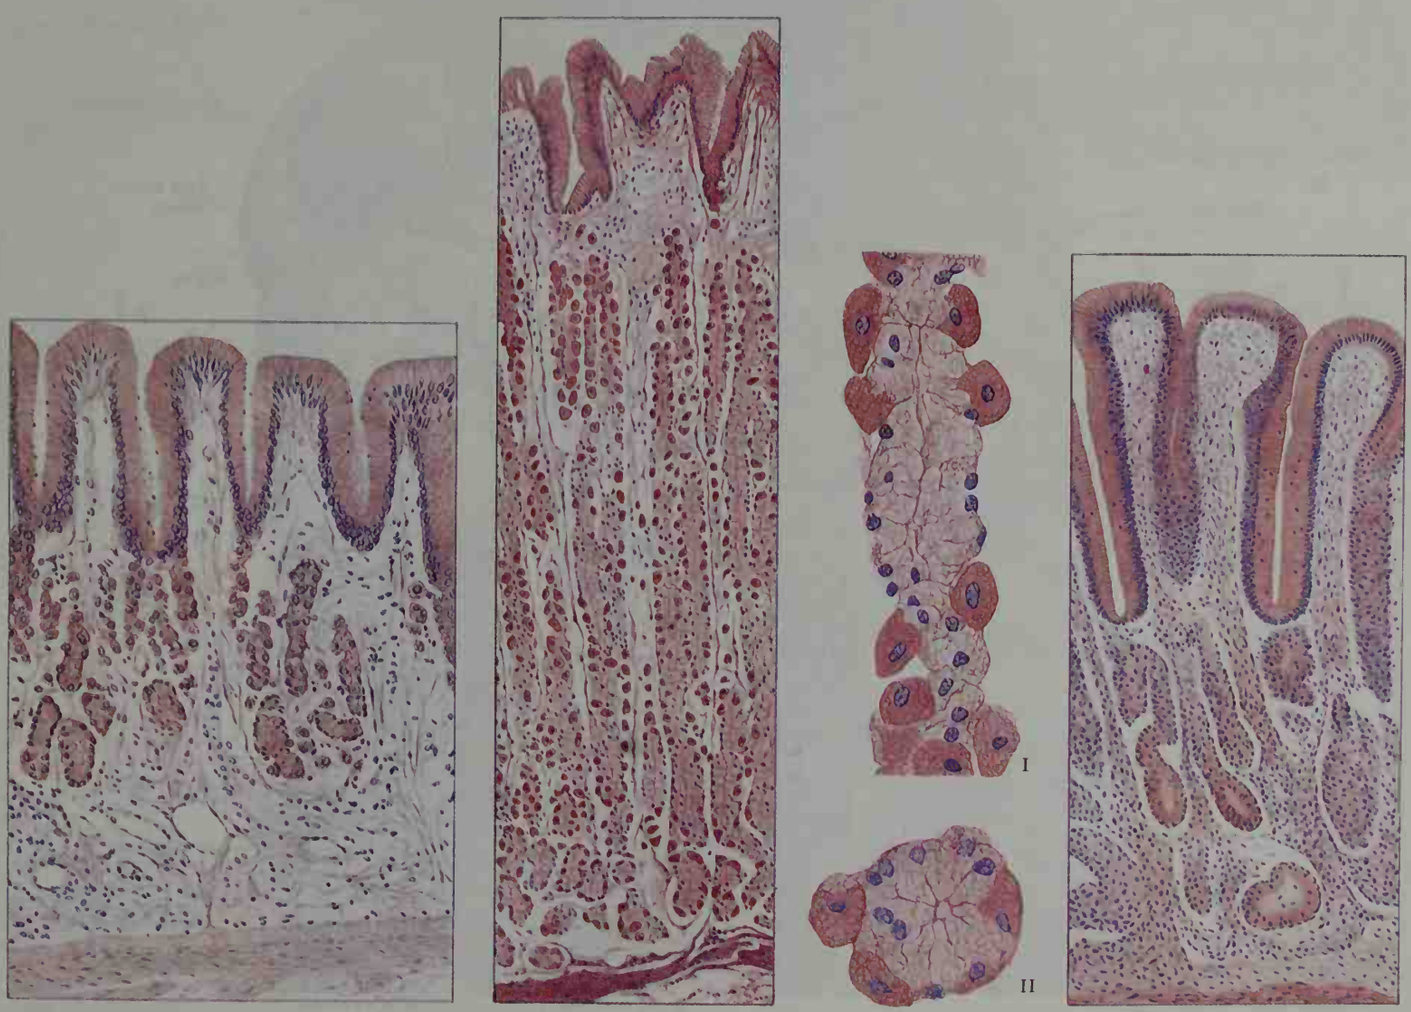
Although the oxyntic cells are relatively few in pyloric glands, they are apparently invariably present, both in fetal and postnatal material; in adults they may also appear in the mucous membrane of the duodenum, but only in its proximal part, near the pylorus (Leela and Kanagasuntheram 1968).



8.108A Radiograph of a normal stomach after a barium meal. The tone of the muscular wall is good and supports the weight of the column in the body of the organ. The arrow points to the duodenal cap, below which a gap in the barium indicates the position of the pylorus.

8.108B Radiograph of an atonic stomach after a barium meal. Note that this stomach contains the same amount of barium suspension as the stomach in **8**.108A. Arrow 1 points to the shadow of the right breast, arrow 2, to the pylorus, arrow 3, to the upper part of the body of the stomach, where longitudinal folds can be seen in the mucous membrane. XX marks a wave of peristalsis.

Between the glands the lamina propria consists of a connective tissue framework, and lymphoid tissue. In places, this latter tissue, especially in early life, is collected into little masses which resemble the solitary follicles of the intestine, and are termed the *gastric lymphatic follicles*. In the mucous membrane, deep to the glands, is a thin stratum of nonstriated muscle fibres, the *muscularis mucosae*; it consists of an inner circular and an outer



8.109 A diagram showing the principal regions of the interior of the stomach, and the histology and ultrastructure of its mucous membrane. Undifferentiated, dividing, cells are shown in white.

longitudinal layer (with a third, outer circular layer, in places). The inner layer sends strands between the glands, the contraction of which probably aids the emptying of the glands.

Vessels and Nerves

The stomach is supplied by the left gastric artery (from the coeliac artery), the right gastric and right gastro-epiploic arteries (from the common hepatic artery), and the left gastro-epiploic and short gastric arteries (from the splenic artery). These vessels not only anastomose extensively on the serosal surface of the stomach, as described elsewhere (p. 712), but they also form anastomotic networks in their intramural distribution at intramuscular, submucosal, and mucosal levels; but it is at the submucosal level that a true plexus of small arteries and arterioles is deployed. This *submucosal plexus*, from which the mucosa is supplied, presents considerable regional variations, not only in the gastric wall, but also in the proximal part of the duodenum. In view of the possible implications of a vascular factor in the genesis of peptic ulcer in these regions, the local details of angio-architecture are of considerable interest. It has been claimed that arteriovenous anastomoses occur in the gastroduodenal mucosa (Spanner 1932; De Busscher 1948; Barlow *et al.* 1951; Boulter and Parkes 1963),

and that dysfunction in these might produce local ischaemia and hence ulceration. Mucosal end-arteries have also been described, and larger vessels such as the supraduodenal artery (p. 713) have similarly been designed end-arterial. These problems have been most recently discussed, from the anatomical point of view, by Piasecki (1974, 1977), and the results of his observations on fetal, neonatal, and adult human stomachs, injected with India ink, form the basis of this account of the gastric intramural arteries. From the anastomotic arcades formed along the greater and lesser curvatures by the main arteries of supply mentioned above, large numbers of branches pass on to both anterior and posterior aspects of the stomach, in directions approximately transverse to the organ's long axis. In addition to these *anterior* and *posterior gastric arteries* smaller rami, which are often paired, pass directly towards the part of the gastric wall subjacent to attachments of omenta. As these vessels ramify on the external surface and then penetrate the muscular layer of the wall to reach the submucous and mucosal levels of connective tissue, they form plexuses—subserosal, intramuscular, and submucosal, of which the second is the most richly developed (**8**.111B, C). The muscular plexus is supplied by branches from both the subserous and submucosal plexuses, and the muscular vessels vary in direction in the different laminae of muscle, perhaps in adaptation to their characteristic directions of contraction. The arteries of the submucosa anastomose freely, but the incidence of arterial anastomoses varies in different regions. Counts by Piasecki (1974) showed that while the *number* of anastomoses along, for example, the lesser curvature increased from its cardiac to its pyloric end, the mean calibre of the anastomosing arteries showed a reverse tendency. The mucosal arteries, which fill the capillary networks supporting the epithelium and its glands, are chiefly derived from the submucous plexus; but along both curvatures a few mucosal arteries are derived directly from extramural (subserosal) sources. These pass through the muscular layers and submucosa, often without lateral communications with submucosal arteries. The incidence of these vessels apparently increases from the cardiac to the pyloric region of the stomach in man. The capillary networks supplied by them are largely independent of those fed by adjacent submucosal arteries, and to that extent the patch of mucosa supplied by such a vessel may be considered more vulnerable to vascular obstruction. According to Piasecki mucosal arteries in general do not form lateral anastomoses, but since their submucosal feeders do, vascular obstruction is to that degree less likely. The same observer examined the pyloric canal and sphincter, and showed a different pattern of supply. Rami of the right gastric and gastro-epiploic arteries (*'pyloric' arteries*) pierce the duodenum immediately distal to the pyloric sphincter around its entire circumference, passing through the muscular layer to reach the submucosa, where each divides into two or three branches. These turn into the pyloric canal, internal to the sphincter, to traverse the submucosa as far as the termination of the pyloric antrum (**8**.111C), supplying the whole of the mucosa of the pyloric canal. Branches of these pyloric submucosal arteries may anastomose at their commencement with duodenal sub-

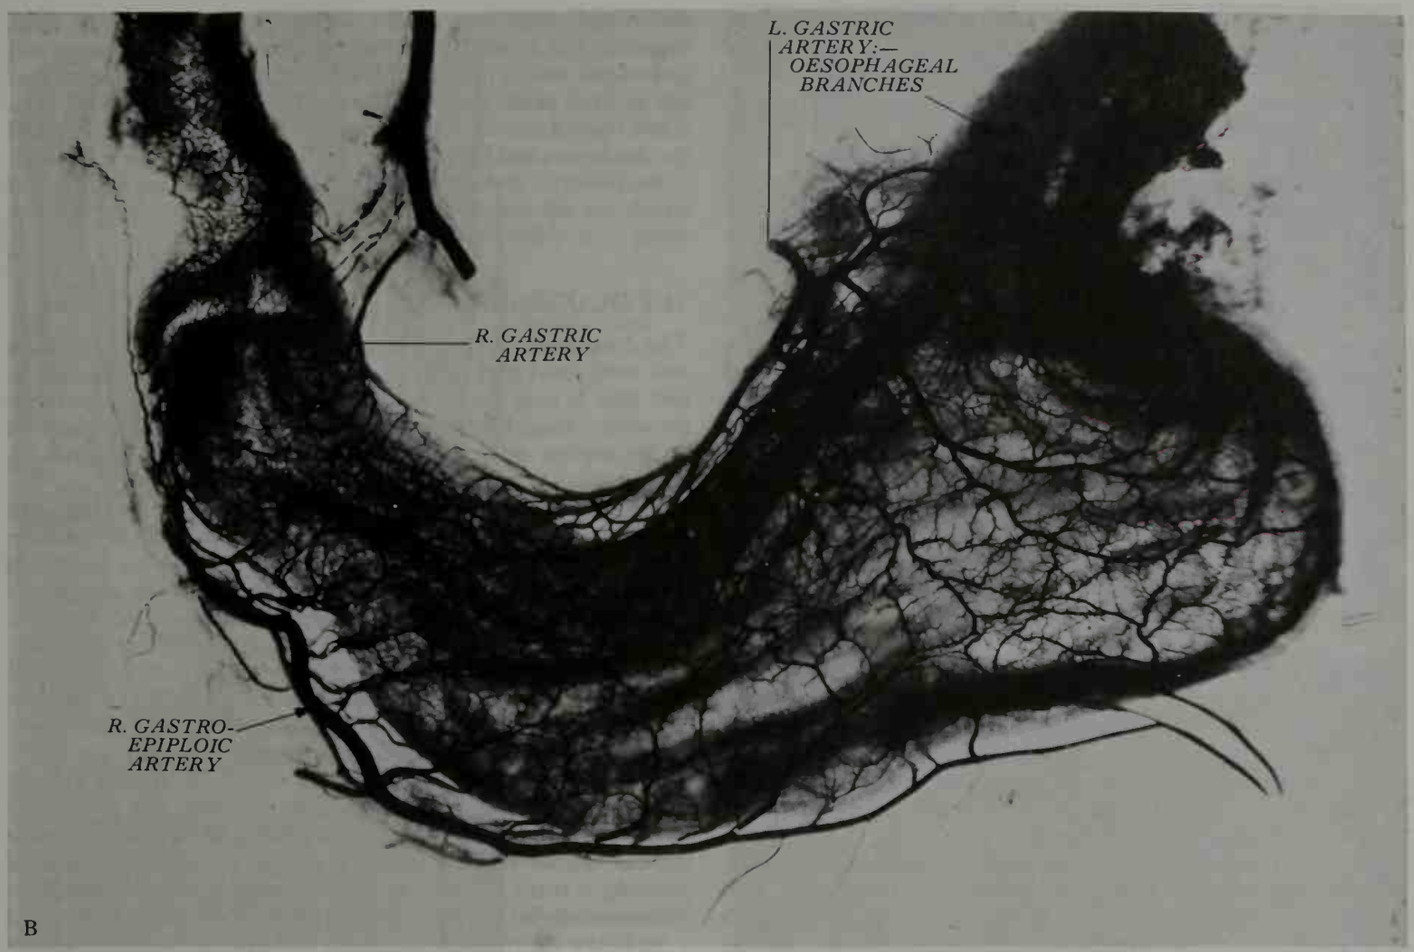
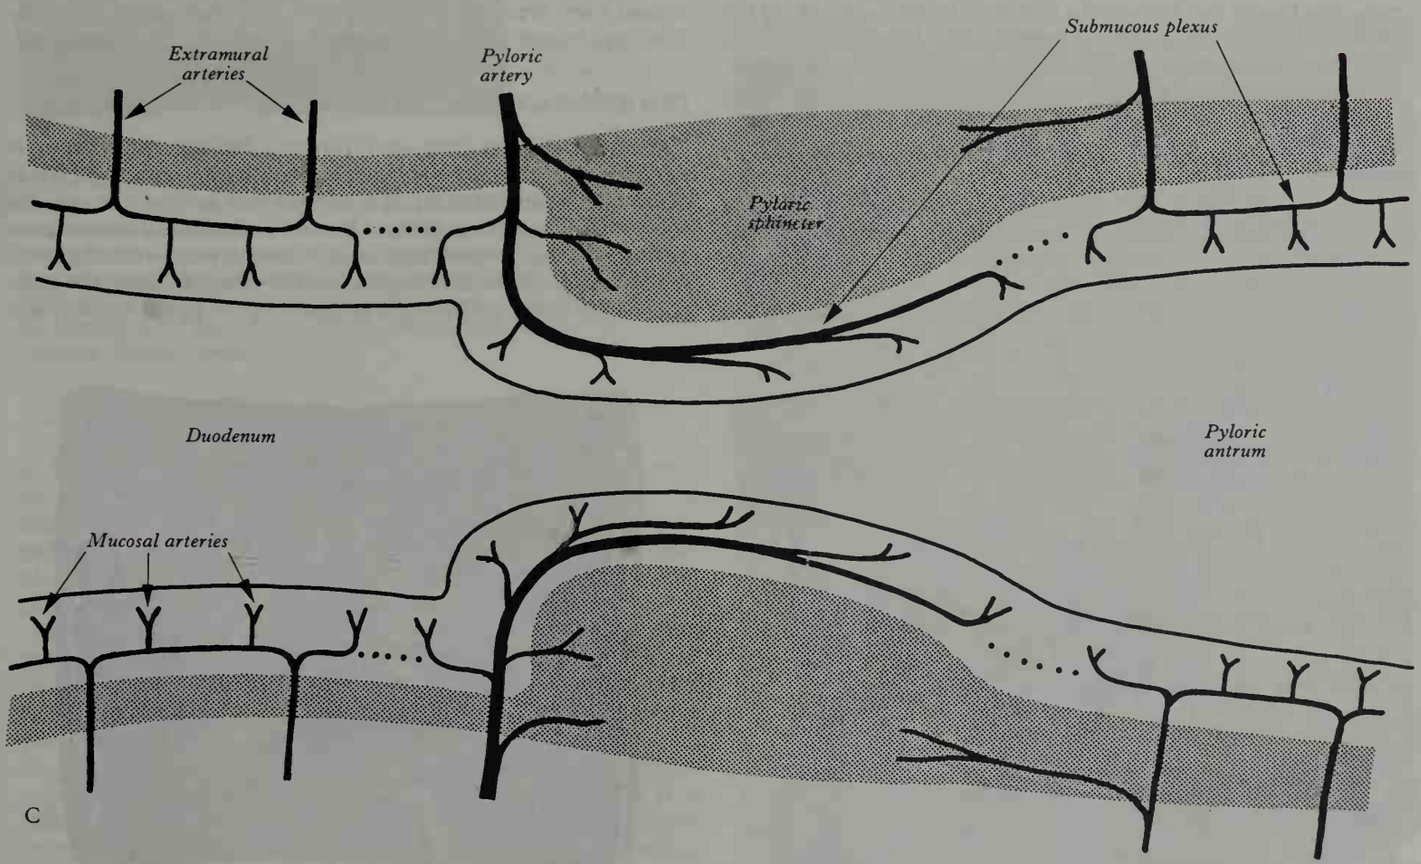
mucosal arteries and, by their terminal branches, with the corresponding gastric arteries. The pyloric sphincter itself is supplied by gastric and pyloric arteries, rami of both of which leave their parent vessels in the subserosal and submucosal parts of their courses to penetrate the sphincter.



The gastric veins commence as straight vessels between the glands of the mucosa, and these drain into submucosal veins. Their further arrangement has not received the same attention as the corresponding arteries; but the larger veins accompany the main arteries to their ultimate drainage into the splenic and superior mesenteric veins, while some pass directly to the portal vein. The smaller lymphatic vessels are said to resemble the veins in distribution. The regional lymph nodes and their final drainage are described on p. 793.



The *nerves* are derived from multiple sources. The sympathetic supply is mainly from the coeliac plexus through the plexuses around the gastric and gastro-epiploic arteries. Some branches from the plexus around the hepatic artery proper reach the lesser curvature by passing between the layers of the hepatogastric ligament (p. 1327). Branches from the left phrenic plexus pass to the cardiac end of the stomach, which also receives a twig from the branch of the left phrenic nerve to the right crus of the diaphragm. Inconstant branches are given to the stomach from the left thoracic splanchnic nerves and from the thoracic and lumbar sympathetic trunks.

The parasympathetic supply is derived from the vagus nerves. Usually one or two nerve trunks lie on the anterior and one or two on the posterior aspect of the gastro-oesophageal junction; the anterior nerves comprise for the most part left vagal fibres, and the posterior right vagal fibres, which have emerged from the oesophageal plexus. The anterior nerves supply several filaments to the cardiac orifice and then divide near the upper end of the lesser curvature into branches. Of these: (*a*) *gastric branches* (4–10) radiate on the anterior surface of the body and fundus of the stomach; one is larger than the others and lies in the lesser omentum near the lesser curvature (the *greater anterior gastric nerve*); (*b*) *pyloric branches*, generally two in number, one running almost horizontally to the right in the lesser omentum towards its free edge and then turning down on the left side of the hepatic artery proper to reach the pylorus, the other usually arising from

8.III A A dissection to show the duodenum, pancreas, stem arterial rami of the gastro-intestinal tract, and surrounding structures. The right and left hepatic veins have been cut away at their points of entry into the inferior vena cava. The superior hypogastric plexus is shown in front of the sacral promontory and the sympathetic nerves which form it are seen descending across the bifurcation of the aorta, the left common iliac vein and the body of the fifth lumbar vertebra. (In this specimen the left renal artery is situated anterior to the left renal vein at the hilum of the kidney.)

8.IIIB and C Blood supply of the stomach and the proximal duodenum. B Arterial system in a fetal human stomach. The muscle layer has been removed. Note double arcade along the lesser curvature. The arteries have been injected with a mixture of 2 per cent gelatin and Indian ink and subsequently cleared by the Spalteholz technique. (Magnification approximately ×6.) C A scheme of arterial arrangements at the gastroduodenal junction. Dotted lines indicate sites where the submucous plexus may be deficient in continuity. Shaded areas represent the muscular layer of the visceral wall. (By courtesy of Dr. C. Piasecki, Department of Anatomy, Royal Free Hospital School of Medicine, London, and the *Journal of Anatomy*.)

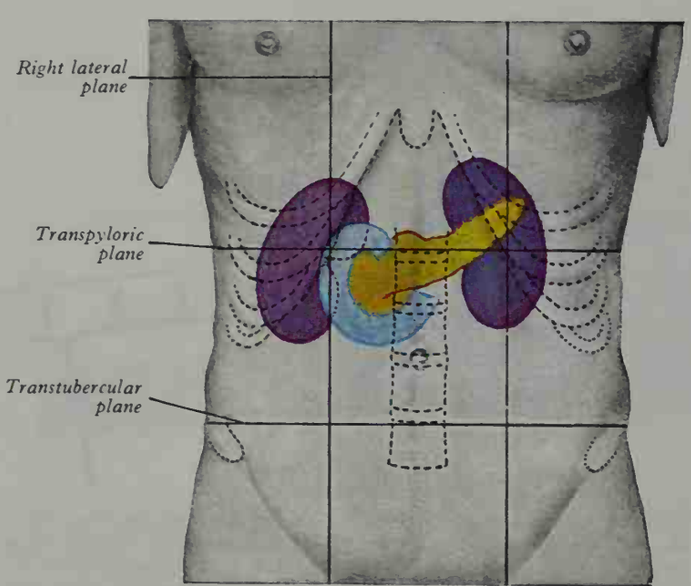
the greater anterior gastric nerve and passing obliquely to the pyloric antrum. The posterior nerves give off two main sets of branches: (*a*) *gastric branches*, radiating on the posterior surface of the body and fundus of the stomach; they extend on to the pyloric antrum but do not reach the pyloric sphincter; one of these is larger than the rest and passes along the posterior margin of the lesser curvature (*greater posterior gastric nerve*), giving branches to the coeliac plexus; (*b*) *coeliac branches*, which are larger than the gastric branches, and pass in the lesser omentum to the coeliac plexus. No true plexiform array of nerves occurs on either the anterior or posterior surface of the stomach. Nerve plexuses are found in the submucosal coat and between the layers of the muscular coat. The latter corresponds to the myenteric (*Auerbach's*) plexus of the intestine and contains numerous nerve cells. From these plexuses fibres are distributed to the muscular tissue and the mucous membrane.

The vagus has both secretory and motor influences on the stomach; stimulation evokes a secretion rich in pepsin and increased gastric motility, while after vagotomy the stomach becomes flaccid and empties slowly. The sympathetic supplies vasomotor fibres to the gastric blood vessels and provides the main pathway for pain fibres from the stomach.

The Small Intestine

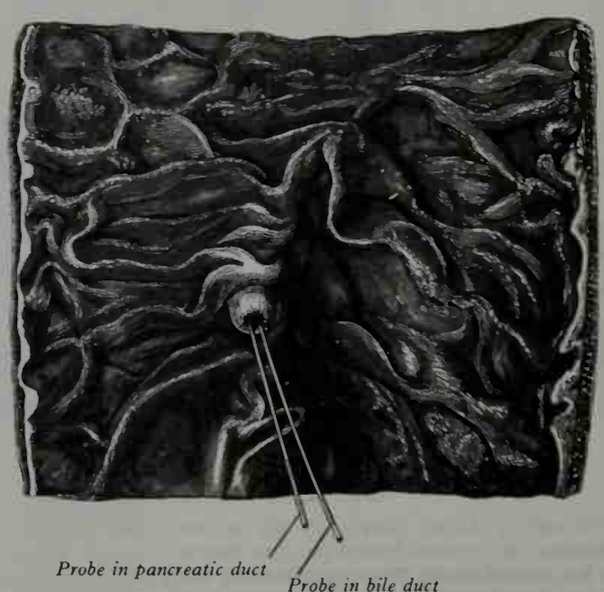
The small intestine is a convoluted tube, extending from the pylorus to the ileocaecal valve, where it joins the large intestine. It is often stated to be 6 to 7 m long, and gradually diminishes in diameter from its commencement to its termination. However, the small intestine is longer after death owing to the absence of muscle tone; during life its average length in the adult is said to be about 5 m (*see* below). It has been reported (Underhill 1955) that in 109 adult subjects shortly after death the small intestine ranged in length from 3·35 to 7·16 m in women and from 4·88 to 7·85 m in men, the average length being 5·92 m in women and 6·37 m in men. The length was found to be correlated with the height of the individual, but independent of the age. The large intestine was found to be much more constant in length in this particular study. Jit and Grewal (1975) have reviewed the literature on this topic, reporting their own findings in a series of 137 Indian subjects. They confirmed an association with height, and the lack of it with weight. They observed a variable reduction in length after fixation in formalin, a contraction which sometimes reached 44 per cent. Various observers have passed flexible tubes through the alimentary canal, recording total lengths of from 2·7 m to 4·5 m (cited by Jit and Grewal 1975).

The small intestine lies in the central and lower parts of the abdominal cavity and usually within the confines of the large intestine; it is in relation, in front, with the greater omentum and abdominal wall; a portion of it extends down into the pelvis and lies in front of the rectum. The small intestine consists of: (1) a short, curved section which is devoid of a mesentery and is named the *duodenum*; and (2) a long, greatly coiled part which is attached to the posterior abdominal wall by the mesentery (p. 1329), and of which the proximal two-fifths constitutes the *jejunum*, and the distal three-fifths the *ileum*.



THE DUODENUM

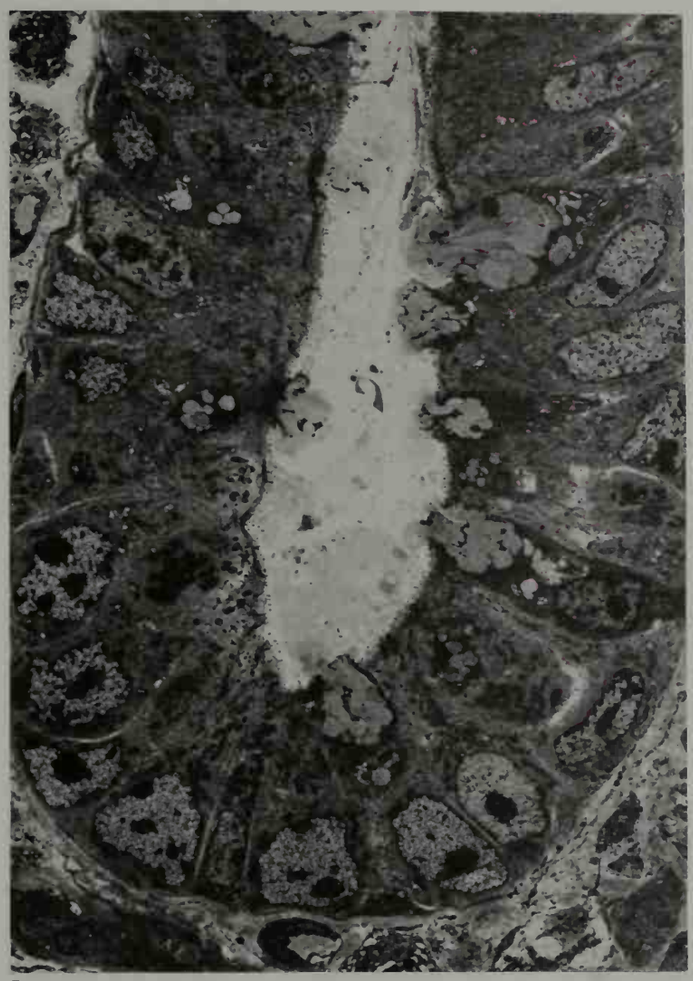
The duodenum (**8**.111A), 20–25 cm long, is the shortest, widest and most fixed part of the small intestine; it has no mesentery, and thus is only partially covered with peritoneum. Its course presents a remarkably constant curve, somewhat of the shape of an incomplete circle, which encloses the head of the pancreas. It lies entirely above the level of the umbilicus.



It begins at the pylorus, passes backwards, up and to the right for about 5 cm, under cover of the posterior part of the quadrate lobe of the liver, to the neck of the gall bladder, varying slightly in direction according to the degree of distension of the stomach; it then makes a sharp curve (*superior duodenal flexure*) and descends for about 7·5 cm in front of the medial part of the right kidney, usually to the level of the lower border of the body of the third lumbar vertebra, just medial to the lateral plane (**8**.112). Here it makes a second bend (*inferior duodenal flexure*), and passes horizontally to the left across the vertebral column for about 5–10 cm, just above the level of the umbilicus, having a slight inclination upwards; it then ascends in front and to the left of the abdominal aorta for about 2·5 cm, and ends opposite the second lumbar vertebra in the jejunum. At its union with the jejunum it turns abruptly forwards, forming the *duodenojejunal flexure*, which is situated 2·5 cm to the left of the median plane and 1 cm below the transpyloric plane. For descriptive purposes it is divided into first, second, third and fourth parts. The first and second parts are respectively superior and descending, while the third and fourth parts are described as horizontal and ascending.

DUODENAL RELATIONS

The superior part (*first part*) is about 5 cm long, and is the most movable of the four sections; it begins at the pylorus, and ends at the neck of the gall bladder. It is covered with peritoneum over the whole of its anterior aspect, but it is devoid of peritoneum posteriorly, *except near the pylorus*, where it takes a small part in the formation of the anterior wall of the omental bursa; the right part of the lesser omentum is attached to the upper border, and



8.112 The surface projection of the duodenum, pancreas and kidneys. The vertebra just above the umbilicus is the 3rd lumbar.

the greater omentum to the lower border of the proximal half. It is in relation above and in front with the quadrate lobe of the liver and the gall bladder; above, and on a more posterior plane, with the epiploic foramen; behind, with the gastroduodenal artery, the bile duct and the portal vein, and below and behind, with the head and neck of the pancreas. It is in such close relation with the gall bladder that it is usually found to be stained by bile after death, especially on its anterior surface.

The descending part (*second part*), from 8 to 10 cm long, descends from the neck of the gall bladder along the right side of the vertebral column as low as the lower border of the body of the third lumbar vertebra. It is crossed by the transverse colon, the posterior surface of which is connected to the duodenum by a small quantity of areolar tissue. The parts above and below the transverse colon are covered in front with peritoneum. It is in relation, in front, from above downwards, with the duodenal impression on the right lobe of the liver, the transverse colon and the root of the transverse mesocolon, and the jejunum; behind, it has a variable relation to the front of the right kidney in the neighbourhood of its hilum, and is connected to it by loose areolar tissue; the right renal vessels, edge of the inferior vena cava, and psoas major are also behind it. Its medial side is related to the head of the pancreas and the bile duct; its lateral side, to the right colic

flexure. Sometimes a small part of the head of the pancreas is actually embedded in the wall of the descending part of the duodenum. The bile duct and the pancreatic duct come into contact at the medial side of this part of the duodenum. The two ducts enter the wall of the gut obliquely and there unite to form a short, dilated tube which is named the *hepatopancreatic ampulla* (*see* p. 1383). The narrow, distal end of this ampulla opens on the summit of a *major duodenal papilla*, which is situated within the descending part of the duodenum at the junction of its medial and posterior walls (**8**.113, 132), from 8 cm to 10 cm distal to the pylorus. The accessory pancreatic duct, when present, opens about 2 cm proximal to the major papilla, on a small rounded *minor duodenal papilla*.

The horizontal part (inferior or *third part*), about 10 cm long, begins at the right side of the lower border of the third lumbar vertebra and passes from right to left, with a slight inclination upwards, in front of the inferior vena cava, and ends in the fourth part in front of the abdominal aorta. Its anterior surface is covered with peritoneum, except near the median plane, where it is crossed by the superior mesenteric vessels and the root of the mesentery. Its posterior surface is uncovered by peritoneum, except towards its left extremity, where the left layer of the mesentery sometimes covers it to a variable extent. This surface rests upon the right ureter, the right psoas major, the right testicular (or ovarian) vessels, the inferior vena cava and the abdominal aorta (with the origin of the inferior mesenteric artery). The upper surface is in relation with the head of the pancreas; the lower, with the coils of the jejunum.

The ascending part (*fourth part*), about 2·5 cm long, ascends on or immediately to the left of the aorta, as far as the level of the upper border of the second lumbar vertebra, where it turns ventrally at the *duodenojejunal flexure* and is continuous with the jejunum. It lies in front of the left sympathetic trunk, left psoas major, the left renal and testicular vessels and the inferior mesenteric vein. Along its right border it gives attachment to the upper part of the root of the mesentery, the left layer of which is continued over its anterior surface and left side. To its left there are the left kidney and ureter; above, there is the body of the pancreas; in front, there is the transverse colon and transverse mesocolon (the latter separating the duodenojejunal flexure from the omental bursa and stomach).

The superior part of the duodenum, as stated above, is to a slight degree mobile, but the rest is relatively fixed, and is sessile upon neighbouring viscera and the posterior abdominal wall. Radiologically, after a barium meal, the superior part of the duodenum is seen as a somewhat triangular homogeneous shadow, called the 'duodenal cap' (**8**.108).

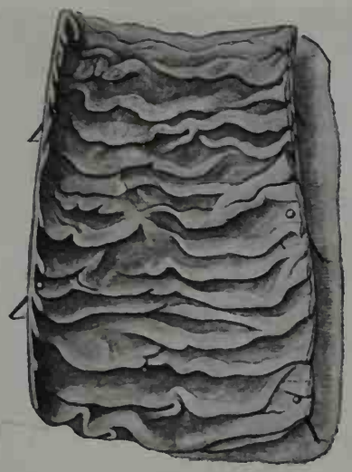
The terminal part of the duodenum and the duodenojejunal flexure are usually described as suspended and fixed in position by the '*suspensory muscle of the duodenum*' (suspensory muscle, or ligament, of Treitz). This is often said to be in two parts: (*a*) a slip of *striated* muscle, derived from the diaphragm near its oesophageal opening and ending in the connective tissue adjacent to the coeliac arterial trunk, and (*b*) a fibromuscular band, containing *nonstriated* muscle, which passes from the duodenum (third and fourth parts and duodenojejunal flexure) to blend with the same pericoeliac connective tissue. Treitz (1853) described both entities, naming the former one the *Hilfsmuskel* (accessory muscle). Some subsequent authorities (Lockwood 1886, and Low 1907) regarded these two structures as parts of a digastric muscle, naming the whole as the suspensory muscle of Treitz, a description perpetuated by many textbooks. The confusion was increased by Haley and Peden (1943), who derived the 'suspensory muscle' from the right crus, and by Argème *et al.* (1970), who described an intermediate tendon but regarded this as part of a 'false' digastric muscle. Jit (1952, 1977) has persistently supported the dual nature of the original description of Treitz, on embryological and histological grounds. The diaphragmatic slip (the Hilfsmuskel) has no satisfactory official name. It is supplied, according to Jit, by myelinated nerve fibres, derived probably from the phrenic nerve (pp. 550, 1094). This slip is sometimes considered to be an aberrant part of iliocostalis thoracis. The suspensory muscle proper (nonstriated) is supplied by autonomic fibres from the coeliac and superior mesenteric plexuses (Jit and Grewal, 1977). Descriptions of the extent of the duodenal attachments of the suspensory muscle vary; none of these accounts contain a convincing view of the function of the muscle, the usual suggestion being that it may kink the duodenojejunal flexure even further, producing a valvular effect.

Vessels and Nerves

The *arteries* supplying the duodenum are derived from the right gastric, supraduodenal, right gastro-epiploic and the superior and inferior pancreaticoduodenal arteries. (They are described on pp. 713, 716; **6**.86.) The superior part of the duodenum receives a leash of small branches from the hepatic artery proper which runs in the right part of the lesser omentum, and a similar leash of vessels from the gastroduodenal artery. These vessels also supply the neighbouring part of the pyloric canal, and there is some anastomosis in the wall of the alimentary canal between these vessels across the pyloroduodenal junction (p. 1338). The *veins* end in the splenic, superior mesenteric and portal veins. The *nerves* are derived from the coeliac plexus.

THE JEJUNUM AND ILEUM

The rest of the small intestine extends from the duodenojejunal flexure to the ileocaecal valve, where it ends in the junction of the caecum and ascending colon of the large intestine; it is arranged in a series of coils or loops which are attached to the posterior abdominal wall by its mesentery. This part of the gut is completely covered with the peritoneum, except for a narrow strip along its mesenteric border, where the two layers of the mesentery diverge from each other to enclose it. It is divided into jejunum and ileum, the former name being given to the first two-fifths and the latter to the distal three-fifths. There is no identifiable level of distinction between these two parts, and the division is arbitrary; but at the same time the character of the intestine gradually undergoes a change from the beginning of the jejunum to the end of the ileum, so that samples from these two situations present characteristic differences.



The jejunum has a diameter of about 4 cm, and is thicker, redder and more vascular than the ileum. The circular folds (p. 1345) of its mucous membrane are large and thickly set, and its villi surpass those of the ileum in size. The aggregated lymphatic follicles (p. 1349) are almost absent in the upper part of the jejunum; in the lower part they are fewer and smaller than in the ileum and tend to assume a circular form. When the jejunum is grasped between the finger and thumb the circular folds can be felt through the wall of the gut; as these folds are absent from the lower part of the ileum, it is possible in this way to distinguish the upper from the lower part of the small intestine.

For the most part the jejunum lies in the umbilical region, but it may extend into any of the surrounding areas. The first coil occupies a recess between the left part of the transverse mesocolon and the anterior surface of the left kidney.

The ileum has a diameter of 3·5 cm, and its wall is thinner than that of the jejunum. A few circular folds are present in the upper part of the ileum, but they are small and disappear almost entirely towards its lower end; the aggregated lymphatic follicles are, however, larger and more numerous than in the jejunum. For the most part the ileum is situated in the hypogastric (pubic) and pelvic regions. The terminal part of the ileum usually lies in the pelvis, from which it ascends over the right psoas major and right iliac vessels to end in the right iliac fossa by opening into the medial side of the junction of the caecum and ascending colon.

The jejunum and ileum are attached to the posterior abdominal wall by an extensive fold of peritoneum, termed the *mesentery*, which allows of very free movement, so that each coil can accommodate itself to changes in form and position.

The mesentery (p. 1329) is fan-shaped; its vertical border or root, about 15 cm long, is attached to the posterior abdominal wall along a line running from the left side of the body of the second lumbar vertebra to the right sacro-iliac joint, and crossing successively the horizontal part of the duodenum, the aorta, the inferior vena cava, the right ureter and right psoas major (**8**.98). Its average breadth from the vertebral to the intestinal border is about 20 cm, but is greater in the middle than at its upper and

8.115A Internal aspect of representative sample of proximal jejunum, showing circular folds.

lower ends. The two layers of the mesentery contain the jejunum, ileum, the jejunal and ileal branches of the superior mesenteric blood vessels, nerves, lacteals and lymph nodes, together with a variable amount of fat.

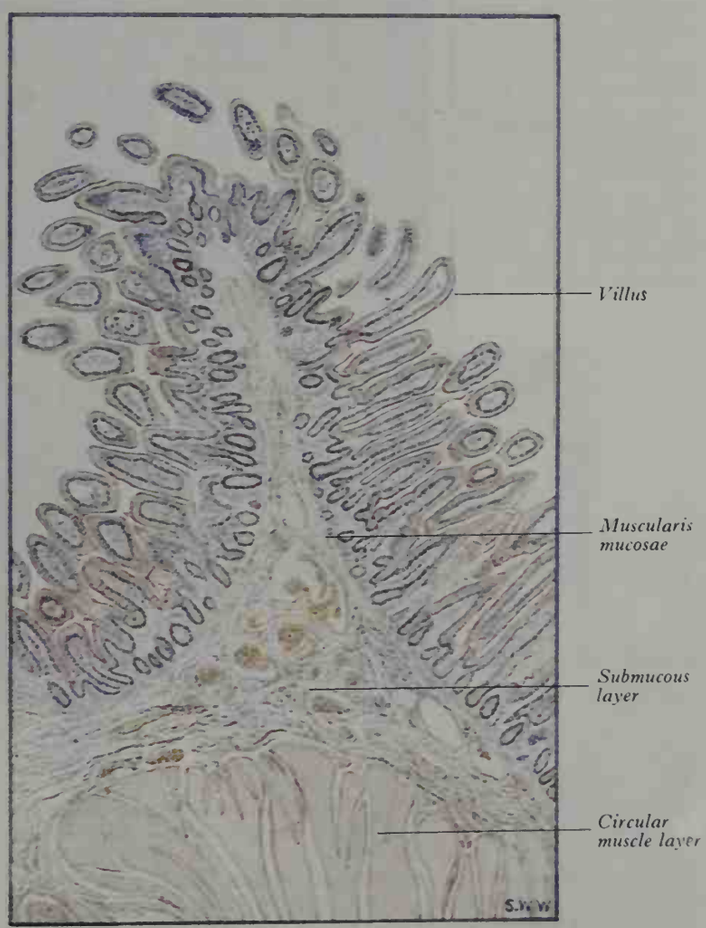
The diverticulum ilei (of Meckel) projects from the antimesenteric border of the lower part of the ileum in about 3 per cent of subjects. Its average position is about 1 m above the ileocaecal valve, and its average length about 5 cm. Its calibre is generally similar to that of the ileum, and its blind extremity may be free or may be connected with the abdominal wall or with some other part of the intestine by a fibrous band. It represents the persistent proximal part of the vitelline or yolk duct, which connects the yolk sac and the primitive digestive tube in early fetal life (pp. 120, 200, 205). The mucous membrane of the diverticulum usually has the same structure as that of the neighbouring ileum, but occasionally small regions of the mucous membrane may have a structure similar to that of the body and fundus of the stomach, with oxyntic cells which secrete acid. Sometimes small heterotopic areas of pancreatic or other tissues may be found in the wall of the diverticulum. In a recently published study of 1816 late fetal and neonatal cadavers Miyabara *et al.* (1974) found a diverticulum ilei present in 61 individuals (3·4 per cent). Of these, gastric mucosa was present in 11, jejunal mucosa in 2, colonic mucosa in 2, and pancreatic tissue in only 1.

STRUCTURE OF THE SMALL INTESTINE

The intestinal wall is composed of the series of layers described previously—serous, muscular, submucous and mucous (**8**.116).

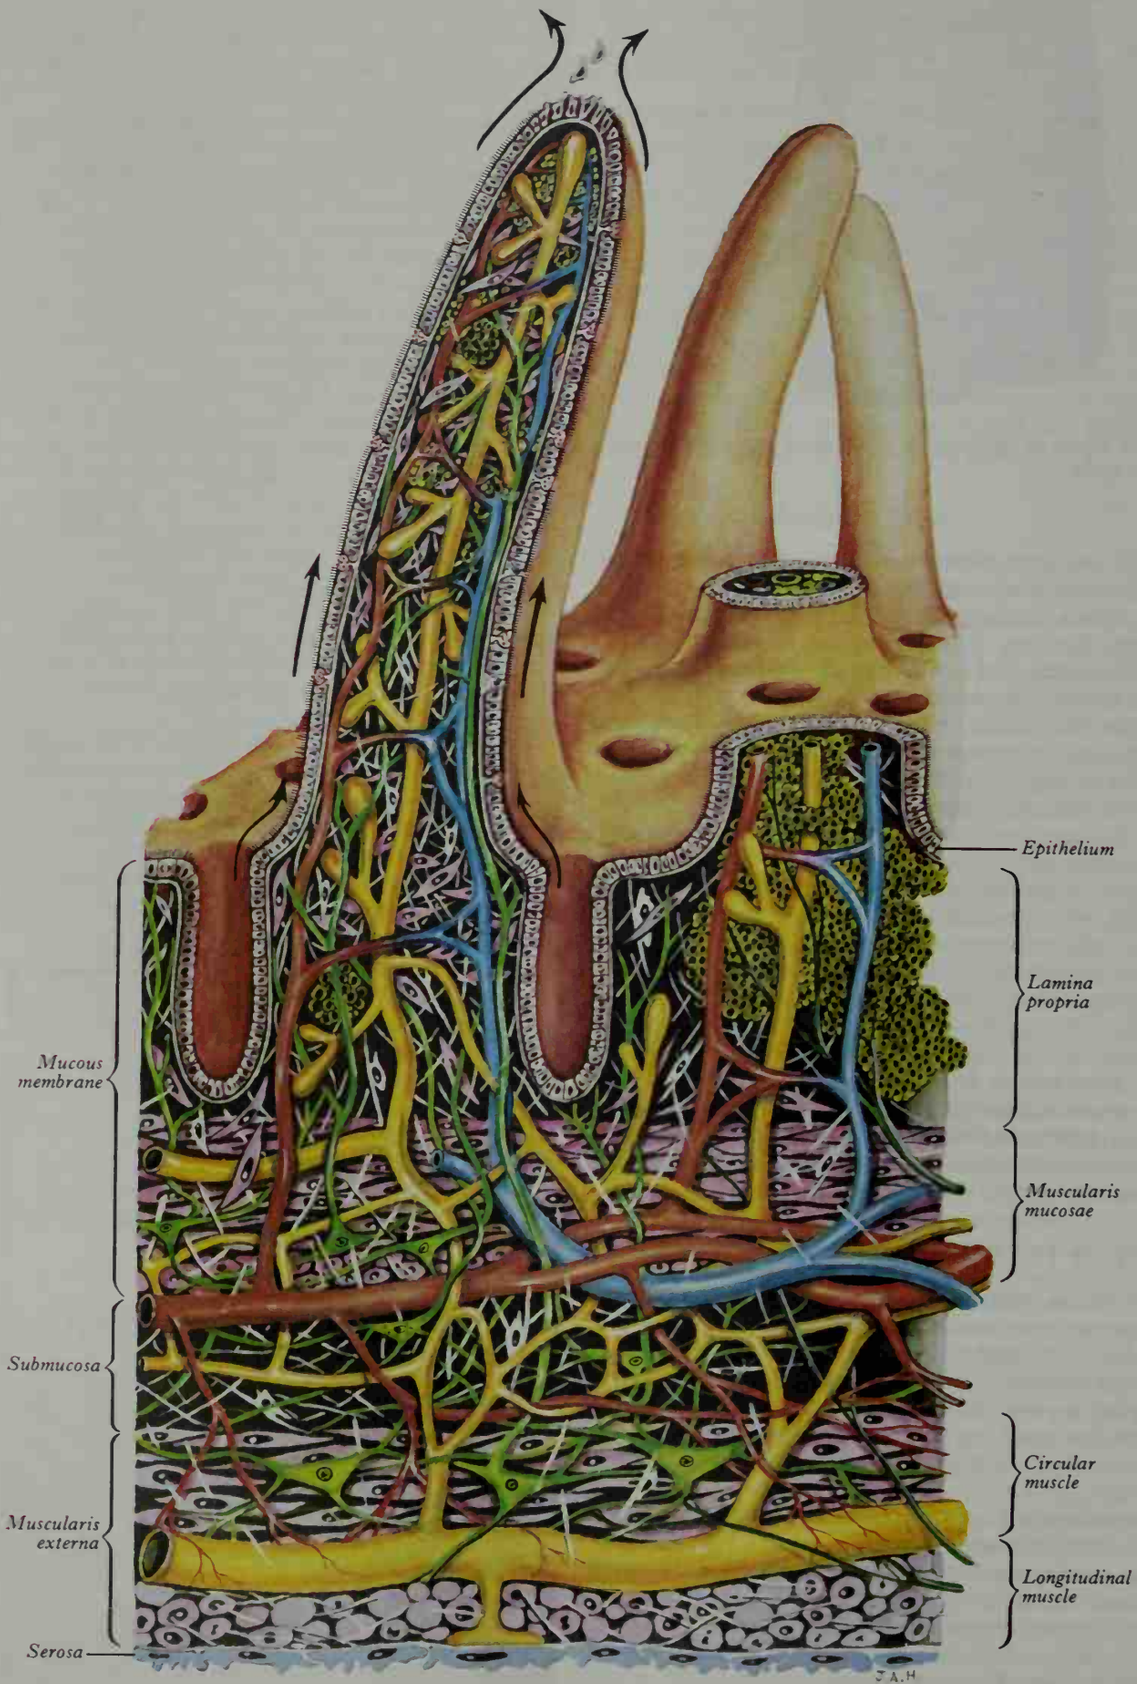
The *serous layer* is formed of visceral peritoneum which merges with a subserous stratum of areolar connective tissue.

The *muscularis externa* is thicker in the cranial than in the caudal part of the small intestine; it consists of a thin outer longitudinal and a thick inner circular layer of nonstriated muscle fibres.



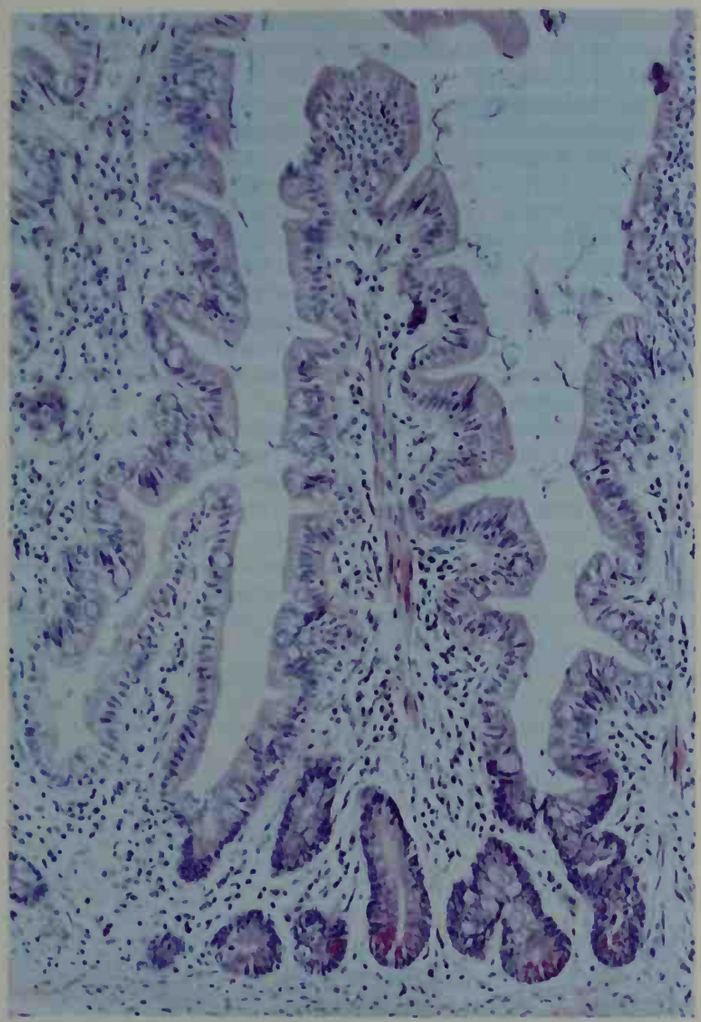
The *submucous layer* consists of loose connective tissue carrying blood vessels, lymphatics and nerves.

The *mucous membrane* is thick and highly vascular in the upper part of the small intestine, but thinner and less vascular in the lower part. It is thrown into circular or spiral pleats or plicae, the *circular folds*, and the whole surface is studded with finger-like, filiform or tongue-shaped projections, the intestinal villi.



The circular folds (*plicae circulares*, or '*valves' of Kerkring*—**8**.115, 119), are large, crescentic folds of mucous membrane which project into the intestinal lumen transversely to its long axis. Unlike the folds in the stomach they are permanent: they are not obliterated when the intestine is distended. The majority extend round the intestine for about one-half or two-thirds of its circumference, but some form complete circles, some bifurcate and join adjacent folds, and others have a spiral direction; the latter usually extend a little more than once round the lumen, but occasionally two or three times. The larger folds are about 8 mm in depth at their broadest part; but the greater number are of smaller size. The larger and smaller folds often alternate. Circular folds do not exist in the commencement of the duodenum, but begin to appear about 2·5 to 5 cm beyond the pylorus. Distal to the point where the common bile duct (ductus choledochus) and pancreatic duct enter the duodenum, the folds are very large and closely approximated. In the proximal half of the jejunum they are large and numerous, but from here to a point midway along the ileum, they diminish considerably in size. In the distal ileum they are almost entirely absent; hence the comparative thinness of this portion of the intestine, as compared with the duodenum and jejunum. The circular folds retard the passage of the food and afford an increased surface for absorption (**8**.119).

The intestinal villi are highly vascular processes, just visible to the naked eye; they project from the mucous membrane of the whole of the small intestine, and give to its surface a velvety appearance. They are large and numerous in the duodenum and jejunum, but are smaller and fewer in the ileum. In the first part of the duodenum they are broad, ridge-like structures, changing to tall leaf-like villi in the distal duodenum and proximal jejunum thereafter they gradually transform into shorter finger-like extensions in the distal jejunum and ileum (Verźar and McDougall 1936; McMinn and Mitchell 1954). They vary in density from 10 to 40 per square millimetre, and are from about 0·5 to 1·0 mm in height. The villi increase the surface area, compared with an unfolded surface, about eightfold. (For details of an experimental analysis of the formation of intestinal villi after lesions of the mucosa in the small intestine of the cat, consult McMinn and Mitchell 1954.)



The mucous membrane (**8**.116) of the small intestine has three layers. Next to the submucous coat is the *muscularis mucosae* which consists of an outer longitudinal and an inner circular layer of nonstriated muscular fibres. This layer extends into the circular folds. Internal to it is a quantity of reticular tissue, the lamina propria, in which, in addition to fibroblasts and fibres, there are lymphocytes, eosinophilic leucocytes, macrophages,

8.115B Section through a circular fold from human small intestine. Stained with haematoxylin and eosin. Magnification about × 19.

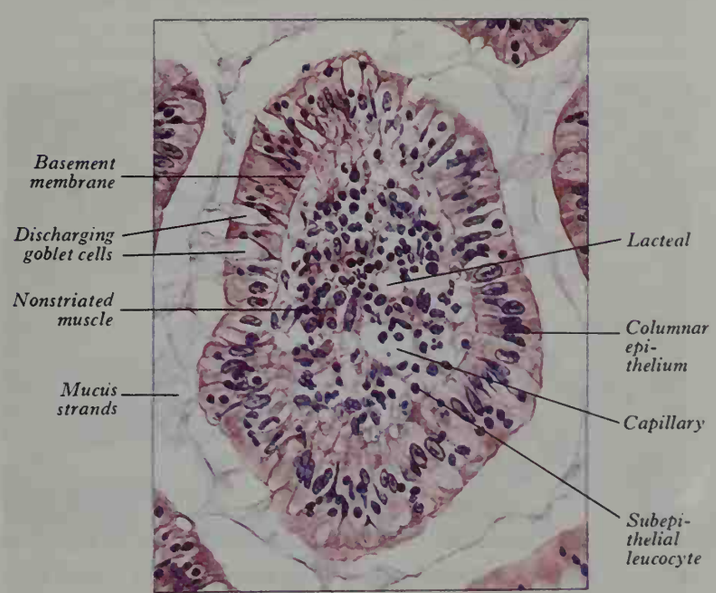
8.116 A three-dimensional reconstruction of the architecture of intestinal villi and subjacent wall; the principal layers of the latter are indicated. Arteries and arterioles—red; veins and venules—blue; central lacteals and other lymphatic channels—orange; aggregations of lymphocytes—yellow; neural elements—green; nonstriated muscle fibres—magenta; fibroblasts—white. Note the orifices of the intestinal crypts (of Lieberkühn). Types of cells in the epithelium include absorptive cells, goblet cells, and entero-endocrine cells. Arrows indicate direction of cell migration. The various layers are not drawn to scale.

8.117A A light micrograph of part of the mucosa of the murine small intestine, showing a villus in longitudinal section. Nonstriated myocytes (pink) can be seen in the lamina propria of the villus. Stained with haematoxylin, eosin, and periodic acid/Schiff. (Prepared and photographed by Mr. Stephen Sitch, Department of Anatomy, Guy's Hospital Medical School, London.) Magnification about × 250.

mast cells, blood capillaries, lymphatic vessels and nonmyelinated nerves. The plasma cells are numerous and the lymphocytic cells are in many regions collected into solitary and aggregated lymphatic follicles, some of which may extend through the muscularis mucosae into the submucous coat. Internal to the lamina propria is a basement membrane supporting an epithelium composed mainly of tall columnar cells, except over lymphatic follicles where they are partly replaced by *membrane* or *M cells*, specialized for transport of antigens (Owen and Nemamic 1978). Extending into the mucosa from the surface between the intestinal villi are simple, tubular, *intestinal glands* or *crypts* (of *Lieberkühn*). They reach almost to the muscularis mucosae. In the duodenum there are also mucous, tubulo-alveolar *duodenal glands* (of *Brunner*), the ducts of which extend through the muscularis mucosae to expand into the submucous coat; the secretions of these glands contain mucosubstances and bicarbonate ions.

Structure of the Intestinal Villi

Each villus has a core of reticular tissue containing a lymph vessel or lacteal, blood vessels, nerves and some nonstriated muscle fibres covered by a layer of columnar epithelium resting on a basement membrane (**8**.116, 117A–D).



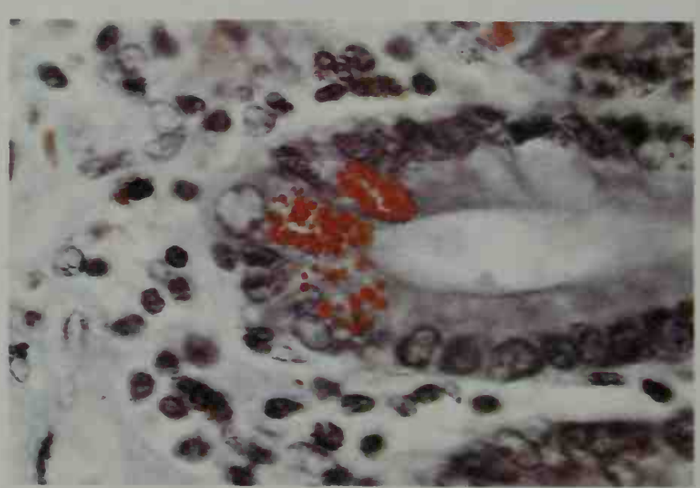
The *lacteal*, usually single but occasionally double, commences in a dilated blind extremity near the summit of the villus and then courses along the axis of the villus and empties into the plexus of lymph vessels in the underlying lamina propria. Its wall is composed of a single layer of endothelial cells.

The *muscle fibres* are derived from the muscularis mucosae, and are arranged in bundles around the lacteal vessel, extending from the base to the summit of the villus, and giving off, laterally, individual muscle cells, which are enclosed by the reticulum, and by it are attached to the basement membrane and to the lacteal. Contraction of the muscularis mucosae therefore has the effect of 'milking' the lacteals.

The *blood vessels* form a capillary plexus in the lamina propria, and are enclosed in the reticular tissue. The capillaries are lined by a fenestrated endothelium, a modification which may be of considerable importance in ensuring the rapid uptake of nutrients diffusing from the epithelium (Clementi and Palade 1969).

The *epithelium* covering the superficial surface of the mucous membrane and the intestinal villi consists mainly of absorptive columnar cells, interspersed with goblet cells.

The columnar cells (**1**.1) are granular in appearance; each possesses a clear oval nucleus located in its basal half. At the free surface of the cell there is a highly refractile, vertically striated border about 1 μm in depth, the *striated* or *brush border*. This border is very rich in alkaline phosphatase and is concerned with the process of active absorption; electron microscope studies show that this border is composed of minute parallel cylindrical microvilli, each about 1 μm long and 0·1 μm broad. Applied to the outer surface of the enveloping plasma membrane of the microvilli is a coating of ultramicroscopic fine filaments, rich in mucosubstances, believed to be formed by the epithelial cells and to constitute an integral part of the surface. In the cytoplasmic core of each microvillus are fine filaments which are continuous at its base with a plexiform band of similar filaments in the apical cytoplasm of the cell; this band is the *terminal web* and, except for occasional vesicles, is free of organelles (**8**.118B). The lateral plasma membranes of the columnar cells are often plicated and interdigitated; at their luminal extremities they show typical junctional complexes (p. 7, **1**.4). Elsewhere scattered desmosomes occur between adjacent plasma membranes; basally, the lateral plasma membranes may be separated by intervals constituting intercellular canaliculi. The basal plasma membranes are usually smooth and lie adjacent to the basement membrane which is about 20 nm wide. Rod-shaped mitochondria are scattered through the cell cytoplasm together with a moderate amount of rough and smooth surfaced endoplasmic reticulum. The Golgi apparatus is supranuclear in position and the apical part of the cell, beneath the terminal web, contains numerous membrane-bound lysosomes. At the summits of the intestinal villi the cells often show signs of degeneration and their microvilli may be stunted and degenerate. The role of these cells in digestion and absorption of nutrients has attracted much attention. It appears likely that absorption of amino acids and simple carbohydrates occurs by facilitated diffusion across the cell membranes, these materials passing



8.117B Transverse section through a villus in human jejunum. Stained with haematoxylin and eosin. Magnification about × 380.

through the cell to the underlying capillary arrays of the lamina propria. Lipid absorption also appears to occur by the diffusion of small molecules (fatty acids, etc.) through the membrane of the luminal surface, the lipid accumulating in the vacuoles within the cytoplasm in the apical region of the cell, before being passed to the underlying lymphatics. It has also been possible to isolate the striated borders of absorptive cells by cell fractionation and centrifugation; digestive enzymes such as disaccharidases are bound to the surface, and there are indications that much of the intestinal digestion may occur close to the site of absorption, digestive enzymes being absorbed on to the cell surfaces, perhaps in the polysaccharide cell coat.

The goblet cells are intercalated at intervals in the epithelial layer. Their nuclei are elongated and basally situated and their apical parts are distended with membrane-bound mucin granules. The Golgi apparatus is well developed and supranuclear in position and the granular endoplasmic reticulum is abundant infranuclearly. The goblet cells have less frequent and more irregular microvilli at their superficial surfaces and the terminal web is poorly marked. The mucin is believed to be generally discharged by fusion of the membranes surrounding the granules with the plasma membrane in the manner of a merocrine secretion (**8**.118A).

8.117 C Intestinal glands and villi in human small intestine. Stained with haematoxylin and eosin. Magnification about × 120.

8.117 D Part of a transverse section of the ileum, showing Paneth cells containing orange-stained zymogen granules at the base of an intestinal gland. 'Undifferentiated' epithelial cells are also visible. Mallory's azan stain. Magnification about × 400.

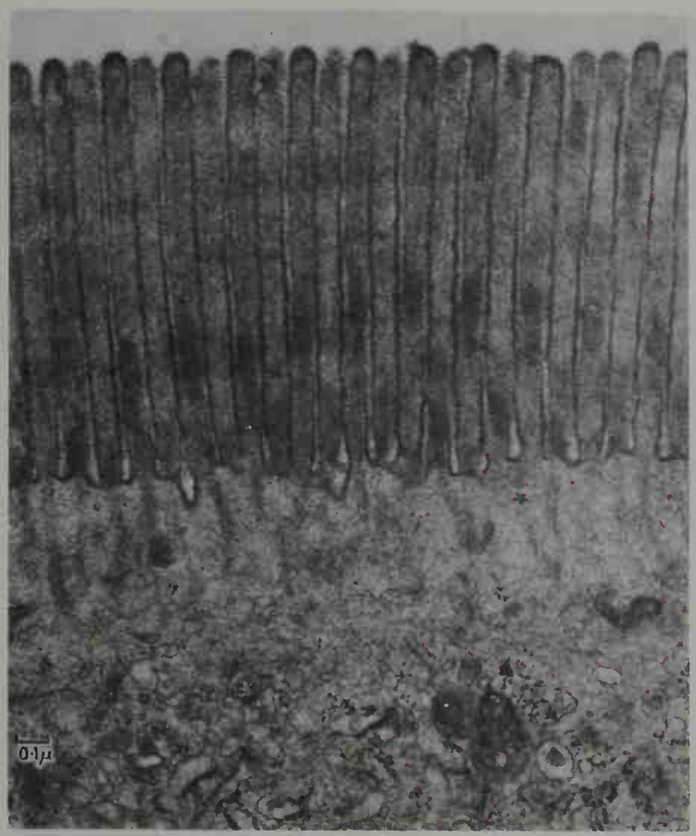
The intestinal glands (*crypts of Lieberkühn*) occur in considerable numbers over every part of the mucous membrane of the small intestine. They are simple tubular pits, arranged perpendicularly to the surface, upon which they open by small circular apertures. Their orifices may be seen with the aid of a lens as minute dots scattered between the villi. Their walls are thin, consisting of columnar epithelium on a basement membrane and associated with a rich mucosal capillary plexus (**8**.116).

The cells lining the intestinal glands consist of so-called 'undifferentiated cells', Paneth and argentaffin cells. **The undifferentiated cells** are the most numerous and proliferate by mitotic division, passing upwards out of the intestinal glands along the sides of the villi, where they differentiate into columnar absorptive elements or into goblet cells; eventually they reach the tips of the villi, from which they are shed. In this way there is a continual renewal of the epithelial covering of the villi. When not dividing, the free surfaces of these cells have fewer and more irregular microvilli than the surface cells with occasional pseudopodia; their lateral plasma membranes are straighter but the attachment areas are similar in both types of cell. Their nuclei are basally placed and the terminal webs are poorly developed. Membrane-bound secretory granules occur in their cytoplasm and are believed to be discharged both in the manner of an apocrine secretion through the surface blebs and by the more usual merocrine mechanism commonly described. The undifferentiated epithelial cells in the intestinal glands multiply at the rate of 1 cell per 100 cells per hour and constitute one of the most rapidly proliferating of tissues in the body (Lipkin *et al.* 1963, MacDonald *et al.*, 1964).

The zymogenic cells (of Paneth) are numerous in the deeper parts of the intestinal crypts, particularly those of the duodenum. They are rich in zinc and contain granules (**8**.117D) which stain with phosphotungstic haematoxylin. Electron microscopy shows irregular microvilli to be present at the apices of these cells, and prominent membrane-bound granules to be present in the supranuclear cytoplasm. Scattered mitochondria, lysosomes and a large amount of granular endoplasmic reticulum also exist, especially in the basal parts of the cells. These zymogenic cells are the source of the digestive enzymes produced by the wall of the small intestine.

Between the cells lining the intestinal glands, and less commonly among those covering the villi, are pyramidal or columnar cells, the cytoplasm of which contains granules that have an affinity for silver salts, by which they are stained black, and for chromium salts, by which they are stained brown. They are called **enterochromaffin cells** or **argentaffin cells** and are a variety of APUD cell (*see* p. 1366). The distributions of these and other cells of the gastro-entero-pancreatic endocrine system are shown in **8**.129C.

The duodenal glands (of Brunner) are limited to the duodenum (**8**.114), and are sited *in the submucous areolar tissue*, i.e. they penetrate through the muscularis mucosae. They are largest and most numerous near the pylorus, forming an almost complete layer in the superior part and proximal half of the descending part of the duodenum; beyond this they gradually diminish in number and disappear at the junction of the duodenum and jejunum. They are small, compound, acinotubular glands, each consisting of a number of alveoli lined with short columnar epithelium and opening by a duct on the inner surface of the intestine. They seemingly contain only one kind of exocrine cell in man; this is a typical mucous element. The nuclei of these cells are small and basal, and they show variations according to the secretory cycle. The Golgi apparatus is extensive; mucin droplets are numerous. Many argentaffin cells (*vide supra*) are present amongst the mucinogenic cells.

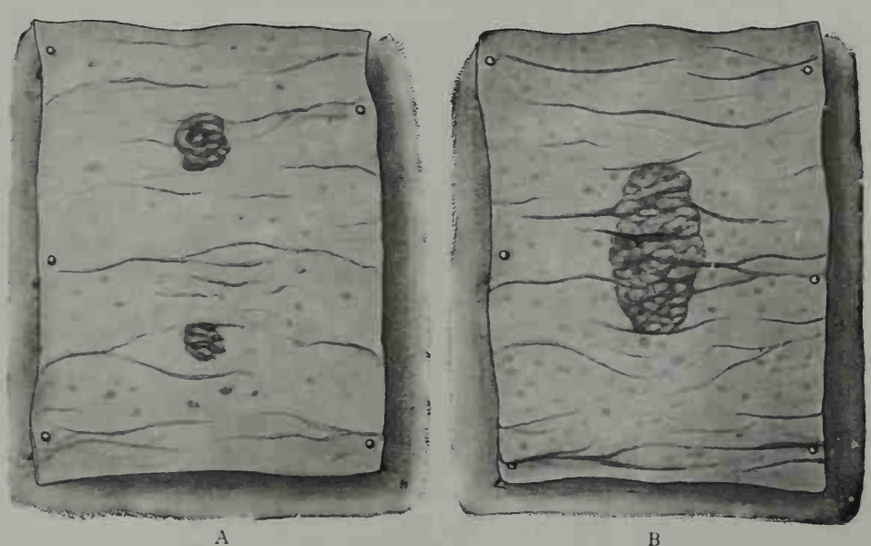


The solitary lymphatic follicles are seen to be scattered throughout the mucous membrane of the small intestine but are most numerous in the lower part of the ileum. Their free surfaces are covered with rudimentary villi, except at the summits, and each follicle is surrounded by the openings of the intestinal glands. Each consists of a dense, interlacing, reticular tissue

closely packed with lymphocytes, and permeated by an abundant, capillary network. The interspaces of the reticular tissue are continuous with larger lymph spaces which surround the follicle, and by this means they are enabled to communicate with the lacteal system. They are situated partly in the submucous tissue and partly in the mucous coat. They are partly covered by 'M' cells (p. 1347).

The aggregated lymphoid follicles (Peyer's patches, **8**.120A, B) form circular or oval patches, individual ones containing from 10 to 260 follicles, and varying in length from 2 to 10 cm. Like the other collections of lymphoid tissue in the body (except the lymph nodes), solitary and aggregated lymphatic follicles are most numerous around puberty and thereafter diminish in number and size but many persist to old age (Cornes 1965). Aggregated follicles are largest and most numerous in the ileum. In the distal part of the jejunum they are small, circular and few in number. They are occasionally seen in the duodenum. They are placed lengthwise in the intestine, and are in the part of its circumference most distant from the attachment of the mesentery. Each patch is formed of a group of solitary lymphoid follicles covered with columnar epithelial cells and 'M' cells (p. 1347); the patches do not, as a rule, possess villi on their free surfaces. They are freely supplied with blood vessels, which form an abundant plexus around each follicle and give off fine branches to permeate the lymphoid tissue in the interior of the follicle. The plexuses of lymph vessels are especially abundant around these patches. In typhoid fever, ulceration of these aggregated lymphatic follicles may occur; the ulcers are thus oval in shape, their long axes are in the long axis of the bowel (so subsequent fibrosis does not constrict the gut), they are present chiefly in the lower part of the ileum, and are situated on or near its antimesenteric border.

8.118A Transmission electron micrograph of the columnar epithelium lining the murine small intestine, showing a mucus-secreting goblet cell between two absorptive cells which bear microvilli. The cells rest on a delicate basal lamina deep to which is the vascular lamina propria. (Magnification × 4,800.) (Prepared and photographed by Mr Derrick J. Lovell, Department of Anatomy, Guy's Hospital Medical School, London.)



8.118B Electron micrograph of the apical region in a columnar cell from the jejunum showing the regular series of microvilli which constitutes the striated border of light microscopy. Filaments can be seen passing from the microvilli to the terminal web. Rat. Magnification about × 32,500.

Vessels and nerves. The *arteries* to the jejunum and ileum (**8**.120C, D) stem from the superior mesenteric artery, the jejunal and ileal branches of which, having reached the mesenteric border extend between the serous and muscular coats. From these vessels numerous branches are given off, which pierce the muscular coat, supplying it and forming an intricate plexus in the submucous tissue. From this plexus minute vessels pass to the glands and villi of the mucous membrane (*see* p. 1347). The anastomoses between the terminal intestinal branches are by no means free, and there is a distinct tendency for the alternate vessels to be distributed to opposite sides of the gut. The *veins* have a course and arrangement similar to the arteries. (For an extensive and detailed investigation into the course, distribution and variations in the coeliac and superior mesenteric arteries consult Nesebar *et al.* 1969.) The *lymph vessels* of the small intestine (lacteals) are arranged in two sets, viz. those of the mucous membrane and those of the muscular coat. The lymph vessels of the villi commence in these structures in the manner described on p. 1347. They form a highly intricate plexus in the mucous and submucous tissue, being joined by the lymph vessels from lymph spaces at the bases of the solitary follicles, and from there pass to larger vessels at the mesenteric border of the gut. The lymph vessels of the muscular coat are situated to a great extent between the two layers of muscular fibres, where they form a close plexus; throughout their course they communicate freely with those from the mucous

8.119 A radiograph of the pyloric end of the stomach, duodenum, jejunum and ileum, one hour after taking a barium meal. The feathery appearance of the profile of the small intestine is due to the presence of numerous circular mucosal folds.

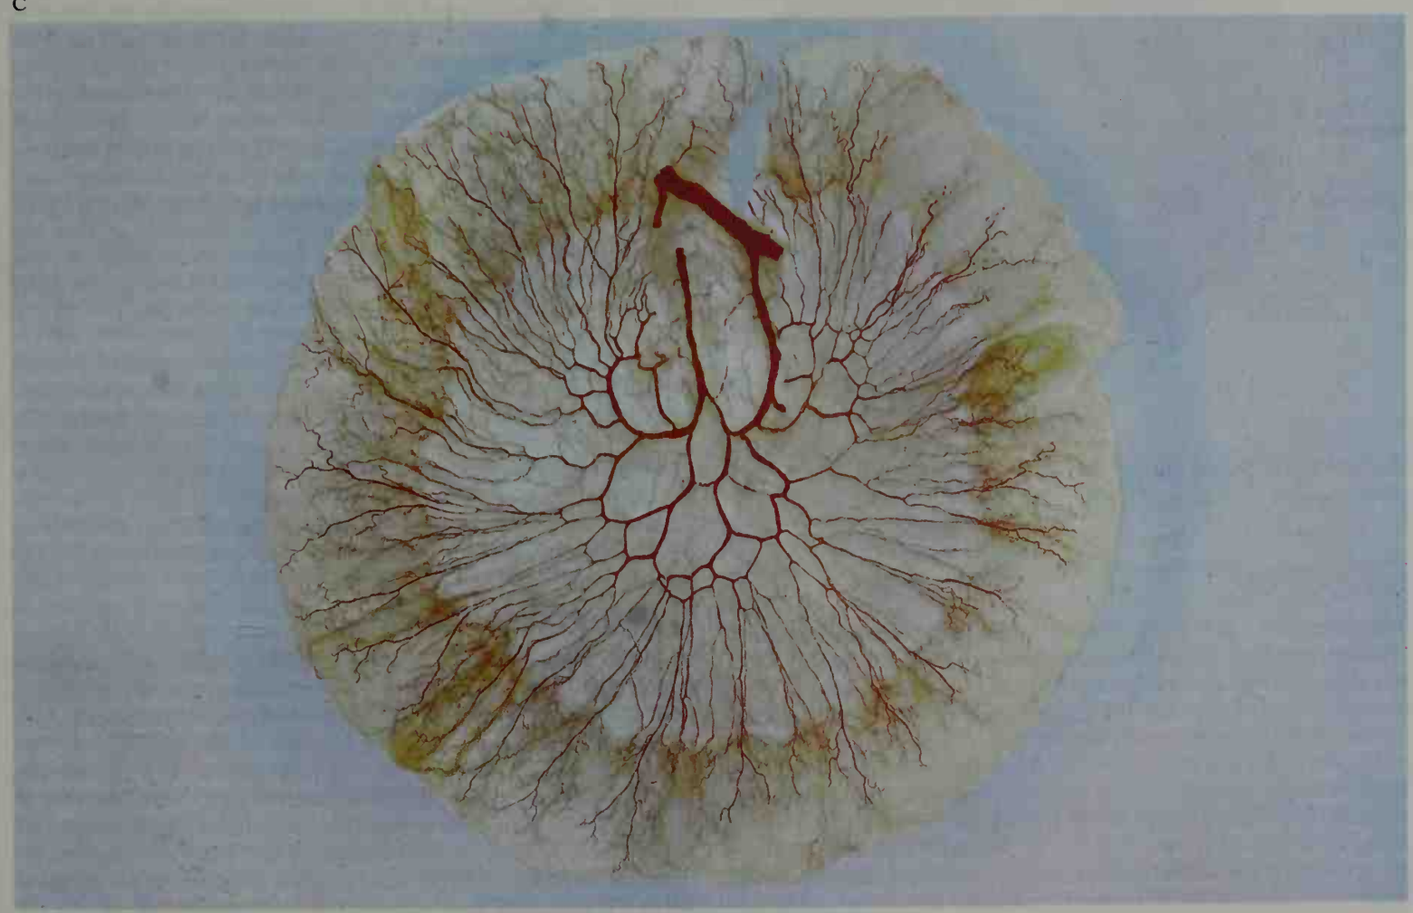
membrane, and open in the same manner as these into the origins of the lacteal vessels at the attached border of the gut.

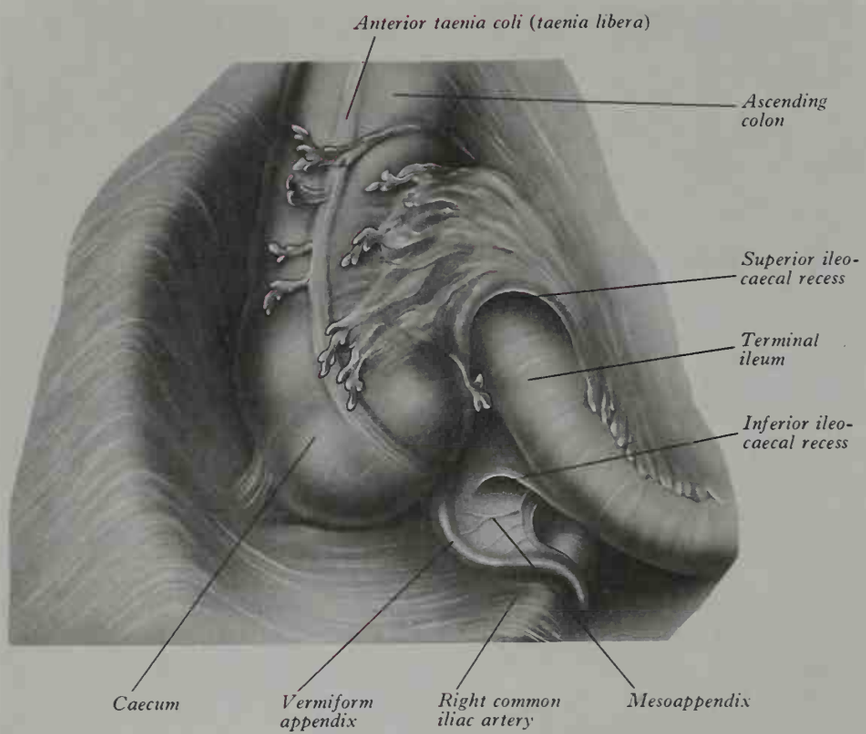
The *nerves* of the small intestine are derived from the vagus and splanchnic nerves through the coeliac ganglia and the plexuses around the superior mesenteric artery. They run to the *myenteric plexus* (p. 1316) of nerves and ganglia, situated between the circular and longitudinal layers of the muscularis externa, which they supply. From the myenteric plexus a secondary plexus, termed the *submucous plexus*, is derived, and is formed by branches which have perforated the circular muscular layer. This plexus also contains ganglionic neurons from which the nerve fibres pass to the muscularis mucosae and to the mucous membrane. The nerve bundles of the submucous plexus are finer than those of the myenteric plexus. The neurons in both plexuses are essentially parasympathetic (vagal). An old controversy as to the source of the postganglionic neurons in the enteric ganglia has been renewed latterly (Andrew 1971). Endodermal and mesodermal origins have been suggested, but the evidence (though largely equivocal) indicates a derivation from the neural crest. In general the sympathetic is inhibitory to the peristaltic movements of the alimentary canal, but stimulates the sphincters and also the muscularis mucosae. While the parasympathetic is generally an augmentor of the peristaltic movements and an inhibitor of the sphincters, the result of stimulation of the parasympathetic appears to depend on the state of contraction or relaxation of the organ at the time of stimulation. The parasympathetic is also augmentory to the intestinal secretion. For an extensive evaluation of the status of the 'intestinal' cells (of Cajal) in the intestinal wall, consult Rogers and Burnstock (1966). It seems probable that these are connective tissue cells, and not neurons. There is some evidence that some of the neurons in the ganglia of the intestinal wall may be afferent (Fehér and Vajda 1974).



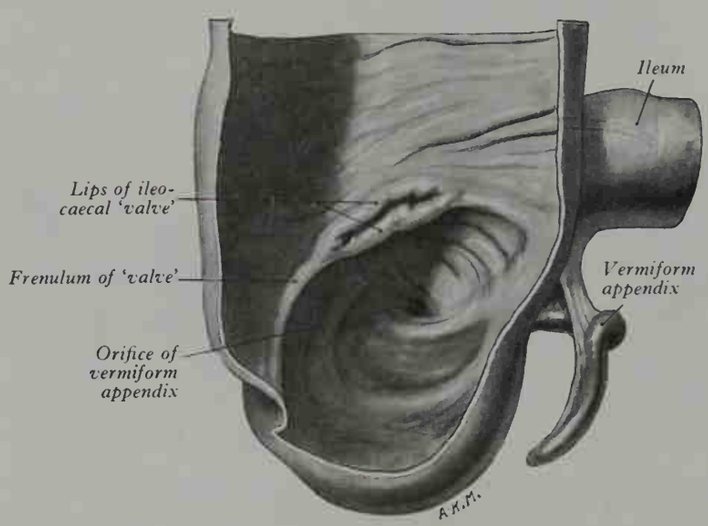
The Large Intestine

The large intestine extends from the end of the ileum to the anus, and is about 1·5 m long. Its calibre is greatest at its commencement at the caecum, and gradually diminishes as far as the rectum, where there is a dilatation of considerable size just above the anal canal. Its functions being chiefly the absorption of fluid and solutes, it differs considerably in appearance, structure, size and arrangement from the small intestine. (1) It has a greater calibre. (2) For the most part, it is more fixed in position. (3) Its longitudinal muscular fibres, although distributed as a *complete* layer, are particularly concentrated to form three longitudinal bands or *taeniae coli*. (4) Since these taeniae are often held to be 'shorter' than the circular muscular coat, the intervening colonic wall is puckered and thrown into *sacculations* (alternatively termed *haustrations*). It is not certain that the sacculation is adequately explained in this manner (*see* p. 1362, and Hamilton 1946; Pace 1968). (5) Small, peritoneum-covered, adipose projections, termed *appendices epiploicae*, are found scattered over the free surface of the whole of the large intestine, with the exceptions of the caecum, the vermiform appendix and the rectum.

In its course the large intestine curves around and usually encloses the convolutions of the small intestine. It commences in the right iliac region, in a dilated part termed the *caecum* (*intestinum crassum caecum*—the term *caecum*, like rectum, duodenum and others, is an adjective, rapidly becoming by linguistic abbreviation a noun). The colon ascends the right lumbar and hypochondriac regions to the inferior surface of the liver; here it bends (the *right colic flexure*, **8**.111) to the left, and, curving with a downward and a forward convexity, passes, as the *transverse colon*, across the abdomen to the left hypochondriac region; it then bends again (the *left colic flexure*, **8**.111), and descends through the left lumbar and iliac regions to the lesser pelvis, where it forms a sinuous loop, the *sigmoid colon* (**8**.125); from this it is continued along the lower part of the posterior wall of the pelvis as the rectum and anal canal. It is divided into the caecum (including the vermiform appendix), the colon, the rectum and the anal canal.



C



D

8.120C and D Specimens of the jejunum (C) and ileum (D) from a subject in whom the superior mesenteric artery was injected with a red coloured mass of gelatin before fixation. Subsequently the specimens were dehydrated, and then cleared in benzene followed by methyl salicylate. The largest vessels present are the jejunal and ileal branches of the superior mesenteric artery, and these are succeeded by anastomotic arterial arcades, which are relatively few in number (1–3) in the jejunum, becoming more numerous (5–6) in the ileum. From the arcades, straight arteries pass towards the gut wall; frequently, successive straight arteries are distributed to opposite sides of the gut. Note the denser vacularity of the jejunal wall. (Specimens prepared by Dr. Michael C. E. Hutchinson, Department of Anatomy, Guy's Hospital Medical School.)

8.121B The interior of the caecum and commencement of the ascending colon, showing the ileocaecal 'valve'. (See text for discussion.)

THE CAECUM

The caecum (**8.121A, B**), the commencement of the large intestine, is in the right iliac fossa—its surface projection hence occupies the triangular area bounded by the right lateral plane, the transtubercular plane and the inguinal ligament. It is a large cul-de-sac continuous superiorly with the ascending colon, and at the point where the one passes into the other the ileum opens into the large intestine from the medial side. Its average axial dimension is about 6 cm and its breadth about 7·5 cm. In the right iliac fossa it is superior to the lateral half of the inguinal ligament: it rests posteriorly on the iliacus and on the psoas major, being separated from both muscles by their covering fasciae and the peritoneum, and posterior to it is the *retrocaecal recess* (p. 1331) which frequently contains the vermiform appendix. In addition, the lateral cutaneous nerve of the thigh intervenes between it and the iliacus. Anteriorly it is usually in contact with the anterior abdominal wall, but the greater omentum, and, if the caecum is empty, some coils of small intestine may be interposed. Usually, it is entirely enveloped by peritoneum, but sometimes the peritoneal covering is incomplete, the superior part of its posterior surface being uncovered and sessile, connected to the iliac fascia by areolar tissue. Commonly, however, the caecum enjoys a considerable amount of movement, so that it may even become herniated through the right inguinal canal. It is also commonplace to deliver the caecum through an appropriate incision in the anterior abdominal wall during the course of an appendicectomy.

Caecal Variations

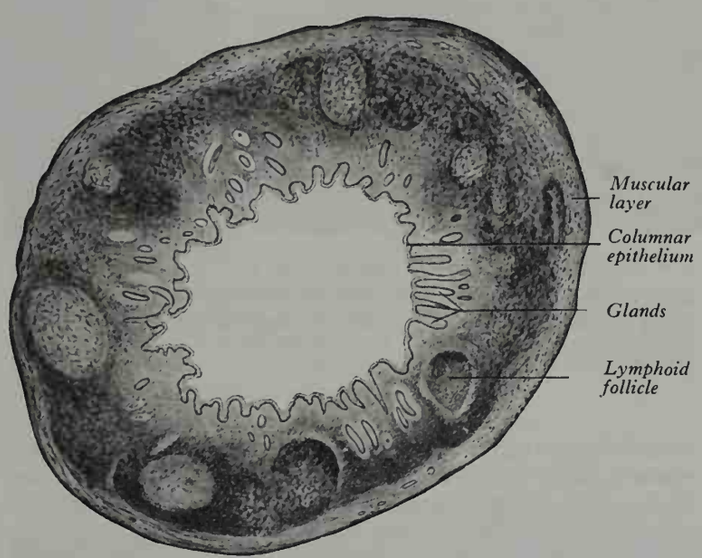
The caecum varies in shape, and it has been classified under one of four types (Treves 1885). In early fetal life it is short, conical and broad at the base, with its apex turned upwards and medially towards the ileocaecal junction. As the fetus grows, the caecum increases in length more than in breadth, so that it forms a longer tube and lacks the broad base, but still has the same inclination of the apex towards the ileocaecal junction. As development continues, the lower part of the tube ceases to grow and the upper part becomes increased, so that at birth the narrow vermiform appendix extends from the apex of a conical caecum. This is the *infantile form* and as it persists throughout life in about 2 per cent of subjects, it was regarded by Treves as the *first* of his four types of human caeca. The three taeniae coli (p. 1362) start from the appendix and are equidistant from each other. In the *second* type, the conical caecum has become quadrate by the outgrowth of a saccule on each side of the anterior taenia. These saccules are of equal size, and the appendix arises from the depression between them, instead of from the apex of a cone. This type is found in about 3 per cent of subjects. The *third* type is the normal type for man. Here the two saccules, which in the second type were uniform, have grown at unequal rates, the right with greater rapidity than the left. In consequence of this an apparently new apex has been formed by the downward growth of the right saccule, and the original apex, with the appendix attached, is pushed over to the left towards the ileocaecal junction. The three taeniae still start from the base of the vermiform appendix, but they are now no longer equidistant from each other, because the right saccule has grown between the anterior and posterolateral taeniae, pushing them over to the left. This type occurs in about 90 per cent of subjects. The *fourth* type is merely an exaggerated condition of the third; the right saccule is still larger, and at the same time the left saccule has become atrophied, so that the original apex of the caecum, with the vermiform appendix, is close to the ileocaecal junction, and the anterior taenia courses medially to the same situation. This type is present in about 4 per cent of subjects.

In a more recent study (Pavlov and Pétrov 1968) covering eighty-two males and forty-four females (adolescent and adult), the third type noted above was designated *ampullary*, and this accounted for 78 per cent. A so-called *infundibular* type, approximating to the conical group, occurred in 13 per cent. The remaining 9 per cent were intermediate. In the same series, the caecum was mobile 20 per cent more often in females. (For further developmental analyses consult Balthazar and Gade 1976.)

THE ILEOCAECAL VALVE

The lower end of the ileum opens into the medial and posterior aspect of the large intestine, at the point of junction of the caecum with the colon (**8.121B**). The ileocaecal orifice is represented on the surface at the point of intersection of the right lateral and transtubercular planes; about 2 cm below this point the vermiform appendix opens into the caecum. The opening is provided with a so-called 'valve', consisting of two segments or flaps which project into the lumen of the large intestine. *After inflation and fixation* of the caecum, the flaps are of a semilunar shape. The upper, approximately horizontal, is attached to the line of junction of the ileum with the colon; the lower, which is longer and more concave, is attached to the line of junction of the ileum with the caecum. At the ends of the aperture the two segments of the valve coalesce, and are continued as narrow membranous ridges for a short distance, forming the *frenula* of the valve. The left or anterior end of the aperture is rounded; the right or posterior is narrow and pointed. In the fresh condition, or in

specimens which have been hardened *in situ*, the lips of the valve project as thick folds into the lumen of the caecum, and the opening may present the appearance of a slit or may be somewhat oval in shape. The circular and longitudinal muscle coats of the terminal part of the ileum are continued into the valve and form a sphincter. It must be added that direct observation of the living ileocaecal 'valve' does not corroborate this description (Rosenberg and DiDio 1969); in nine cases studied (through a caecostomy) the ileal projection was papillary in shape. Moreover, radiological evidence contradicts the concept of an effective valve at this junction.

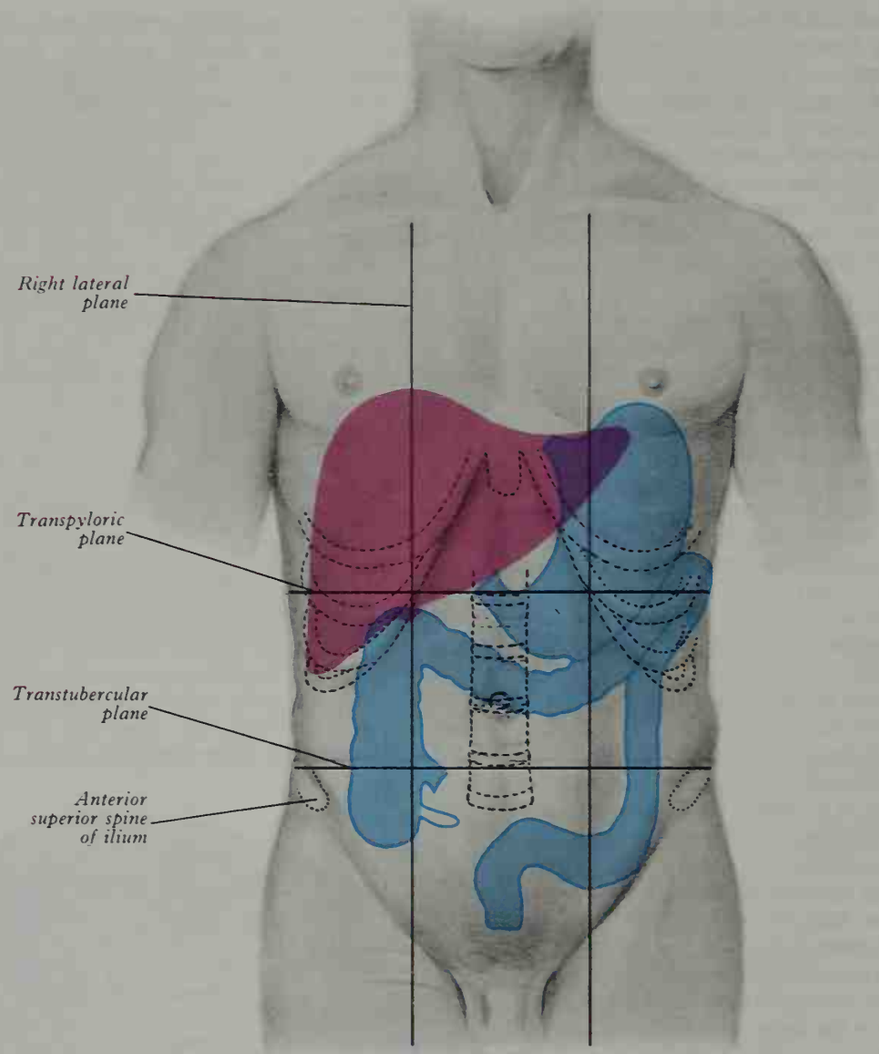


It may be added here that accumulations of circular fibres, sometimes described as sphincters, have been observed at various levels in all parts of the colon, and a large literature has developed on this topic (*see* DiDio and Anderson 1968; Rosenberg and DiDio 1969). The functional reality of most of these entities has not been established. It should be noted that all such sphincteric mechanisms must be balanced by an opposite, dilatatory activity.

The margin of the ileocaecal valve is formed by a reduplication of the mucous membrane and of the circular muscular fibres of the intestine. The longtitudinal fibres are partly reduplicated as they extend into the valve (Jit and Singh 1956), though the more superficial longitudinal elements and the peritoneum are continued uninterruptedly from the small to the large intestine.

The surfaces of the valve directed towards the ileum are covered with villi and present the characteristic structure of the mucous membrane of the small intestine; while those turned towards the large intestine are destitute of villi and marked with the orifices of the numerous tubular glands peculiar to the mucous membrane of the large intestine. It is usually considered that the valve not only prevents reflux from the caecum into the ileum, but in all probability it also acts as a sphincter at the end of the ileum and prevents the contents of the ileum from passing too quickly into the caecum; the valve is kept in a condition of tonic contraction by impulses which reach it through the sympathetic nerves. The taking of food into the stomach initiates contraction of the duodenum and the rest of the small intestine, followed by the passage of ileal contents into the large intestine through the ileocaecal opening (the so-called gastro-ileal reflex).

THE VERMIFORM APPENDIX



The vermiform appendix (**8**.121A, B) is a narrow, worm-shaped tube, which springs from the posteromedial wall of the caecum, 2 cm or less below the end of the ileum, and may occupy one of several positions: (*a*) it may lie behind the caecum and the lower part of the ascending colon (*retrocaecal and retrocolic*); (*b*) it may descend over the brim of the lesser pelvis (*pelvic* or *descending*), in which case it lies in close relation to the right uterine tube and ovary in the female; (*c*) it may lie below the caecum (*subcaecal*); (*d*) it may lie in front of the terminal part of the ileum and may then be in contact with the anterior abdominal wall; or (*e*) it may lie behind the terminal part of the ileum. In a study of 10,000 subjects (Wakeley 1933), the vermiform appendix was retrocaecal and retrocolic in 65·28 per cent, pelvic in 31·01 per cent, subcaecal in 2·26 per cent, pre-ileal in 1·0 per cent, and post-ileal in 0·4 per cent. Although these classical figures were based upon a very large series, subsequent literature, both anatomical and surgical, shows much contradiction. Buschard and Kjaeldgaard (1973), reporting upon a short series (234 autopsies), have compared the results of a number of studies (from 1885 to 1973), of which Wakeley's remains by far the largest. They classify all positions into two groups: *Anterior* (=pelvic and ileocaecal) and *Posterior* (retrocaecal and subcaecal). On this basis all but three of the eleven series quoted found the *anterior* positions more frequent. Like Wakeley these observers found *posterior* positions more commonly in their own Danish series, while in their German autopsies, the finding was reversed. Collins (1932) in the second largest series (4680), returned percentages which are the reverse of Wakeley's, the partition between anterior and posterior being 78·5 per cent and 21·5 per cent (Collins) and 32·4 per cent and 67·6 per cent (Wakeley). In view of these and other less contrasted disagreements, it is scarcely useful to continue to quote such figures. Perhaps the different observers involved have used different criteria in their examinations; perhaps, even, there are population divergencies. For the present, however, positional percentages for the vermiform appendix must be regarded as unreliable. The surface marking most used for the base of the appendix is the junction of the lateral and middle thirds of the line joining the right anterior superior iliac spine to the umbilicus (*McBurney's point*). (The latter is a useful surgical approximation, but as noted, considerable variation may occur). The three taeniae coli on the ascending colon and caecum converge on the base of the appendix, where they merge into its longitudinal muscular layer. The anterior taenia of the caecum is generally distinct and can be easily traced to the root of the appendix, thus affording a ready guide to it. The appendix varies from 2 to 20 cm in length, the average being about 9 cm. It is longer in the child than in the adult and may atrophy and become smaller after mid-adult life. It is connected by a short *mesoappendix* to the lower part of the mesentery of the ileum. This fold, in the majority of cases, is more or less triangular, and as a rule extends along the entire length of the tube. The main artery to the appendix, a branch of the lower division of the ileocolic artery (p. 716), runs behind the terminal part of the ileum and enters the mesoappendix a short distance from the base of the appendix. Here it gives off a recurrent branch which anastomoses at the base of the appendix with a branch of the posterior caecal artery, the anastomosis sometimes being of considerable size. The main appendicular artery runs towards the tip of the appendix, lying at first near to and afterwards in the free border of the mesoappendix. The terminal part of the artery, however, lies actually on the wall of the appendix and may become

8.122 A transverse section of human vermiform appendix. Magnification about × 20.

thrombosed in inflammation of the appendix, which may result in gangrene or necrosis of its distal part. However, the arterial supply of the vermiform appendix may vary considerably. Numbers of accessory arteries are common; in 80 per cent of individuals there are two or more arteries of supply (Solanke 1968). The canal of the vermiform appendix is small, and communicates with the caecum by an orifice which is placed below and a little behind the ileocaecal opening. The orifice is sometimes guarded by a semilunar valve formed by a fold of mucous membrane. The lumen of the appendix may be partially or completely obliterated after mid-adult life. In view of its rich blood supply and histological differentiation, the vermiform appendix is probably more correctly regarded as a specialized than as a degenerate, vestigial structure. The configuration of the caecum and appendix in man and the anthropoid apes is probably less primitive than in the monkeys.

Structure. The layers of the vermiform appendix are the same as those of the intestine: serous, muscular, sub-mucous and mucous. The *serous* coat forms a complete investment for the tube, except along the narrow line of attachment of its mesentery.

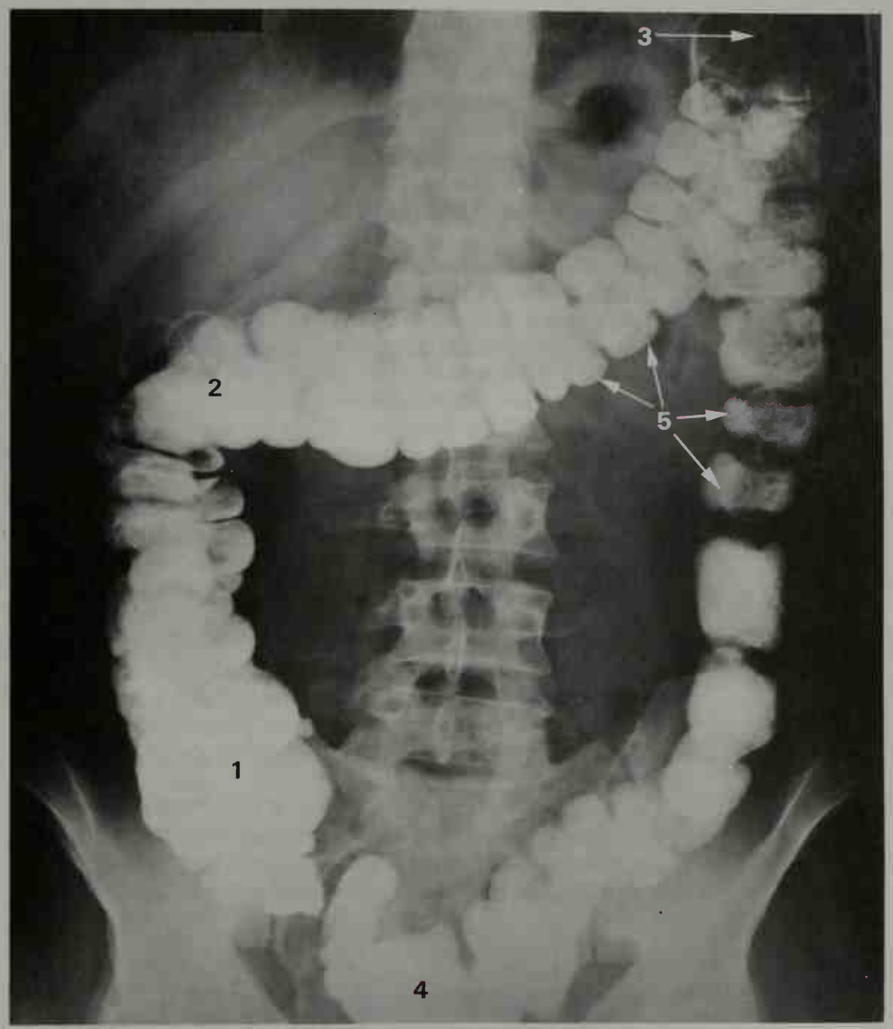
8.123A Surface projection of the stomach, liver and colon. The outlines of the lumbar vertebral bodies, lower ribs, xiphoid process, and parts of the iliac crests are indicated.

Beneath it lies a layer of subserous areolar tissue. The *longitudinal muscular fibres* form a uniformly thick layer which invests the whole organ, except at one or two points where the longitudinal and circular layers may be both deficient, so that the peritoneal and submucous coats are contiguous over small areas. At the base of the appendix, the longitudinal muscle becomes thickened around the perimeter, to form incipient taeniae coli which becomes continuous with those of the caecum and colon. The *circular muscular fibres* form a thicker layer than the longitudinal fibres, and are separated from them by a small amount of connective tissue. The *submucous layer* is well developed, and contains a large number of masses of lymphoid tissue which cause the mucous membrane to bulge into the lumen and so render the latter of small size and irregular shape. The *mucous membrane* is covered by columnar epitheliocytes and attenuated antigen-transporting membrane or M cells (Owen and Nemanic 1978). Glands are few in number and penetrate deeply amongst the lymphoid tissue (**8**.122). In the normal human appendix the lymphoid tissue lies in the lamina propria and in the submucosa, where follicular and parafollicular zones can be distinguished; clusters of lymphocytes or immunoblasts also lie within or between surface epithelial cells where they possibly mature or differentiate into plasma cells (Gorgollón 1978). The lymphoid tissue of the lamina propria contains many plasma cells, together with lymphocytes, acidophilic leucocytes, mast cells and macrophages, all embedded in a fibrocellular reticulum. The submucosal follicles (germinal centres) contain immunoblasts, lymphocytes, macrophages, plasma cells and dendritic reticular cells, the last two being most abundant in the central regions of the follicles; cells similar to the dendritic reticular cells have been found in the human thymus (Kaiserling *et al.* 1974). The parafollicular zones are distinguished by aggregations of small lymphocytes, a scarcity of plasma cells, and by the presence of post-capillary venules lined by a tall endothelium through which lymphocytes may migrate. These endothelial cells have a surface coat of immunoglobulins which may be involved in the control of lymphocyte recirculation (Sordat *et al.* 1971). The *lymphoid masses* provide a local defence against infection, and have also been suggested as a possible homologue of the *bursa of Fabricius* in birds (p. 61) which is concerned with the acquisition of immunological competence by certain lymphocytes. Experimental evidence is, however, lacking. In many mammals, particularly herbivores, the caecum and associated appendix are large, and form an important site for the digestion of cellulose by symbiotic bacteria.

THE COLON

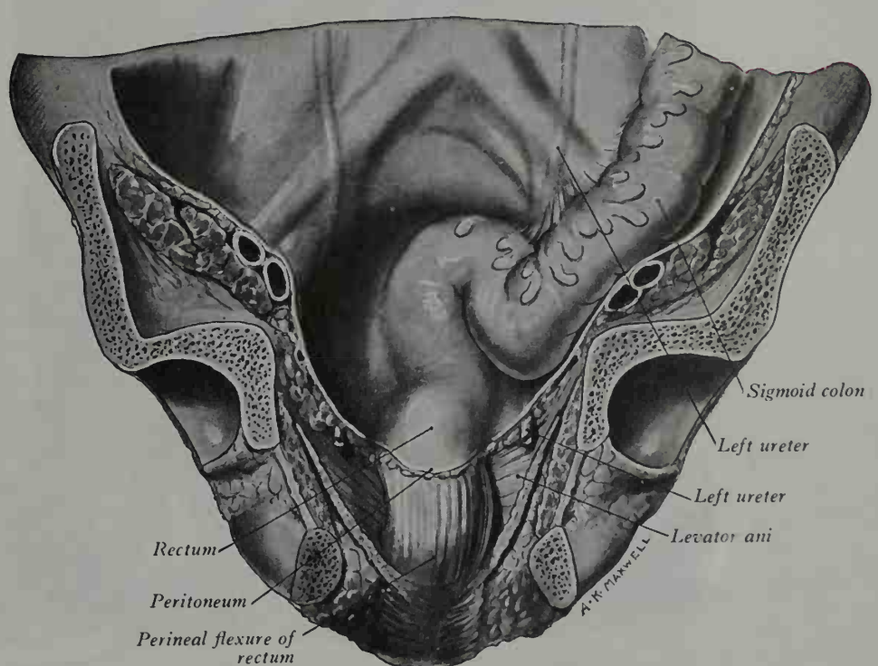
The colon may be considered in four parts—the ascending, transverse, descending and sigmoid.

The ascending colon, about 15 cm long, is narrower than the caecum. It begins at the caecum, and ascends to the inferior surface of the right lobe of the liver, where it is lodged in a shallow colic depression; here it bends abruptly forwards and to the left, forming the *right colic flexure* (**8**.111A). In surface projection it ascends to the right of the right lateral plane (**8**.123A), from the transtubercular plane to midway between the subcostal and transpyloric planes. It is surrounded by peritoneum except where



its posterior surface is connected by areolar tissue to the fascia over the iliacus, iliolumbar ligament, quadratus lumborum and the aponeurotic origin of the transversus abdominis, and to the perirenal fascia in front of the inferolateral part of the right kidney. The lateral cutaneous nerve of the thigh, usually the fourth lumbar artery and, sometimes, the ilio-inguinal and iliohypogastric nerves cross behind it. Sometimes it is almost completely invested with peritoneum, thus possessing a distinct but narrow mesocolon. In a series of 100, 52 per cent had neither an ascending nor a descending mesocolon, 14 per cent had both, 12 per cent an ascending, and 22 per cent a descending mesocolon (Treves 1885). It is in relation, anteriorly, with the convolutions of the ileum, the right edge of the greater omentum and the abdominal wall.

The right colic flexure comprises the terminal part of the ascending colon and the commencement of the transverse colon, which turns downwards, forwards and to the left. Behind, it is in relation with the lower and lateral part of the anterior surface of the right kidney. Above and anterolaterally, it is related to the right lobe of the liver; anteromedially, to the descending part of the duodenum and the fundus of the gall bladder. It is not covered by peritoneum on its posterior surface, so that this surface is in direct contact with the renal fascia. The flexure is not so acute as the left colic flexure.



The transverse colon (**8**.103), about 50 cm long, begins at the right colic flexure, placed in the right lumbar region, passes across the abdomen into the left hypochondriac region, and here curves sharply on itself, downwards and backwards, beneath the lateral end of the spleen, forming the *left colic flexure*. In its course across the abdomen it describes an arch, the concavity of which is usually directed backwards and upwards; towards its splenic end there is often an abrupt U-shaped curve which may descend lower than the main curve. Its surface projection (**8**.123) is drawn from a point, situated immediately lateral to the right lateral plane and midway between the subcostal and transpyloric planes, to the umbilicus, and then upwards and to the left to a point a little above and lateral to the intersection of the left lateral and transpyloric planes. The precise position occupied by the transverse colon is difficult to define, for it not only shows individual variation but its position varies in the same individual from time to time. Very commonly it lies in the lower umbilical or upper hypogastric region. It may be higher but frequently descends in a V-shaped manner, the apex of the V reaching well below the level of the iliac crests (*see* p. 1321). In a radiological assessment of the position of the transverse colon in the living (upright position), the level of the lowest part of the tube in 1,000 young adults varied greatly, even descending into the true pelvis. Moreover, the level varied as much as 17 cm in the same individual between the upright and recumbent positions (Moody 1927).

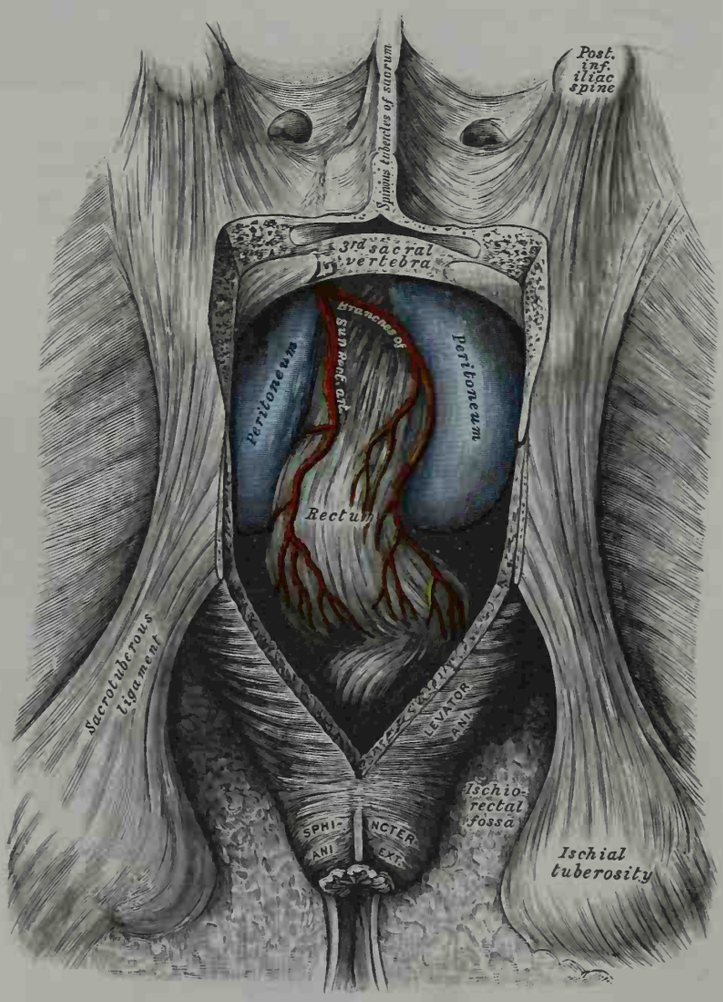
The posterior surface of its right extremity is devoid of peritoneum, and is attached by areolar tissue to the front of the descending part of the duodenum and the head of the pancreas. Between the head of the pancreas and the left colic flexure, the transverse colon is almost completely invested by peritoneum, and is connected to the anterior border of the body of pancreas by the *transverse mesocolon*. It is in relation, by its upper surface, with the liver and gall bladder, the greater curvature of the stomach, and the lateral end of the spleen; by its under surface, with the small intestine; by its anterior surface with the posterior layers of the greater omentum; its posterior surface is in relation with the descending part of the duodenum, the head of the pancreas, the upper end of the mesentery, the duodenojejunal flexure and some of the coils of the jejunum and ileum.

The left colic flexure (**8**.111) is the junction of the transverse and descending sections of the colon in the left hypochondriac region, and is in relation with the lower part of the spleen and the tail of the pancreas above, and with the anterior aspect of the left kidney medially; the flexure is so acute that the end of the transverse colon usually lies in contact with the front of the descending colon. The left colic flexure lies at a higher level than, and on a plane posterior to, the right colic flexure, and is attached to the diaphragm, opposite the tenth and eleventh ribs, by a peritoneal fold, named the *phrenicocolic ligament*, which lies below the lateral end of the spleen (p. 1330).

8.123B A radiograph of the abdomen after the administration of a barium enema which has filled the whole of the large intestine as far as the caecum and ileocaecal valve. (1) the caecum; (2) the right or hepatic flexure of the colon, which is much inferior to (3) the left or splenic flexure of the colon; (4) the sigmoid colon; and (5) the sacculations, or haustrations, which are clearly visible throughout most of the colon.

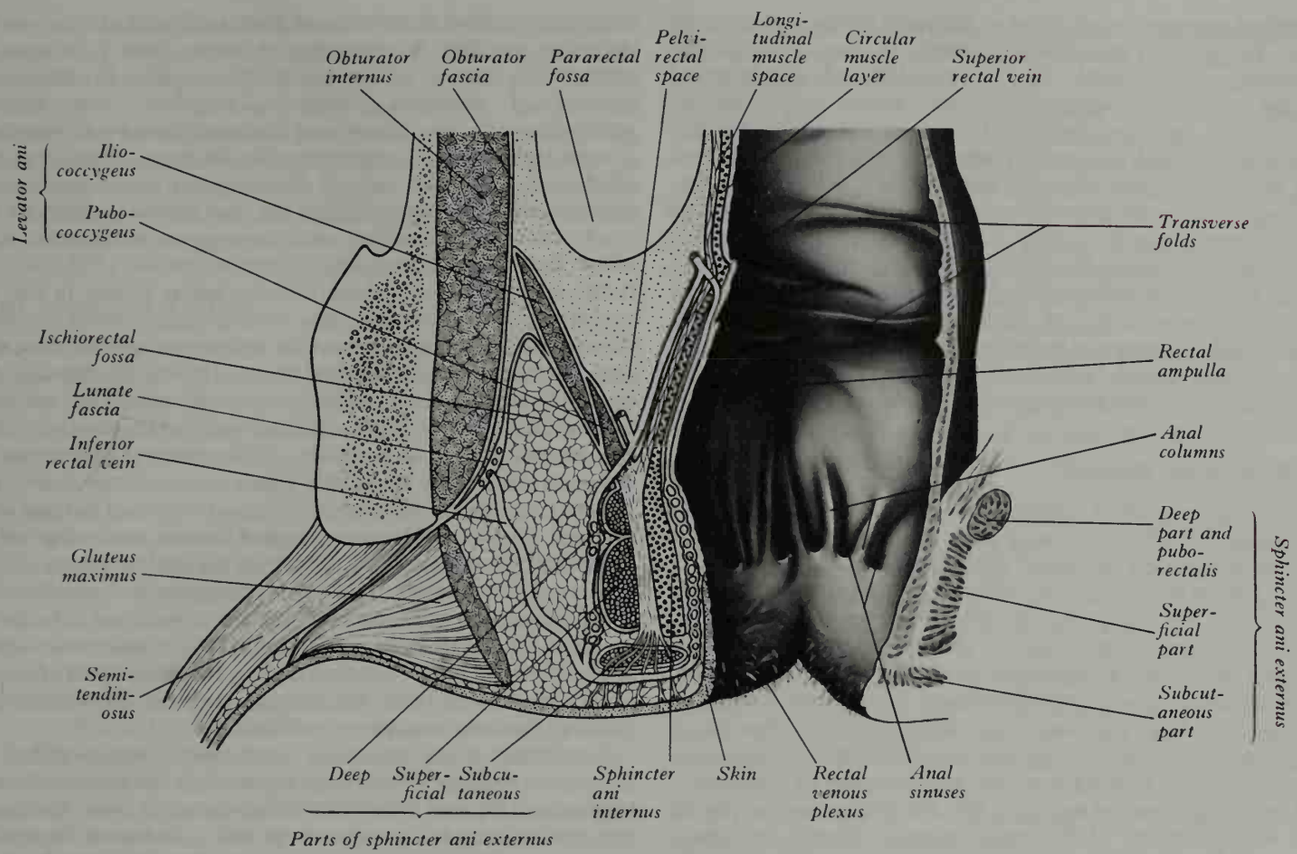
8.123C Oblique coronal section through the pelvis to expose the anterior aspect of the rectum.

The descending colon (8.111A), about 25cm long, passes downwards through the left hypochondriac and lumbar regions. At first it follows the lower part of the lateral border of the left kidney and then, at the lower pole of that organ, it descends, in the angle between psoas major and quadratus lumborum, to the crest of the ilium; it then curves downwards and medially in front of the iliacus and psoas major, and ends in the sigmoid colon at the inlet of the lesser pelvis. (The descending colon is sometimes described as ending at the level of the iliac crest, the part between that level and the inlet of the true pelvis being named the *iliac colon*.) In surface projection (8.123A) it passes downwards, just lateral to the left lateral plane, from a point situated a little above and to the left of the intersection of the transpyloric and left lateral planes, as far as the inguinal ligament. The peritoneum covers its anterior surface and sides, while its posterior surface is connected by areolar tissue with the fascia over the lower and lateral part of the left kidney, the aponeurotic origin of the transversus abdominis, the quadratus lumborum, the iliacus and the psoas major (8.111A). Numerous structures cross behind it. They include: the subcostal vessels and nerve, the iliohypogastric and ilio-inguinal nerves, the fourth lumbar artery (as a rule), the lateral femoral cutaneous, femoral and genitofemoral nerves, the testicular (or ovarian) vessels and the external iliac artery, all of the left side. The descending colon is smaller in calibre, more deeply placed, and more frequently covered with peritoneum on its posterior surface, than the ascending colon (p. 1355). Anteriorly it is related to coils of the jejunum, except in its lower part, which can be felt through the anterior abdominal wall when the abdominal muscles are relaxed.



The sigmoid colon (pelvic colon) (8.123C) begins at the inlet of the lesser pelvis, where it is continuous with the descending colon; it forms a loop which varies greatly in length, but averages about 40 cm, and normally lies within the lesser pelvis. The loop consists of three parts; the first part descends in contact with the left pelvic wall; the second crosses the pelvic cavity, between rectum and bladder in the male, and rectum and uterus in the female, and may come into contact with the right pelvic wall; the third arches backwards and reaches the median plane at the level of the third piece of the sacrum, where it bends downward and ends in the rectum. The sigmoid colon is closely surrounded by peritoneum, which forms a mesentery, the *sigmoid mesocolon* (p. 1330); this diminishes in length from the centre towards the ends of the loop, where it disappears, so that the loop is fixed at its junctions with the descending colon and rectum, but enjoys a considerable range of movement in its central region. Its relations are therefore subject to considerable variation. *Laterally* it is related to the external iliac vessels, the obturator nerve, the ovary (in the female), the ductus deferens (in the male) and the lateral pelvic wall. *Posteriorly* it is related to the internal iliac vessels, the ureter, the piriformis and the sacral plexus, all of the left side. *Inferiorly* it rests on the bladder, in the male, and on the uterus and bladder, in the female. *Above* and on its *right* side, it is in contact with the terminal coils of the ileum.

The position and shape of the sigmoid colon vary very much, and depend on (*a*) its length; (*b*) the length and freedom of its mesocolon; (*c*) the condition of distension; when distended it rises out of the lesser pelvis into the abdominal cavity, and when empty it sinks again into the pelvis; (*d*) the condition of the rectum and bladder (and the uterus, in the female); when these organs are distended the sigmoid colon tends to rise, and conversely. Racial variation in the size of the sigmoid colon has been noted (Lisowski 1969); in some groups—and particularly in Ethiopians—the incidence of a suprapelvic loop, which may be conducive to volvulus, is particularly high.

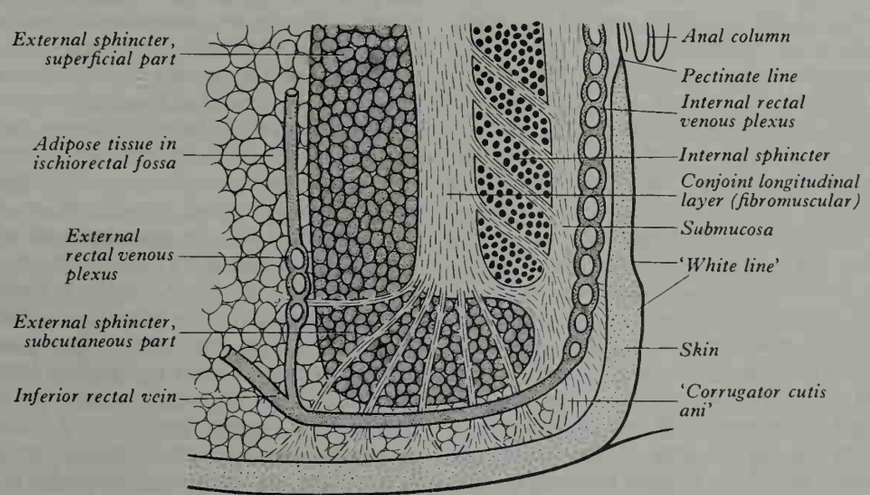


THE RECTUM

The rectum (8.123C–124C) is continuous with the sigmoid colon at the level of the third sacral vertebra, the junction being indicated by the lower end of the sigmoid mesocolon. From its origin it descends, following the concavity of the sacrum and coccyx, forming an anteroposterior curve known as the *sacral flexure* of the rectum. It thus passes at first downwards and backwards, then downwards, and finally downwards and forwards to become continuous with the anal canal by passing through the pelvic diaphragm (p. 560). The *anorectal junction* is situated 2 to 3 cm in front of, and slightly below the tip of the coccyx; from this level, which in the male is opposite the apex of the prostate, the anal canal passes downwards and backwards from the lower end of the rectum, the backward bend of the gut at the anorectal junction being termed the *perineal flexure* of the rectum. In addition to its anteroposterior curve, the rectum deviates from the midline in the form of three lateral curves; the upper one is convex to the right, the middle one (which is the most prominent) bulges to the left, and the lower one is convex to the right; the beginning and end of the rectum are in the median plane (8.124A).

The rectum is about 12 cm long and its upper part has the same diameter as the sigmoid colon (about 4 cm in the empty state), but its lower part is dilated to form the *rectal ampulla*. The rectum differs from the sigmoid colon in that it has no sacculations, appendices epiploicae or mesentery, while the taeniae coli blend about 5 cm above the junction of the rectum and sigmoid colon to form two wide muscular bands which descend, one in the anterior and the other in the posterior wall of the rectum. The peritoneum is related only to the upper two-thirds of the rectum, covering at first its front and sides, but lower down its front only; from the latter it is reflected on to the bladder in the male, forming the rectovesical pouch of peritoneum, and on to the posterior wall of the vagina in the female, forming the recto-uterine pouch. The level of peritoneal reflexion is higher in the male, the rectovesical pouch being about 7·5 cm from the anus (the height to which the index finger inserted through the anus can reach); in the female the recto-uterine pouch is about 5·5 cm from the anus. In the male fetus the peritoneum extends on the front of the rectum as far as the lower end of the prostate (*see* p. 1420). On the sigmoid colon, the peritoneum is firmly attached to the muscle coat by fibrous

8.124A Posterior aspect of the rectum exposed by removal of the lower part of the sacrum and coccyx. Note superior rectal artery (red) and peritoneum of the pararectal fossae (blue).



8.124B Diagram of a coronal section of the rectum and anal canal and the adjacent structures. (Adapted from Rauber-Kopsch, *Lehrbuch und Atlas der Anatomie des Menschen*, 1929.) The internal pudendal vessels, the dorsal nerve of the penis and the perineal nerve are shown transected in the lateral wall of the ischiorectal fossa, where they are traversing the 'lunate fascia' (pudendal canal).

connective tissue; but as it descends on the rectum, the peritoneum becomes more loosely attached to the muscle by fatty areolar tissue, thus allowing considerable expansion of this part of the gut.

In the empty state of the rectum, the mucous membrane of its lower part presents a number of longitudinal folds which are effaced by distension of the rectum. Besides these, there are permanent *transverse* or *horizontal folds* of a semilunar shape, which are most marked when the rectum is distended. Two forms of horizontal folds have been recognized (Jit 1961). One, consisting of mucous membrane, the circular muscle coat, and part of the longitudinal muscle coat, is marked on the outer surface of the rectum by an indentation. The other form is devoid of longitudinal muscle coat fibres, and bears no external surface marking. Commonly three folds are present, but their number is variable. The upper one is situated near the commencement of the rectum and may be on the left or the right side; occasionally it may encircle the gut and the lumen of the gut is then somewhat constricted at this site. The middle fold is the largest and most constant, and is situated immediately above the ampulla of the rectum; it projects from the anterior and right walls of the rectum just below the level at which the peritoneum is reflected from the anterior surface of the rectum; the circular muscle in this fold is more marked than in the others. The lowest fold is inconstant and lies on the left side, about 2·5 cm below the middle fold; sometimes a fourth fold is present on the left side, about 2·5 cm above the middle fold described above.

It has been suggested (Paterson 1912) that the rectum consists functionally of two parts, one above and the other below the middle fold, the upper part containing faeces and being free to distend towards the peritoneal cavity, while the lower part occupies a more confined situation, enclosed in a tube of

8.124C Part of **8.124B**, enlarged to show greater detail.

condensed extraperitoneal tissue and (except during defaecation) empty in normal individuals, though in cases of chronic constipation, or after death, it may contain faeces. It may be noted that the part of the rectum above the middle fold is usually considered to be developed from the hindgut while the part below, together with the upper part of the anal canal, is derived from the cloaca (post-allantoic gut). Others (O'Beirne 1833; Hurst 1919), however, considered that the sigmoid colon acts as a faecal reservoir, that in normal individuals the rectum is empty (though it may contain faeces in cases of chronic constipation), and that the passage of faeces into the rectum normally excites the desire to defaecate. It has been shown experimentally, by registering the pressure in balloons inserted into the rectum and anal canal, that considerable distension of the rectum results in a desire to defaecate and relaxation of the anal sphincters (Denny-Brown and Robertson 1935).

Relations of the Rectum

Posteriorly the rectum is related in the median plane to the lower three sacral vertebrae, the coccyx, the median sacral vessels, the ganglion impar and branches of the superior rectal vessels, while on each side of the midline the following structures, particularly those of the left side, lie behind the rectum: namely, the piriformis, the anterior rami of the lower three sacral and coccygeal nerves, the sympathetic trunk, the lower lateral sacral vessels and the coccygei and levatores ani. The rectum is attached to the sacrum along the lines of the anterior sacral foramina by fibro-areolar tissue which encloses the sacral nerves, the pelvic splanchnic nerves passing from the anterior rami of the second, third (and fourth) sacral nerves to join the pelvic plexuses on the rectal wall, branches of the superior rectal vessels, lymphatic vessels and lymph nodes, and loose perirectal fat. *Anteriorly*, the relations of the rectum differ in the two sexes. In the male, above the site of reflexion of the peritoneum from the rectum, the upper parts of the base of the bladder and of the seminal vesicles, and the rectovesical pouch of the peritoneum and its contents (terminal coils of the ileum and the sigmoid colon) are in front of the rectum; while below the peritoneal reflexion the rectum is related anteriorly to the lower parts of the base of the bladder and of the seminal vesicles, the deferent ducts, the terminal parts of the ureters and the prostate. In the female, above the peritoneal reflexion, the uterus, the upper part of the vagina and the recto-uterine pouch of the peritoneum and its contents (terminal coils of the ileum and the sigmoid colon) lie in front of the rectum, while below the peritoneal reflexion the rectum is related anteriorly to the lower part of the vagina. *Laterally*, the upper part of the rectum is related to the pararectal fossa of the peritoneum and its contents (sigmoid colon or lower part of the ileum), while below the peritoneal reflexion the pelvic sympathetic plexuses, the coccygei and levatores ani, and branches of the superior rectal vessels constitute its immediate lateral relations.

THE ANAL CANAL

The anal canal (*see* Milligan *et al.* 1937; Gabriel 1945; Wilde 1949; Goligher *et al.* 1955; Fowler 1957) begins where the lower end of the ampulla of the rectum suddenly narrows, passing downwards and backwards to end at the anus (**8**.124B, C). It is about 3.8 cm long in the adult, its anterior wall being slightly shorter than its posterior, and in the empty condition its lumen has the form of an anteroposterior or triradiate longitudinal slit. *Posteriorly*, is a mass of fibrous and muscular tissue, termed the *anococcygeal ligament*, which separates it from the tip of the coccyx; *anteriorly*, it is separated by the *perineal body* (p. 562) from the membranous part of the urethra and the bulb of the penis in the male, and from the lower end of the vagina in the female; *laterally*, it is related to the ischiorectal fossae. Over its whole length it is surrounded by sphincter muscles, which normally keep the canal closed.

The lining of the canal differs in various parts. The mucous membrane of the lower part of the rectum is pale pink in colour and semitransparent, allowing the pattern of the branching radicles of the superior rectal vessels to be seen through it. The upper half (15 mm) of the anal canal is also lined by mucous membrane and is plum-coloured owing to the blood in the subjacent internal rectal venous plexus. The epithelium in this region is variable in character; in some cases it is stratified columnar in type, in others it is mainly stratified squamous with patches of stratified columnar, together with stratified polyhedral cells (the cells nearest the lumen being columnar), and a single layer of simple columnar cells like those lining the rectum (Walls 1958). In this part of the canal the mucous membrane presents six to ten vertical folds, the *anal columns*, which are well marked in the child but are sometimes not so well defined in the adult. Each column contains a terminal radicle of the superior rectal artery and vein, these radicles being largest in the left-lateral, right-posterior and right-anterior quadrants of the wall of the anal canal; enlargements of the venous radicles in these three sites constitute primary internal haemorrhoids. The lower ends of the columns are joined together by small crescentic valve-like folds of mucous membrane, the *anal valves*, above each of which lies a small recess or *anal sinus*. The sinuses, deepest on the posterior wall of the canal, may retain faecal matter and become infected, leading to abscess formation in the wall of the anal canal; the anal valves may be torn by hard faeces, producing an anal fissure (p. 1361). The line along which the anal valves are situated is termed the *pectinate line*; it lies opposite the middle of the sphincter ani internus and is commonly considered to be the site at which the anal membrane is situated in the early fetus; thus it represents the place of junction of the endodermal part of the anal canal (developed from the cloaca) and the ectodermal part (derived from the anal pit or proctodeum).

Sometimes small epithelial projections (anal papillae) are present on the edges of the anal valves; they are considered to be remnants of the anal membrane. It has, however, been maintained that the junction of the ectodermal and endodermal parts of the anal canal is situated lower down, at the lower border of the pecten (Johnson 1914). The succeeding part of the anal canal extends for about 15 mm below the anal valves, and is known as the *transitional zone* or *pecten*. Its epithelium is stratified and is intermediate in thickness between the epithelium lining the upper part of the canal and the skin lining the lower part; unlike the latter, it contains no sweat glands. The transitional zone also overlies part of the internal rectal venous plexus and is shiny and bluish in appearance. Its submucosa contains fairly dense connective tissue, in contrast with the lax connective tissue of the upper half of the anal canal, suggesting a firm support and anchorage of the lining of the pecten to the surrounding muscle coats of this part of the anal canal. The transitional zone ends below at a narrow wavy zone, commonly called the '*white line*' (of Hilton); in the living subject this 'line' is bluish pink in colour and is only rarely recognizable macroscopically (Ewing 1954). Its only interest lies in the fact that it is situated at the level of the interval between the subcutaneous part of the external sphincter and the lower border of the internal sphincter, and on digital examination of the anal canal in the living subject an *anal intersphincteric groove* can be felt at this site. Below the white line, the lower 8 mm or so of the anal canal are lined by true skin which may be dull white or brownish in colour and contains sweat glands and sebaceous glands. There are considerable variations in the zones of epithelium described above and there is frequently an interpenetration of the various types of epithelia, so that the zones may not be rigidly separated from each other.

In the region of the anal sinuses, *anal glands* (Fowler 1957; McColl 1967) extend upwards or downwards into the submucosa and occasionally even penetrate deeply into the internal sphincter. Each gland consists of one to six spiral or straight tubules, which may be branched and which are lined by two or three layers of cells that are secretory in nature and contain mucin. The duct of each gland, which is lined by stratified columnar epithelium, opens into a small depression of the lining of the anal canal, called an *anal crypt*. The glands are surrounded by lymphocytes in a form resembling lymphatic follicles, and the submucosal nonstriated muscle is thick in their vicinity. Occasionally the terminal part of a duct is not canalized; in these circumstances, the secretion may distend the gland to form a cyst. The glands are important clinically in that they may become infected, with the result that an abscess or a fistula may be produced. The glands vary widely in number and in their depth of

penetration, and they may even extend in the submucosa above the anorectal junction. (For a detailed and extensive study of the comparative anatomy and pathology of the anal glands, consult McColl 1967. In this series, fifty normal anal canals were examined, and half of these had anal glands passing right through the internal sphincter; the average number of such extensions was four, but they may number up to sixteen. This author considers that the human glands are not homologous with the *anal scent glands* of some other mammals.)

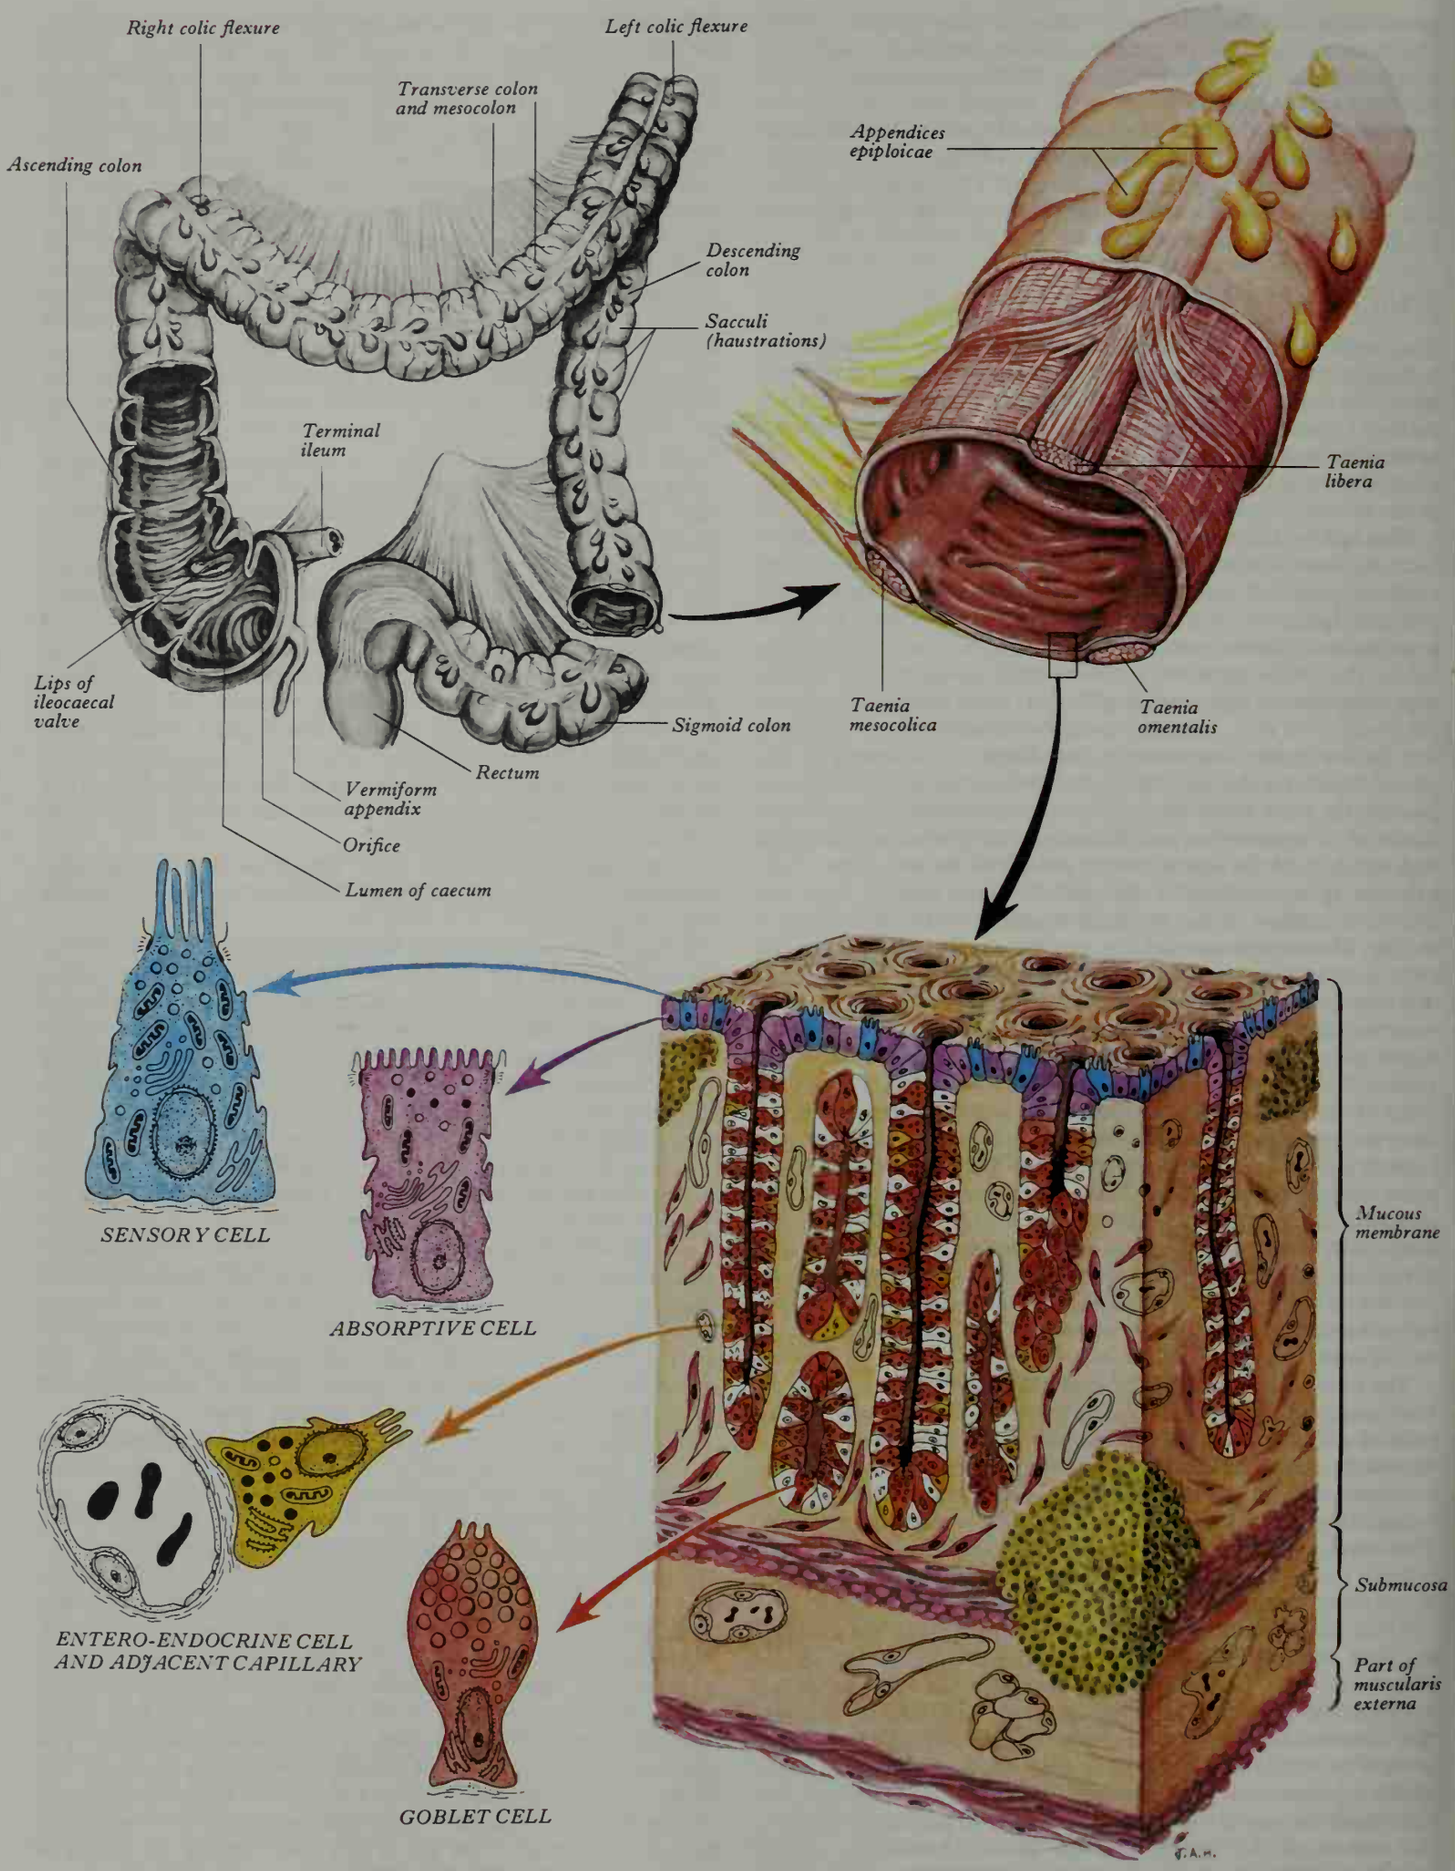
ANAL MUSCULATURE

The walls of the anal canal are surrounded by a complex of muscular sphincters (**8**.124), divided into internal and external parts. At the anorectal junction the circular muscle coat of the rectum becomes considerably thickened (5 to 8 mm) to form the **sphincter ani internus**. This nonstriated sphincter surrounds the upper three-quarters (30 mm) of the anal canal and ends below at the level of the white line (*vide supra et infra*).

The sphincter ani externus surrounds the whole length of the anal canal; it is usually described as consisting of three parts, each composed of striated muscle. The *subcutaneous part* of the external sphincter is a flat band, about 15 mm broad, which surrounds the lower part of the anal canal and lies horizontally below the lower borders of the internal sphincter and of the superficial part of the external sphincter; it lies beneath the skin at the anal orifice and, centrally, it is subcutaneous below the white line in the canal. Anteriorly a few fibres are attached to the perineal body (or the superficial transverse perineal muscles), and posteriorly some fibres are usually attached to the anococcygeal ligament. The *superficial part* of the external sphincter is elliptical and lies deep to the subcutaneous part. It is the only part of the external sphincter that is attached to bone, arising from the posterior surface of the terminal segment of the coccyx by a median fibrous aponeurosis, the anococcygeal raphe; anteriorly, after surrounding the lower part of the internal sphincter, it is inserted chiefly into the perineal body. The *deep part* of the external sphincter is a thick annular band which surrounds the upper part of the internal sphincter; its deeper fibres are fused with and inseparable from those of the puborectalis (p. 561). In front of the anal canal many of the fibres of the deep part of the external sphincter decussate and become continuous with the superficial transverse perineal muscles, this arrangement being more marked in the female. Posteriorly some fibres are usually attached to the anococcygeal ligament. However, it has been asserted by some that there is no clear separation of the three parts of the external sphincter from each other (Goligher *et al.* 1955). In the female, according to Oh and Kark (1972), the muscle is a single band, at least, in its anterior part. (*See* also Wendell-Smith and Wilson 1977).

The tone of both internal and external anal sphincters keeps the anal canal and anus closed; during defaecation these muscles are relaxed and the lower part of the anal canal is opened out and flattened, so that the mucous membrane of the upper part of the canal appears at the surface. The external sphincter can be voluntarily contracted and thus more firmly occlude the anus. The nerve supply of the external sphincter is derived from the inferior rectal branch of the pudendal nerve (S. 2 and 3) and from the perineal branch of the fourth sacral nerve.

At the anorectal junction the pubococcygeal fibres of the levator ani fuse with the longitudinal nonstriated muscle coat of the rectum to form a *conjoint longitudinal coat* for the anal canal, between the internal and external sphincters (**8**.124). Distally, this conjoint coat becomes increasingly fibro-elastic, and at the level of the white line it breaks up into 9 to 12 fibro-elastic septa which spread out fanwise and pass mainly through the subcutaneous part of the external sphincter to become attached to the corium of the skin around the anus. These septa consist mainly of yellow elastic fibres and the most lateral septum passes between the subcutaneous and superficial parts of the external sphincter and becomes lost in the fat of the ischiorectal fossa. It has been maintained that the most medial septum passes between the internal sphincter and the subcutaneous part of the external sphincter to reach the lining of the anal canal at the white line, being called the *anal intermuscular septum*, and that it produces the *anal intersphincteric groove* referred to above. Other investigators (Wilde 1949; Goligher *et al.* 1955; Fowler 1957), however, point out that the longitudinal fibres in this position, compared with those penetrating through the subcutaneous part of the external sphincter, are too weak and scanty to warrant the name of anal intermuscular septum, and maintain that the intersphincteric groove is caused by the mass of muscle on each side of it (internal sphincter above, subcutaneous external sphincter below), as well as by contraction of the subcutaneous external sphincter. In the submucosa of the anal canal below the level of the anal sinuses there is a well-marked layer composed of nonstriated muscle, yellow elastic fibres and connective tissue. These fibres are derived mainly from strands of the conjoint longitudinal coat of the anal canal which pass inwards and downwards between bundles of the internal sphincter (**8**.124C). Some of the strands end inferiorly by passing laterally around the lower edge of the internal sphincter to join the main longitudinal coat. The majority, however, continue downwards and laterally, superficial to the subcutaneous part of the external sphincter, to be attached to the corium of the skin from the level of the white line to well beyond the anus. These fibres produce the corrugation of the skin characteristic of this region and constitute the so-called *corrugator cutis ani muscle*. It has been claimed (Wilde 1949) that these fibres are exclusively yellow elastic fibres, although others (Goligher *et al.* 1955) have noted the presence of nonstriated muscle fibres among them. Another investigator (Fowler 1957) who failed to find muscle fibres in this site suggested that the puckering of the perianal skin is due to the combined effects of levator ani pulling on the longitudinal coat and the tone of the subcutaneous external sphincter.



A *muscularis mucosae* has been described in the anal canal immediately above the pectinate line and possibly extending below it (Jit 1974).

Between the subcutaneous external sphincter and the skin of the anal canal lies the inferior part of the internal rectal venous plexus; veins connect the external and internal rectal plexuses and thus establish connexions between the portal and systemic venous systems. The radiating elastic septa end below by breaking up into a network which subdivides the narrow interval between the subcutaneous external sphincter and the skin into a compact honeycomb; this arrangement accounts for the severe pain produced by collections of pus or blood which may occur in this region and for the localization of a haemorrhage following the rupture of a vein of the external rectal plexus. The submucosa above the white line, containing the superior part of the internal rectal venous plexus, is known as the *submucous space*, while that below the white line, containing the inferior part of the internal rectal plexus, is the *perianal space*. These two spaces are separated by the dense submucous layer of nonstriated muscle and connective tissue referred to above, which is especially well marked for a short distance below the anal valves.

It has been concluded (Fowler 1957) that the anal canal proper extends between two readily palpable muscular landmarks, namely, the *anorectal ring* above and the *intersphincteric ring* below. In the relaxed state the lower border of the internal sphincter and the intersphincteric groove lie at the anal orifice, the subcutaneous external sphincter being lateral to the orifice, and it is only when the external sphincter contracts that it becomes withdrawn to surround the lower part of the 'apparent' anal canal.

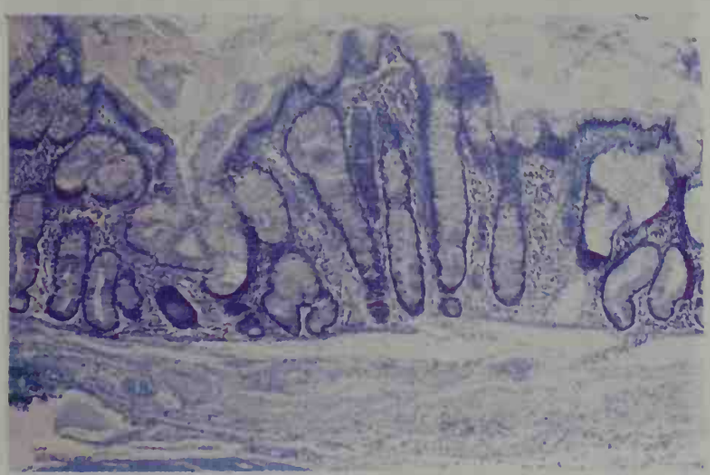
At the anorectal junction the puborectalis, deep external sphincter and internal sphincter collectively form the *anorectal ring* of muscle, which can be felt by a finger in the anal canal; surgical division of the ring results in rectal incontinence. The anterior part of the ring is not so well marked, since relatively few fibres of the puborectalis pass in front of the anorectal junction, most of the fibres of this muscle forming a sling which loops round the sides and back of the gut at this site, slinging the anorectal junction forwards towards the pubis.

Correlated with the *dual development* of the anal canal, the part above the anal valves being derived from the endodermal cloaca and the part below from the ectodermal proctodeum (p. 202), the following facts may be noted. In the *ectodermal part*, the lining is skin which is supplied by spinal nerves (inferior rectal nerve), the

8.125 Diagrams of the disposition of the major regions of the large intestine, the micro-architecture and histology of the colonic wall, and the ultrastructure of its epithelial cells. Note aggregations of lymphocytes (shown in yellow), and undifferentiated epithelial cells (shown in white).

arterial blood supply is from the inferior rectal artery, the venous drainage is by the inferior rectal vein which passes to the internal pudendal vein (a systemic vein), and the lymphatics drain with those of the perianal skin into the superficial inguinal lymph nodes. In the *endodermal part*, the mucous membrane is supplied by autonomic nerves, the arterial blood supply (Griffiths 1961) is mainly from the superior rectal artery, the venous drainage is by the superior rectal vein which continues as the inferior mesenteric vein (a tributary of the portal venous system), and the lymphatics drain with those of the rectum (p. 795). In cases of obstruction of the portal venous system, the collateral circulation opened up by the anastomosis between the portal and systemic veins in the anal canal may result in the dilatation of these veins. The different nerve supply of the two parts is correlated with a response to different types of stimuli; the lower part is very sensitive and responds to touch, pain and thermal stimuli like skin in general; the upper part, like the gut, has a high threshold for the above stimuli and responds more readily to increase in tension. The effects of the difference in the innervation of the two parts of the anal canal are seen in cases of haemorrhoids (varicosities in the anal canal) which may be covered with skin in their lower parts and mucous membrane in their upper parts; in injection to cause thrombosis in such distended veins, the needle is inserted into the insensitive upper part and not into the very sensitive ectodermal part. Fissure *in ano* (tearing of the anal valves) is very painful, because it involves the lower sensitive part of the anal canal.

RECTAL EXAMINATION



On inserting the index finger through the anal orifice, it is first grasped by the subcutaneous part of the external sphincter, and then, higher up in the anal canal, by the internal sphincter, the superficial and deep parts of the external sphincter and the puborectalis; beyond this, it may reach the inferior (or even the middle) transverse rectal fold. Many of the structures related to the anal canal and lower part of the rectum may be felt through the walls of these parts of the gut.

In the male, through the anterior rectal wall, the bulb of the penis and (particularly if a catheter is placed in the urethra) the membranous part of the urethra are first identified, and then, about 4 cm above the anus, the prostate can be felt; beyond this the seminal vesicles (if enlarged) and the base of the bladder (especially if the viscus is distended) may be recognized. Posteriorly, the pelvic surfaces of the lower part of the sacrum and the coccyx may be palpated. Laterally, the ischial spine, ischial tuberosity and (if enlarged) the internal iliac lymph nodes may be felt. Pathological thickening of the ureters, swellings in the ischiorectal fossae and abnormal contents of the rectovesical peritoneal pouch may also be detected.

In the female, the uterine cervix can be palpated through the anterior wall of the rectum (and, for example, its degree of dilatation during childbirth determined), and pathological conditions which cause tenderness or changes of shape, size, consistency or position of the ovaries, uterine tubes, broad ligaments and recto-uterine pouch may be detected. In both sexes tenderness of an inflamed vermiform appendix can be elicited, if that organ occupies a pelvic position.

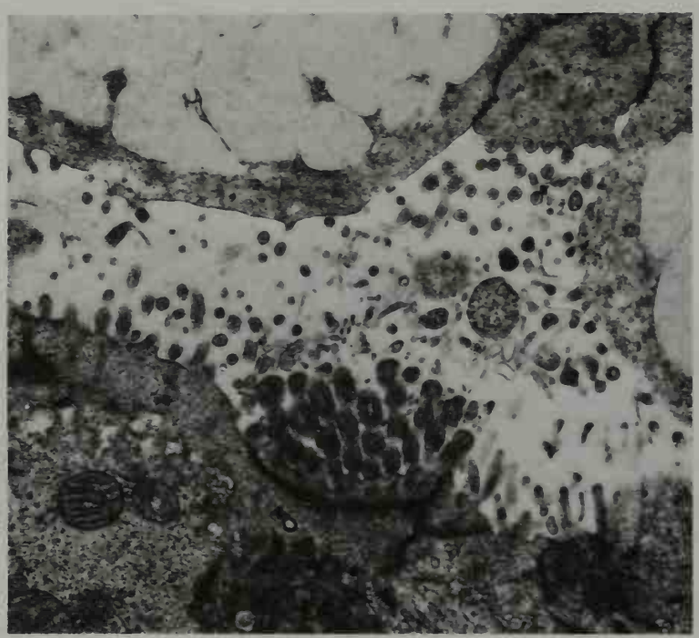
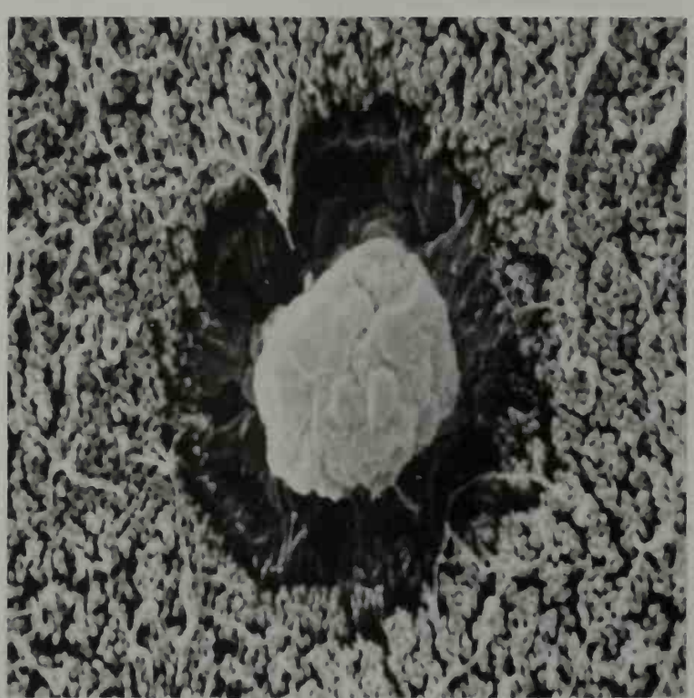
8.126B Medium power light micrograph of human large intestinal mucosa showing crypts containing goblet cells. Stained with haematoxylin and eosin. (Material kindly provided by Dr. J. Heaton; prepared and photographed by Mr. Stephen Sitch, Department of Anatomy, Guy's Hospital Medical School, London.)



THE RECTAL FASCIAE AND 'SPACES'

Various parts of the pararectal pelvic fascia are composed of loose connective tissue, whilst others are more dense, with particular orientations and attachments. The latter are often considered as mechanical 'supports' for the rectum, and their surgical division is necessary to produce mobilization of the organ. From the anterior surface of the lower part of the sacrum a stout avascular condensation of fascia passes forwards to the posterior aspect of the anorectal junction; it is known as the *fascia of Waldeyer*. The fascia around the middle rectal vessels passes from the posterolateral wall of the lesser pelvis (at the level of the third sacral vertebra) to the rectum, constituting on each side the *lateral ligament of the rectum*. Anteriorly the fascia between the rectum and the seminal vesicles and prostate (the *rectovesical fascia*, p. 1421) is more loosely attached to the latter structures than to the rectum, and in surgical excision of the rectum this fascia is separated along the plane between it and the prostate and seminal vesicles.



In addition to the ischiorectal fossae (p. 561), the following *spaces* of surgical importance are described in relation to the rectum and anal canal. The *pelvirectal space* comprises the loose extraperitoneal connective tissue above the levator ani; it is divided into anterior and posterior regions by the *lateral ligaments of the rectum*. The *submucous space* of the anal canal lies between the mucous membrane of the canal (above the white line) and the internal sphincter, and contains the superior part of the internal rectal venous plexus and lymphatics; above, it is continuous with the rectal submucosa, and below with the *perianal space* (*see* p. 1358); the lateral part of which is bounded above by the most lateral of the radiating elastic septa that pass through the subcutaneous external sphincter; the latter septum divides the ischiorectal fossa into an upper main space containing coarsely

A

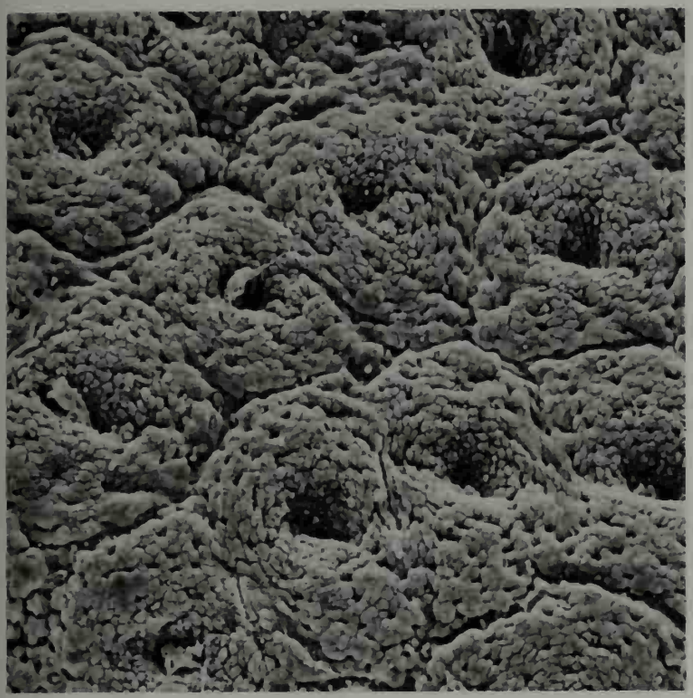
B

C

lobulated fat and a lower perianal space which contains finer and more compact fat. The perianal space contains the subcutaneous external sphincter, the external rectal venous plexus and the terminal branches of the inferior rectal vessels and nerves. Owing to the arrangement of the radiating septa passing through the subcutaneous external sphincter, pus in the perianal space tends to spread to the anal canal at the white line or to the surface of the perianal skin rather than to the main part of the ischiorectal fossa. Since the perianal space surrounds the lower part of the anal canal, pus on one side may spread round the canal in the space.

STRUCTURE OF THE LARGE INTESTINE

The tissue layers in the wall of the large intestine are the same as in the small intestine.



The *serosa* or *visceral peritoneum* invests the different regions of the large intestine to a variable extent. In the course of the colon the peritoneum is thrown into a number of small pouches filled with fat, the *appendices epiploicae*; they are most numerous on the sigmoid and transverse colon, but absent on the rectum. Beneath the peritoneum lies a subserous layer of loose connective tissue.

The *muscularis externa* consists of an outer longitudinal and an inner circular layer of nonstriated muscle fibres.

The *longitudinal fibres* form a continuous layer over the surface of the large intestine (Hamilton 1946), but in certain situations this layer is thickened to form conspicuous longitudinal bands, termed *taeniae coli*, and in the intervals between them the longitudinal coat is less than half the thickness of the circular coat. In the caecum and colon three taeniae are present, ranging from 6 to 12 mm in width in different individuals. One (the *taenia libera*) is placed anteriorly on the caecum, ascending, descending and sigmoid colon, but is placed inferiorly on the transverse colon; the second (the *taenia mesocolica*) is situated on the posteromedial surface of the caecum, ascending, descending and sigmoid colon, but posteriorly on the transverse colon, at the site of attachment of the transverse mesocolon; the third (the *taenia omentalis*) is placed posterolaterally in the caecum, ascending, descending and sigmoid colon, but is situated on the anterosuperior surface of the transverse colon, at the site where the posterior (ascending) layers of the greater omentum meet this part of the large intestine. These bands are said to be shorter than the other coats of the intestine, and may produce the sacculi or haustrations which are characteristic of the caecum and colon; accordingly, when they are dissected off, the tube can be lengthened, and its sacculated character becomes lost. In the descending colon the taeniae increase in thickness at the expense of the rest of the longitudinal coat, and on the sigmoid colon this coat undergoes a real increase in its total bulk. In the sigmoid colon the longitudinal fibres become more scattered; round the rectum they spread out and form a layer, which completely encircles this portion of the gut, but is thicker on the anterior and posterior surfaces, so that an anterior and a posterior broad band can be recognized. At the rectal ampulla, a few strands of the anterior longitudinal fibres pass forwards to the perineal body (p. 562); they constitute the *recto-urethralis muscle*. In addition, two fasciculi of nonstriated muscle arise from the front of the second and third coccygeal vertebrae, and pass downwards and forwards to blend with the longitudinal muscular fibres on the posterior wall of the anal canal. These are known as the *rectococcygeal muscles* (Wesson 1951).

The *circular fibres* form a thin layer over the caecum and colon, being especially accumulated in the intervals between the sacculi; in the rectum they form a thick layer, and in the anal canal they

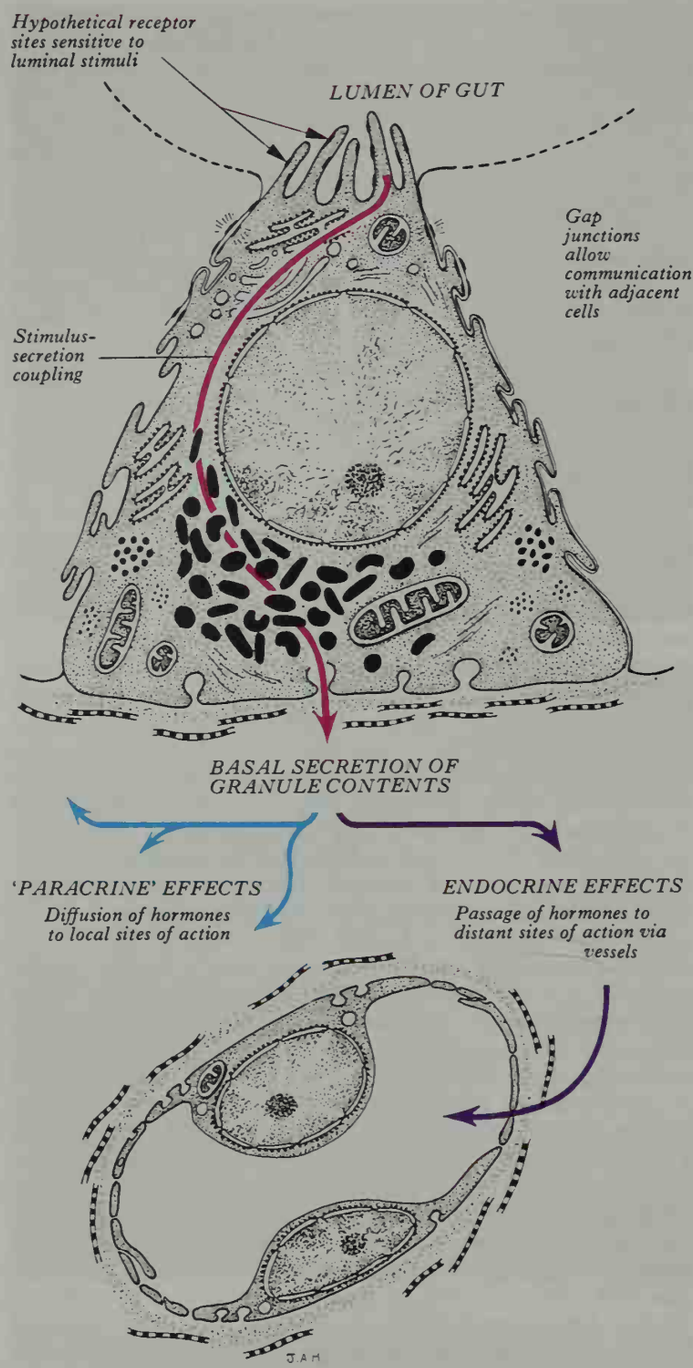
become numerous, and constitute the sphincter ani internus. Older observations, which recorded an interchange of fascicles of muscle fibres between the circular and longitudinal layers, have amply been confirmed in a study covering 112 post-mortem cadavers (from early fetal life to 88 years). By microdissection and histological sampling, interchanges of fibres, especially near the taenia coli, were observed to be commonplace. The deviation of longitudinal fibres from the taenia towards the circular layer may, in some instances, account for the haustration of the colon (Pace 1968).

The *submucosa* and *muscularis mucosae* are similar to those of the small intestine.

The *mucous membrane* of the caecum and colon is pale, smooth, destitute of villi, and raised into numerous crescentic folds which correspond with the intervals between the sacculi; that of the rectum is thicker, of a darker colour, more vascular, and connected more loosely with the muscular coat. The *epithelium* of the caecum, colon, and upper rectum consists of scattered mucus-secreting (goblet), columnar absorptive (Pittman and Pittman 1966) and M cells (p. 1354). Epithelium also lines the walls of the intestinal glands which are numerous and provide a large surface area for mucus secretion and absorption of water, salts and other materials; these functions are important in providing lubrication for the passage of faeces, and in resorbing many of the substances secreted into the alimentary canal in the buccal cavity, stomach and small intestine. The large intestine also provides an environment for a large bacterial flora; in many animals intestinal bacteria, in addition to being of digestive importance, metabolize essential organic compounds which supplement the vitamin intake in the normal diet. The columnar cells, which carry microvilli on their luminal surfaces, show junctional complexes at the luminal ends of their lateral borders, and their cytoplasm contains a subapical terminal web and the usual cytoplasmic organelles. Many of them also contain secretory granules in their apical cytoplasm. The secretion provided by such cells appears to be mucoid in nature, but is also rich in antibodies of the IgA group (p. 62) which provide a measure of protection against invasion by micro-organisms (Schofield and Atkins 1970). Other columnar cells posses an apical tuft of particularly long microvilli (**8.127**A, B), and have been suggested as a type of sensory ending (Silva 1966).



The *glands* of the large intestine are minute tubular prolongations of the mucous membrane arranged perpendicularly to its surface; they are longer, more numerous, and placed in much closer apposition than those of the small intestine; they open by minute orifices upon the surface (**8.128**), giving it a cribriform appearance. As mentioned above, each gland is lined with short columnar epithelium, the majority of the cells being goblet cells (**8.126**), between which lie columnar absorptive cells.

The *solitary lymphoid follicles* of the large intestine are most abundant in the caecum and vermiform appendix, but are irregularly scattered over the rest of the large intestine also. They are similar to those of the small intestine, and they have epithelial M cells, specialized for antigenic transport, associated with them (Owen and Nemanic 1978).

VESSELS AND NERVES OF THE LARGE INTESTINE

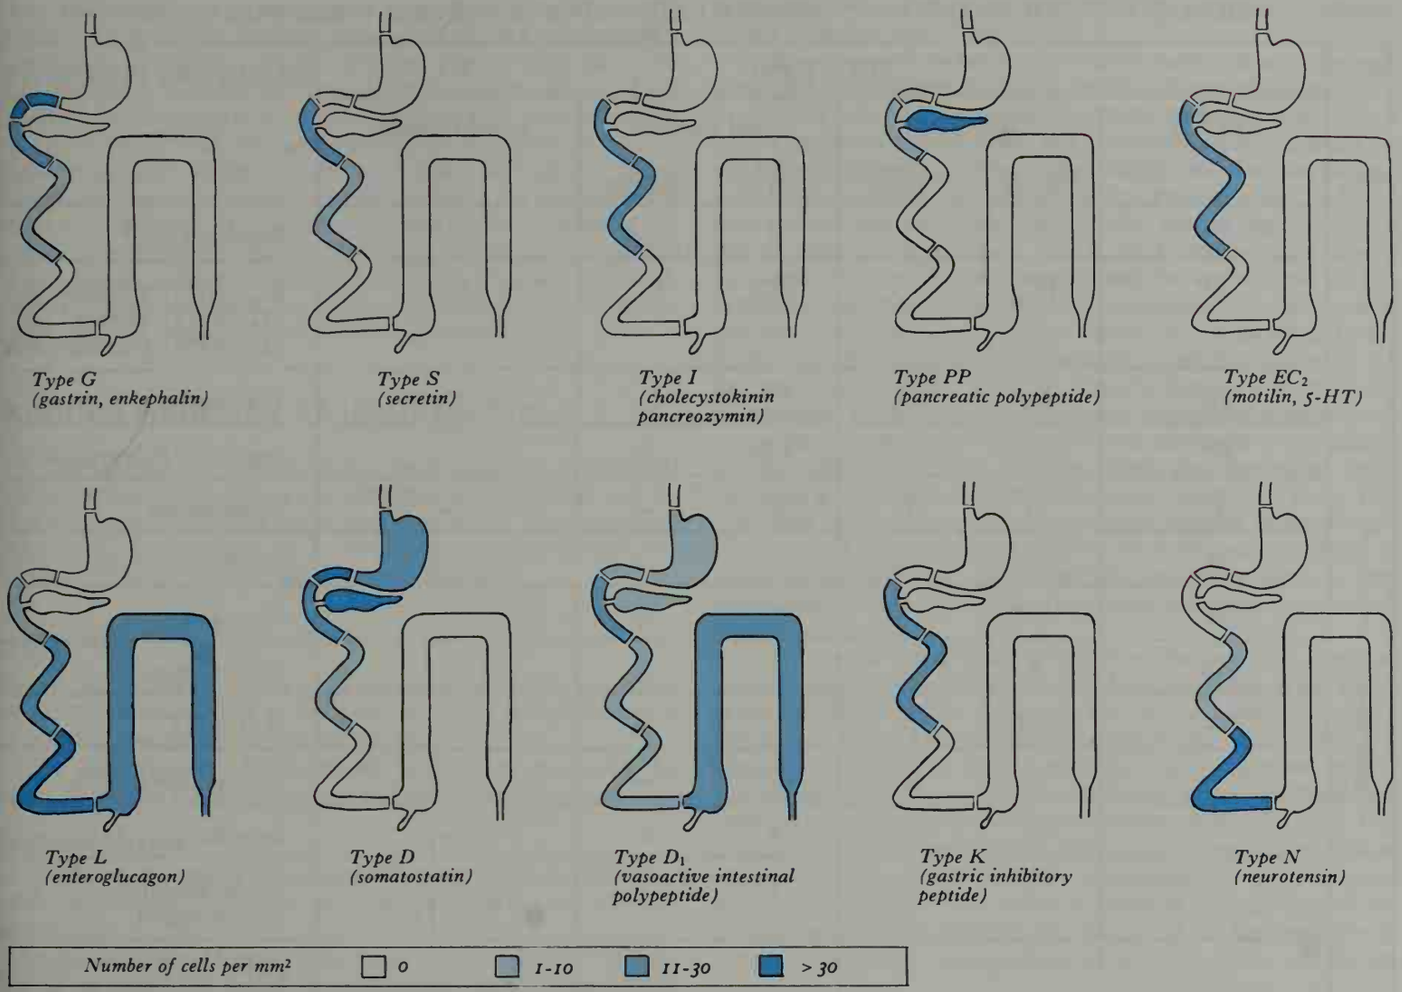
The *arteries* which supply the part of the large intestine developed from the mid-gut (caecum, appendix, ascending colon, right two-thirds of transverse colon) are derived from the colic branches of the superior mesenteric artery; those supplying the left part of the transverse colon, descending colon, sigmoid colon, rectum and upper half of the anal canal (hindgut derivatives) are the inferior mesenteric artery (and its terminal branch, the superior rectal) and the middle rectal artery. They give off large branches, which ramify between and supply the muscular coats, and after dividing into small vessels in the submucous tissue pass to the mucous membrane. The arteries of the rectum and anal canal are (*a*) the superior rectal artery (the continuation of the inferior mesenteric), which is the chief artery of the rectum; this divides into two branches that run down, one each side of the rectum, and break up into terminal branches that pierce the muscular coat and pass in the submucosa of the rectum and thence in the anal columns as far as the anal valves, where they form looped anastomoses; (*b*) the middle rectal arteries, which run in the 'lateral ligaments of the rectum' to supply the muscle coats of the lower part of the rectum and anastomose with each other but only form poor anastomoses with the superior and inferior rectal arteries; (*c*) the inferior rectal arteries, which supply the internal and external sphincters, the anal canal below the anal valves, and the perianal skin; (*d*) the median sacral artery, which supplies the posterior wall of the anorectal junction and of the anal canal. The *veins of the large intestine* are the superior and inferior mesenteric veins, which drain the same parts of the large intestine as are supplied by the corresponding arteries. The veins of the rectum and anal canal are (*a*) the superior rectal veins, which commence from the internal rectal plexus in the anal canal and pass up in the rectal submucosa in the form of about six vessels of considerable size, to pierce the muscular wall of the rectum about 7.5 cm above the anus and unite to form a single trunk, the superior rectal vein, which is continued as the inferior mesenteric vein; (*b*) the middle rectal veins, which begin in the submucosa of the rectal ampulla and drain chiefly the muscular walls of this part of the rectum; (*c*) the inferior rectal veins, which begin from the external rectal plexus and drain the lower part of the anal canal.

The *nerve supply of the large intestine* (exclusive of the lower half of the anal canal) is derived from the sympathetic and parasympathetic systems. The caecum, appendix, ascending colon and the right two-thirds of the transverse colon (all derivatives of the midgut) have their sympathetic supply from the coeliac and superior mesenteric ganglia, and their parasympathetic supply from the vagus; in each case the nerves are distributed to the gut in the plexuses around the branches of the superior mesenteric artery. The left third of the transverse colon, descending colon, sigmoid colon, rectum and upper half of the anal canal (derivatives of the hindgut) derive their sympathetic supply from the lumbar part of the trunk and the superior hypogastric plexus by means of the plexuses on the branches of the inferior mesenteric artery. The sympathetic supply of the colon is largely vasomotor in function. The parasympathetic supply to this part of the gut is derived from the pelvic splanchnic nerves (nervi erigentes). From these latter, fibres pass to the inferior hypogastric plexuses to supply the rectum and upper half of the anal canal: in addition, some fibres pass up uninterruptedly through the superior hypogastric plexus to be distributed along

8.129A Diagram showing the ultrastructure and possible modes of action of an entero-endocrine cell.

the inferior mesenteric artery to the transverse, descending and sigmoid colon (p. 1356). Further, branches from the pelvic splanchnic nerve pass up on the posterior abdominal wall behind the peritoneum, independently of the inferior mesenteric artery, to be distributed directly to the left colic flexure and descending colon (Mitchell 1953). The ultimate distribution in the gut wall is similar to that in the wall of the small intestine (p. 1350). A study of the adrenergic and cholinergic activity in the nerve supply of the taenia coli, coupled with observations on the distribution of nerve fibres, suggests that (in the guinea-pig) few muscle cells are directly innervated, propagation of activity being chiefly through the 'electrical synapse' type of intercellular contact (Bennett and Rogers 1967).

The sympathetic nerves to the rectum and upper part of the anal canal pass mainly along the inferior mesenteric and superior rectal arteries and partly via the superior and inferior hypogastric plexuses, the latter supplying the lower part of the rectum and the internal sphincter. The parasympathetic supply from the pelvic splanchnic nerve passes forwards as long strands (about 3 cm long) from the sacral nerves to join the inferior hypogastric plexuses on the sides of the rectum, being motor to the musculature of the rectum and inhibitory to the internal sphincter. The external sphincter ani is supplied by the inferior rectal branch of the pudendal nerve (S. 2, 3) and the perineal branch of the fourth sacral nerve (p. 1115). In surgical excision of the rectum, the dissection is kept close to the rectal wall, otherwise these nerves may be damaged, with consequent dysfunction of the bladder and, in the male, impotence resulting from failure of erection of the penis. Afferent impulses underlying sensations of physiological distension are conveyed by the parasympathetic nerves, while pain impulses are conducted by both the sympathetic and parasympathetic nerves supplying the rectum and upper part of the anal canal. In the condition of *aganglionosis* of the colon (*megacolon*) there is commonly a marked reduction or complete absence of (postganglionic) autonomic neurons in the wall of the organ (Bodian *et al.* 1961; Bodian 1966; Soltero-Harrington *et al.* 1969). Garrett *et al.* (1969) have studied the myenteric plexus and its ganglion cells by electron microscopy and histochemical techniques for transmitter substances. They found that in cases of megacolon there is not only a variable diminution, amounting sometimes to absence, of ganglion cells, but that there is also a failure of innervation of the muscle layers, even when ganglionic neurons are present.



The *lymph nodes and vessels* of the large intestine are described on p. 795.

The Gastro-entero-pancreatic Endocrine System

The gastro-entero-pancreatic (GEP) endocrine system (Fujita 1973) consists of the scattered, frequently solitary, hormone-

producing cells of the stomach, intestine and pancreas. The application of electron microscopy to ultra-thin (0·07 μm) sections and of immunocytochemical techniques to adjacent semi-thin (1 μm) sections of resin-embedded tissue has led to the identification of a wide range of GEP endocrine cell types and their secretory products (*see* p. 1366). Of the fifteen specific cell types so far recognized in man, only one (type B) is restricted to the pancreatic islets, and at least three are distributed in both the gastro-intestinal mucosa and the pancreas.

The ultrastructure of human GEP endocrine cells has been described in detail by Rubin (1972), Sasagawa *et al.* (1973), Capella *et al.* (1976) and Cavallero *et al.* (1976) and summarized by Solcia *et al.* (1978). The gastric and intestinal endocrine cells are scattered in the epithelium lining the lumen and glands of the gut, lying with their bases resting on the basal lamina. As a rule, those of the oxyntic mucosa do not extend as far as the lumen of the gut and are referred to as 'closed', while most of those of the pyloric and intestinal mucosae do and are referred to as 'open'. Their osmiophilic secretory granules vary characteristically in shape, size and ultrastructure in the different cell types and are generally infranuclear in position, while the Golgi complexes are supranuclear; the luminal aspects of cells of the 'open' type are covered with microvilli of variable number, length and shape. Typical entero-endocrine cells are shown in Fig. **8.**129A, B. Human *P cells* contain very small (100–140 nm mean diameter) secretory granules with a slight reactivity to Grimelius' silver (Capella *et al.* 1977); they are rare in normal adult tissues, and possibly contain a bombesin-like polypeptide (Polak *et al.* 1976). *EC cells*, which contain osmiophilic, argentaffin, Grimelius' silver-reactive granules, are sub-divided into three types, termed EC_1, EC_2 and EC_n; in addition to storing 5-hydroxytryptamine, the EC_1 cells store substance P (Heitz *et al.* 1977), the EC_2 cells store motilin (Polak *et al.* 1975), and the EC_n cells an as yet unidentified material. The *D_1 cells* contain granules which are argyrophilic and about 140–190 nm in diameter (Capella *et al.* 1977); they store a vaso-active intestinal peptide-like material. The *PP cells*, which occur commonly in the pancreatic islets and rarely in the exocrine pancreas, store pancreatic polypeptide in granules of 150–170 nm mean diameter; they are equivalent to the F cells identified in other mammals (Baetens *et al.* 1976). Human *D, B* and *A cells* are described in detail in the section on the endocrine pancreas (p. 1371). *X cells* have been described in the human oxyntic mucosa by Solcia *et al.* (1977); their function is as yet unknown. Human *ECL cells* (Vassallo *et al.* 1971) store an amine with reducing powers, possibly 5-hydroxytryptamine, in granules with an intensely argyrophilic core; histamine many also be present. Human *G cells* (Vassallo *et al.* 1971) manufacture gastrin, and possibly enkephalin (Polak *et al.* 1978), and have slightly argyrophilic granules with floccular contents. The *S cells* (Capella *et al.* 1976) are scattered in the duodenojejunal mocosa and produce secretin (Larsson *et al.* 1977); they are structurally similar to D_1 cells but differ in their secretory product. Human *I cells* (Capella *et al.* 1976) are most common in the duodenum and jejunum, occurring only rarely in the ileum; they are the source of cholecystokinin-pancreozymin (more correctly, pancreaticozymin) (Buchan *et al.* 1977). Human *K cells* (Capella *et al.* 1976) contain large granules (approximately 350 nm in diameter) with osmiophilic, argyrophobic cores; like the I cells, they are most common in the duodenum and jejunum. K cells produce gastric inhibitory peptide. *N* and *L cells* are difficult to distinguish cytologically in man; the granules of the N cells are, however, generally homogeneous and about 300 nm in

Abbreviations used for secretory products:
5-HT = 5-hydroxytryptamine
VIP = Vaso-active intestinal peptide
H = Histamine
GIP = Gastric inhibitory peptide
GLI = Glicentin

(Based mainly on the Lausanne 1977 classification of gastro-entero-pancreatic endocrine cells reported by Solcia *et al.* in 1978).

diameter, while those of the L cells sometimes have argyrophilic cores and tend to be somewhat smaller (about 260 nm in diameter). The N cells produce neurotensin (Orci *et al.* 1976) while the L cells produce enteroglucagon or glicentin.

The concentration of endocrine cells in the gastro-intestinal mucosa is very low and generally decreases progressively in an aboral direction. This is illustrated diagrammatically in Fig. 8.129c.

The GEP endocrine cells have certain common features which allow them to be classified in a variety of other ways. They are all able to produce peptides and/or amines active as hormones or as neurotransmitters, and are all derived from neuro-endocrine-programmed cells of ectoblastic origin. As such they belong to the *APUD cell series* (Pearse 1968; Pearse 1977; Pearse and Polak 1978) and modulate not only the actions of the autonomic nervous system but also of each other. The APUD concept is described in more detail elsewhere (p. 1454). An intriguing finding, reported in recent years, of supposedly similar neurohormones and neurotransmitter-like peptides in the neurons of the brain and in some GEP endocrine cells, together with other neuron-like characteristics of the latter cells, has led to their designation as *paraneurons* (Fujita 1976). Peptides common to the brain and the gastro-intestinal mucosa include the following: substance P, somatostatin, vaso-active intestinal peptide, bombesin, neurotensin, cholecystokinin and the opiate-like enkephalin (Bloom and Polak 1978). The GEP endocrine cells are presumed to have receptor sites on their surfaces, adequate stimulation of which by 'secretogogues' triggers stimulus-secretion coupling (Kanno 1973) as in chromaffin cells (Douglas 1968); the GEP endocrine cells can thus also be termed *receptosecretory cells* (Fujita 1976).

There is still some doubt as to the mode of action of the endocrine cells restricted to the gastro-intestinal mucosa. It might be supposed, from their ultrastructure and proximity to blood capillaries, that their secretory products are endocrinal in action, exerting distant, diffuse effects after transportation in the blood. However, of the many products of these cells, only the following have been shown to act as circulating hormones: gastrin, secretin, cholecystokinin-pancreozymin, gastric inhibitory peptide, motilin and enteroglucagon (Bloom and Polak 1978). There are several fundamental differences between the endocrine cells of the gastric and intestinal mucosae and those of the endocrine system proper: they are not aggregated into glands, but are scattered among what may well be their local target cells; most are closely related to the lumen of the gut, allowing specialized regions of

their plasmalemmae to detect and respond to luminal stimuli directly; there are no common hyposecretory or hypersecretory syndromes; and the relationship between plasma hormone levels and functional response (modulation of the neural control of gut motility, for example) is not stoichiometric. It has been suggested (Wingate 1976) that the gastro-intestinal hormones may have local 'paracrine' as well as distant 'endocrine' effects; direct actions on gastro-intestinal smooth muscle, on neighbouring endocrine cells, on other enterocytes, and on the neurons of the gut are speculative but feasible. Although the gut can be regarded as the largest endocrine organ of the body (Pearse 1974) it is, perhaps, better to regard it as a region in which neural, paracrine and endocrine control of activity are intimately linked.

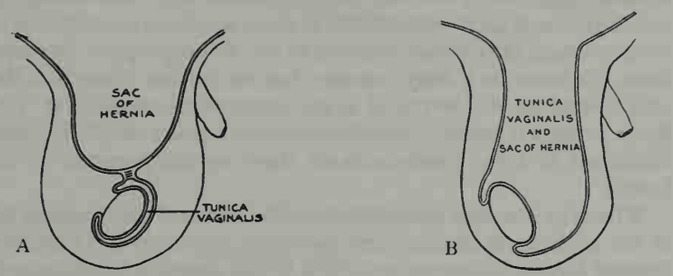
Applied Anatomy of the Intestine

The infrequency of rupture of the small intestine by external injury to the abdominal wall is attributable to its elasticity and the ease with which the coils glide over each other; the more fixed duodenum, particularly its horizontal part as it crosses the vertebral column, is more liable to such damage.

HERNIA

In external hernia the ileum is the intestinal part most frequently herniated. When a part of the large intestine is involved it is usually the caecum or the sigmoid colon.

The chief sites at which external hernia may occur are the inguinal region, the femoral canal and the umbilical region.



Inguinal Hernia

In this form, the viscus is protruded through the inguinal region of the abdominal wall. The two principal varieties are oblique, and direct.

In *oblique inguinal hernia* the intestine is protruded through the lateral inguinal fossa (which lies behind the deep inguinal ring). Here the herniated gut pushes before it a pouch of the parietal peritoneum and extraperitoneal areolar tissue. It enters the inguinal canal at the deep inguinal ring and becomes invested by the internal spermatic fascia which encloses the constituents of the spermatic cord. In passing along the canal it displaces upwards the arched fibres of the transversus abdominis and obliquus internus, receives a covering from the cremasteric fascia and muscle, and lies in front of the constituents of the spermatic cord. It emerges from the canal at the superficial inguinal ring and here becomes invested by the external spermatic fascia. Lastly, it descends into the scrotum, here receiving additional coverings from the superficial fascia and the skin. Such a herniated part of the gut may become constricted at the deep inguinal ring, with consequent interference with its blood supply (strangulation). In relieving the strangulation, the deep inguinal ring should be cut in an upward and lateral direction to avoid the inferior epigastric vessels. In most cases, the occurence of oblique inguinal hernia depends upon congenital defects in the processus vaginalis, the peritoneal pouch which precedes the descent of the testis (p. 217). Obliteration of the processus vaginalis may be complete at birth, or it may begin shortly before birth and be completed subsequently; the closure occurs first at the deep inguinal ring and at the top of the epididymis and gradually extends until the whole of the intervening portion is converted into a fibrous cord. Complete or partial failure of closure of the processus may occur, with consequent variations in the relation of the hernial protrusion to the testis and tunica vaginalis; e.g. where the processus is patent throughout, the herniated gut descends in front of the testis into the tunica vaginalis (complete congenital hernia), the processus and tunica vaginalis constituting the sac of the hernia. In incomplete congenital hernia (or hernia into the funicular process), the gut descends as far as the top of the testis, where the processus is sealed off from the tunica vaginalis (**8**.130). Although the above types of inguinal hernia are called congenital, the actual extrusion of the hernia into the pre-existing peritoneal sac may not take place until adult life and then be produced by such factors as increased intra-abdominal pressure or sudden muscular strain. (For recent critique of the anatomy of inguinal hernia consult Lytle 1979.)

In *direct inguinal hernia* the protrusion makes its way through some part of the inguinal triangle, which is bounded inferiorly by the medial half of the inguinal ligament, medially by the lower part of the lateral border of the rectus abdominis, and laterally by the inferior epigastric artery. The triangle overlies the medial inguinal fossa and part of the supravesical fossa (p. 1324). A direct hernia may pass either through (*a*) the medial inguinal fossa where only extraperitoneal tissue and transversalis fascia intervene between the peritoneum and the aponeurosis of the external oblique; or through (*b*) the supravesical fossa and the falx inguinalis (conjoint tendon) which lies in front of the fossa. In the former the hernial protrusion escapes from the abdomen on the lateral side of the conjoint tendon, pushes before it the peritoneum, extraperitoneal tissue and transversalis fascia, and enters the inguinal canal. It passes along nearly the whole length of the canal and finally emerges from the superficial ring, receiving an investment from the external spermatic fascia. The coverings of this form of hernia are similar to those of the oblique form, except that a portion derived from the general layer of transversalis fascia replaces the internal spermatic fascia, so that the hernia lies between the innermost and the middle covering of the spermatic cord.

In the second form, which is the more frequent, the hernia is either forced through the fibres of the falx inguinalis, or the falx is gradually distended in front of it so as to form a complete investment for it. The intestine then enters the lower end of the inguinal canal, escapes at the superficial ring, lying on the medial side of the cord, and receives additional coverings from the external spermatic fascia, the superficial fascia and the skin. The coverings of this form therefore differ from those of the oblique form in that the conjoint tendon is substituted for the cremaster, and the internal spermatic fascia is replaced by a portion of the general layer of the transversalis fascia. In all the varieties of inguinal hernia the most superficial covering is an investment from the external spermatic fascia and is identical with the outermost covering of the spermatic cord. An oblique inguinal hernia lies within the spermatic cord and shares all its coverings, but the covering which a direct hernia acquires from the transversalis fascia is distinct from the covering which the spermatic cord receives from that layer.

8.130A and B Diagrams representing varieties of oblique inguinal hernia. A Incomplete congenital. B Complete congenital.

Direct inguinal hernia is of much less frequent occurrence than oblique, and occurs more often in men than in women. The main differences in position between it and the oblique form are: (*a*) it is placed over the body of the pubic bone and not in the course of the inguinal canal; (*b*) the inferior epigastric artery runs lateral (*not* medial) to the neck of the sac; (*c*) the spermatic cord lies along its lateral and posterior sides, not directly behind it as in oblique inguinal hernia. A direct hernia is always of the acquired variety.

The seat of stricture in both varieties of direct hernia is usually found either at the neck of the sac or at the superficial ring. In that form which perforates the conjoint tendon it may occur at the edges of the fissure through which the gut passes. In all cases of inguinal hernia, whether direct or oblique, it is proper to divide the stricture upwards: by cutting in this direction the incision is made parallel to the inferior epigastric artery, and all chance of wounding the vessel is thus avoided.

Femoral Hernia

In femoral hernia the protrusion of the intestine takes place through the femoral ring (p. 725). This ring is closed by the femoral septum, a partition of modified extraperitoneal tissue; it is therefore a weak spot in the abdominal wall, especially so in the female, where the ring is larger, and where profound changes are produced in the tissues by pregnancy. Femoral hernia is therefore more common in women than in men.

When a section of the intestine is forced through the femoral ring, it carries before it a pouch of peritoneum which forms the hernial sac. It receives an investment from the extraperitoneal tissue (or femoral septum), and descends along the femoral canal as far as the saphenous opening; at this point it changes its course, being prevented from extending further down the sheath on account of the narrowing of the latter, its close contact with the vessels, and also the close attachment of the superficial fascia and femoral sheath to the lower part of the circumference of the saphenous opening. (See also p. 595.) The hernia is consequently directed forwards, pushing before it the cribriform fascia, and then curves upwards over the inguinal ligament and the lower part of the aponeurosis of the obliquus externus. While the hernia is contained in the femoral canal it is usually of small size, owing to the resisting nature of the surrounding parts, but when it escapes from the saphenous opening into the loose areolar tissue of the groin it becomes considerably enlarged. The direction taken by a femoral hernia is at first downwards, then forwards and upwards; in the application of taxis (manual pressure) for the reduction of a femoral hernia, therefore, pressure should be directed in the reverse order, and the thighs should be passively flexed in order that the greatest degree of relaxation may be obtained.

The coverings of a femoral hernia from within outwards are: peritoneum, femoral septum, femoral sheath, cribriform fascia, superficial fascia and skin. A fibrous investment (*fascia propria*) of a femoral hernia lies immediately external to the peritoneal sac but is frequently separated from it by some adipose tissue. Surgically it is important to remember the frequent existence of this layer on account of the ease with which an inexperienced operator may mistake the fascia for the peritoneal sac and the contained extraperitoneal fat for omentum, as there is often a great excess of subperitoneal fatty tissue enclosed in the 'fascia propria'. In many cases it resembles a fatty tumour, but on further dissection the true hernial sac will be found in the centre of the mass of fat. The fascia propria is merely a modified femoral septum which has been thickened to form a membranous sheet by the pressure of the hernia.

When the intestine descends along the femoral canal only as far as the saphenous opening the condition is known as *incomplete femoral hernia*, in contradistinction to the *complete hernia*, which has passed through the opening. The small size of the protrusion in the incomplete form of hernia renders it an exceedingly dangerous variety of the disease, from the extreme difficulty of detecting the existence of the swelling, especially in corpulent subjects.

The site of strangulation of a femoral hernia varies: it may be at the neck of the hernial sac; more often it is at the point of junction of the falciform margin of the saphenous opening with the free edge of the pectineal part of the inguinal ligament, or it may be at the margin of the saphenous opening. (*See*, however, comments on the 'lacunar ligament' on p. 552.) The stricture should in every case be divided in a direction upwards and medially for a distance of about 4 to 6 mm. All normally positioned vessels and other structures of importance in relation to the neck of the sac will thus be avoided. (However, an abnormal obturator artery may be imperilled by such an incision—see p. 721.)

The pubic tubercle forms an important landmark in serving to differentiate the inguinal from the femoral variety of hernia. The neck of the inguinal protrusion is above and medial to the tubercle, while the neck of the femoral protrusion is below and lateral to it.

Umbilical Hernia

There are three varieties of umbilical hernia.

(*a*) *Congenital umbilical hernia.* This variety is due to a failure of retraction of the umbilical loop of gut (p. 205).

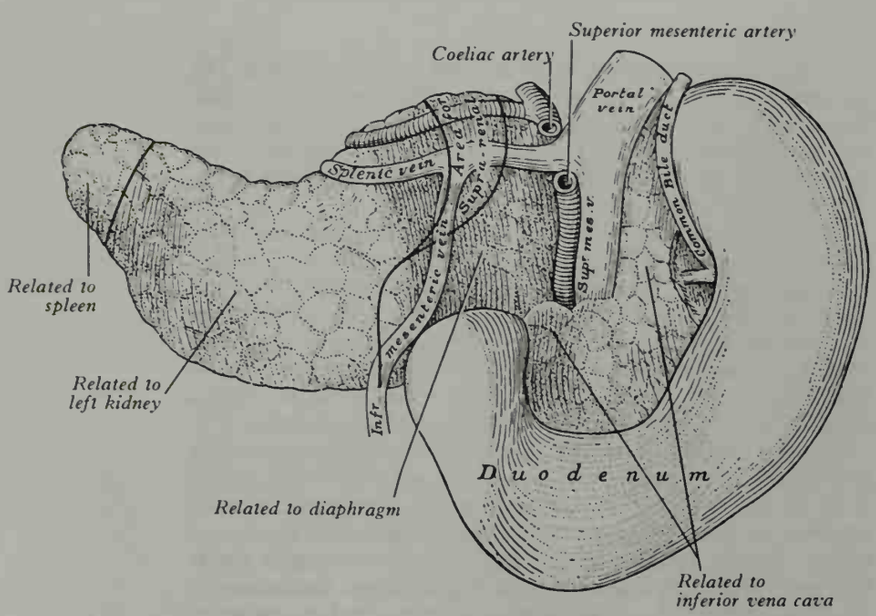
(*b*) *Infantile umbilical hernia.* This is due to stretching of the scar tissue in the umbilical region. It occurs usually within the first three years after birth and is associated with conditions causing increased intra-abdominal pressure.

(*c*) *Acquired umbilical hernia.* This variety really occurs through the linea alba, usually immediately above the umbilicus (para-umbilical hernia), and most frequently occurs in obese multiparous females.

Rarely, hernia may occur at other sites, e.g. through the *lumbar triangle* (p. 565), via the *obturator foramen*, the *greater* or *lesser sciatic foramen*, or the *ischiorectal fossa*. Occasionally *incisional hernia* may occur at the site of a scar following an abdominal operation, particularly if the wound becomes septic.

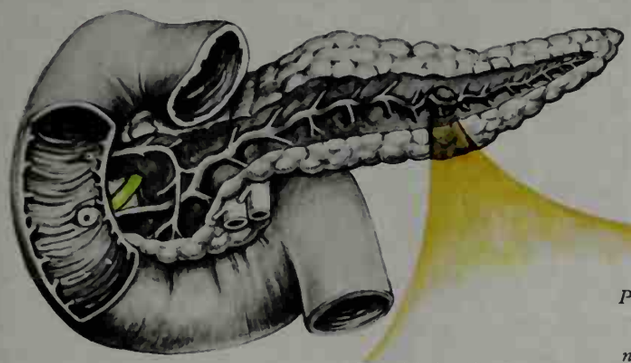
Both the small intestine and colon are subject to considerable variations, which may be of medical and surgical importance. Consult Goligher (1967), and Kanagasuntheram (1970) for details and literature.

The Pancreas



The pancreas is a soft, lobulated, greyish-pink gland, 12–15 cm long, extending nearly transversely across the posterior abdominal wall, behind the stomach, from the duodenum to the spleen. Its broad, right extremity is called the *head*, and is connected to the main part, or *body*, by a slightly constricted *neck*; its narrow, left extremity forms the *tail*. It passes obliquely to the left and slightly upwards, across the posterior wall of the abdomen, in the epigastric and left hypochondriac regions.

RELATIONS OF THE PANCREAS



The structures in close topographic relationship to the pancreas are considered systematically with respect to the head, neck, body and tail (*see* **8**.111, 131, 132).

The head, flattened from before backwards, is sited within the curve of the duodenum. Its upper border is overlapped by the superior part of the duodenum; the other borders are grooved to receive the adjacent margin of the duodenum, which they overlap in front and behind to a variable extent. Sometimes a small part of the head of the pancreas is actually embedded in the wall of the descending part of the duodenum. From the lower and left part of the head there is a prolongation, the *uncinate process*, which projects upwards and to the left behind the superior mesenteric vessels. In or near the groove between the duodenum and the right and lower borders of the head are the anastomosing superior and inferior pancreaticoduodenal arteries (pp. 713, 716; **6**.86).

the pancreas, the neck juts forwards, upwards and towards the left, to be continued into the body of the pancreas. The boundary between the head and neck, on the right side (and in front), is a groove for the gastroduodenal artery; on the left side (and behind) a deep notch intervenes between the head and the neck, and in it the superior mesenteric and splenic veins unite to form the portal vein. Below and to the right of the neck the anterior surface of the head is in contact with the transverse colon, only areolar tissue intervening, while still lower the surface is covered with peritoneum continuous with the inferior layer of the transverse mesocolon (**8**.98), and is in contact with a coil of the jejunum. The uncinate process is crossed anteriorly by the superior mesenteric vessels.

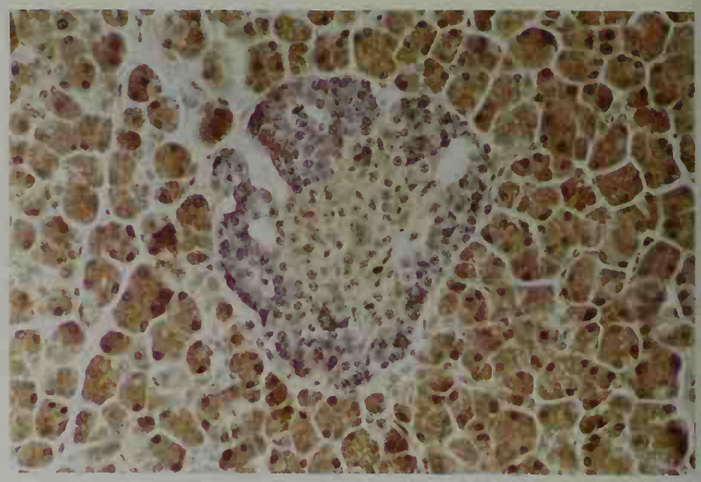
Posterior surface. The posterior surface of the head of the pancreas is related to the inferior vena cava, which runs upwards behind it and covers nearly the whole of this aspect. In addition, it is related to the terminal parts of the renal veins and the right crus of the diaphragm. The uncinate process passes in front of the aorta. The bile duct lies either in a groove on the upper and lateral part of the posterior surface of the head of the pancreas, or in a canal in its substance (p. 1383).

The neck, about 2 cm long, extends forwards, upwards and to the left from the head, and merges imperceptibly into the body. Its anterior surface is covered with peritoneum and adjoins the pylorus, part of the omental bursa intervening; the gastroduodenal and the anterior superior pancreaticoduodenal arteries descend in front of the gland at the right side of the junction of the neck with the head; its posterior surface is in relation with the superior mesenteric vein and the beginning of the portal vein.

The body is somewhat prismoid in section, and has three surfaces, generally termed anterior, posterior and inferior (although, more precisely, these surfaces are largely antero-superior, posterior and antero-inferior, and furthermore are obliquely set).

The *anterior surface* is concave, and is directed forwards and upwards; it is covered with peritoneum, which is continuous antero-inferiorly with the anterior of the two ascending layers of the greater omentum (**8**.97), and is separated from the stomach by the omental bursa. On reaching the level of the taenia mesocolica, the posterior of the two ascending layers of the greater omentum generally fuses with the anterosuperior surface of the transverse mesocolon, while the anterior layer continues upwards to the root of the mesocolon, and is then reflected superiorly over the anterior surface of the pancreas.

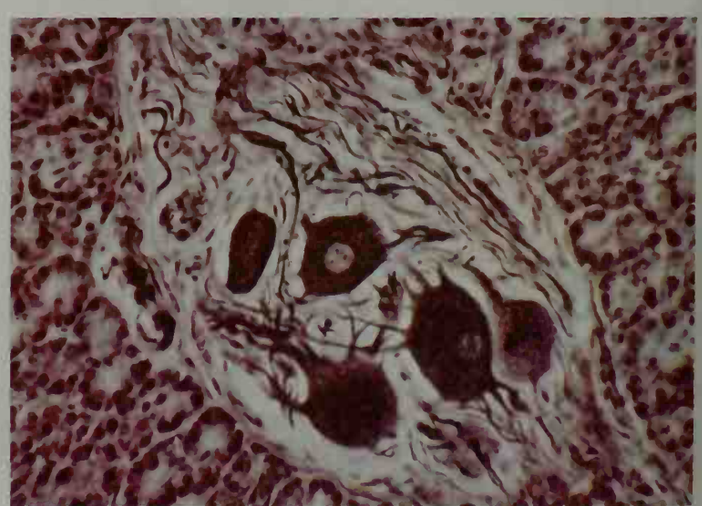
The *posterior surface* is devoid of peritoneum, and is in contact with the aorta and the origin of the superior mesenteric artery, the left crus of the diaphragm, the left suprarenal gland and the left kidney and its vessels, particularly the left renal vein. It is intimately related to the splenic vein, which courses from left to right and separates it from the structures mentioned. The left kidney is also separated from the pancreas by the perirenal fascia and fat.



The *inferior surface* is narrow on the right but broader on the left, and is covered with peritoneum of the postero-inferior layer of the transverse mesocolon; it lies upon the duodenojejunal flexure and on some coils of the jejunum; its left extremity rests on the left colic flexure.

The *superior border* is blunt and flat to the right; narrow and sharp to the left, near the tail. An *omental tuberosity* usually projects from the right end of the superior border above the level of the lesser curvature of the stomach, and is in contact with the posterior surface of the lesser omentum. It is in relation above with the coeliac artery, from which the common hepatic artery courses to the right just above the gland, while the splenic artery runs towards the left following a wavy course along this border.

The *anterior border* separates the anterior from the inferior surface, and along this border the two layers of the transverse mesocolon diverge from each other: one passing upwards over the anterior surface, the other backwards over the inferior surface.



The *inferior border* separates the posterior from the inferior surface: the superior mesenteric vessels emerge under its right extremity.

The tail of the pancreas is narrow, and usually lies in contact with the inferior part of the gastric surface of the spleen. It is contained within the two layers of the lienorenal (splenorenal) ligament together with the splenic vessels, to which it is closely related.

8.133A An islet of Langerhans and surrounding exocrine glandular tissue in the pancreas of a rhesus monkey, stained with orange G and aldehyde fuchsin. Within the islet, the B cells stain purple, whereas the A cells are pale yellow in colour. (Kindly provided by Dr. J. Henderson, Department of Physiology, Guy's Hospital Medical School.)

The main pancreatic duct traverses the pancreas from left to right, lying nearer its posterior than its anterior surface (**8**.132). It begins by the junction of the small ducts of the lobules situated in the tail of the pancreas, and, running from left to right through the body, receives the ducts of the various lobules composing the gland, the latter joining the main duct almost at right angles ('herringbone pattern'). Considerably augmented in size, it reaches the neck of the pancreas, and turning downwards, backwards and to the right, comes into relation with the bile duct, which lies to its right side. Together the two ducts pass obliquely into the wall of the descending part of the duodenum, and there unite to form a short dilated *hepatopancreatic ampulla* (or ampulla of the bile duct) (*see* p. 1383). The constricted distal end of this ampulla opens on the summit of the *major duodenal papilla*, which is situated within this part of the duodenum at the junction of its medial and posterior walls, from 8 to 10 cm distal to the pylorus. As a rule the two ducts do not unite until they approach very close to the opening on the major duodenal papilla. Sometimes the pancreatic duct and the bile duct open separately into the duodenum. Frequently there is an additional duct, which receives the ducts from the lower part of the head, and is known as the

Palmgren silver impregnation. (Kindly provided by Dr. J. Henderson, Department of Physiology, Guy's Hospital Medical School, London.)

accessory pancreatic duct (**8**.132). It runs upwards in front of the main pancreatic duct, to which it is connected by a communicating duct, and opens into the duodenum about 2 cm above and slightly ventral to the major duodenal papilla on a small rounded *minor duodenal papilla*. The terminal part of the accessory duct may fail to expand and the secretion from the lower part of the head of the pancreas is then diverted along the communicating duct into the main pancreatic duct. It is, however, usually fully patent (Dawson and Langmann 1961).

Surface Anatomy. The head of the pancreas lies within the curve of the duodenum. The neck lies in the transpyloric plane, behind the pylorus. The body passes obliquely to the left and slightly upwards for about 10 cm, its left part lying a little above the transpyloric plane. The tail lies a little above and to the left of the intersection of the transpyloric and left lateral planes.

PANCREATIC STRUCTURE

The pancreas is composed of two quite separate types of glandular tissue which are, however, in intimate topographic association with each other. The main mass of tissue is the *exocrine part* of the pancreas, embedded in which are clusters of *endocrine cells* constituting the *pancreatic islets*.

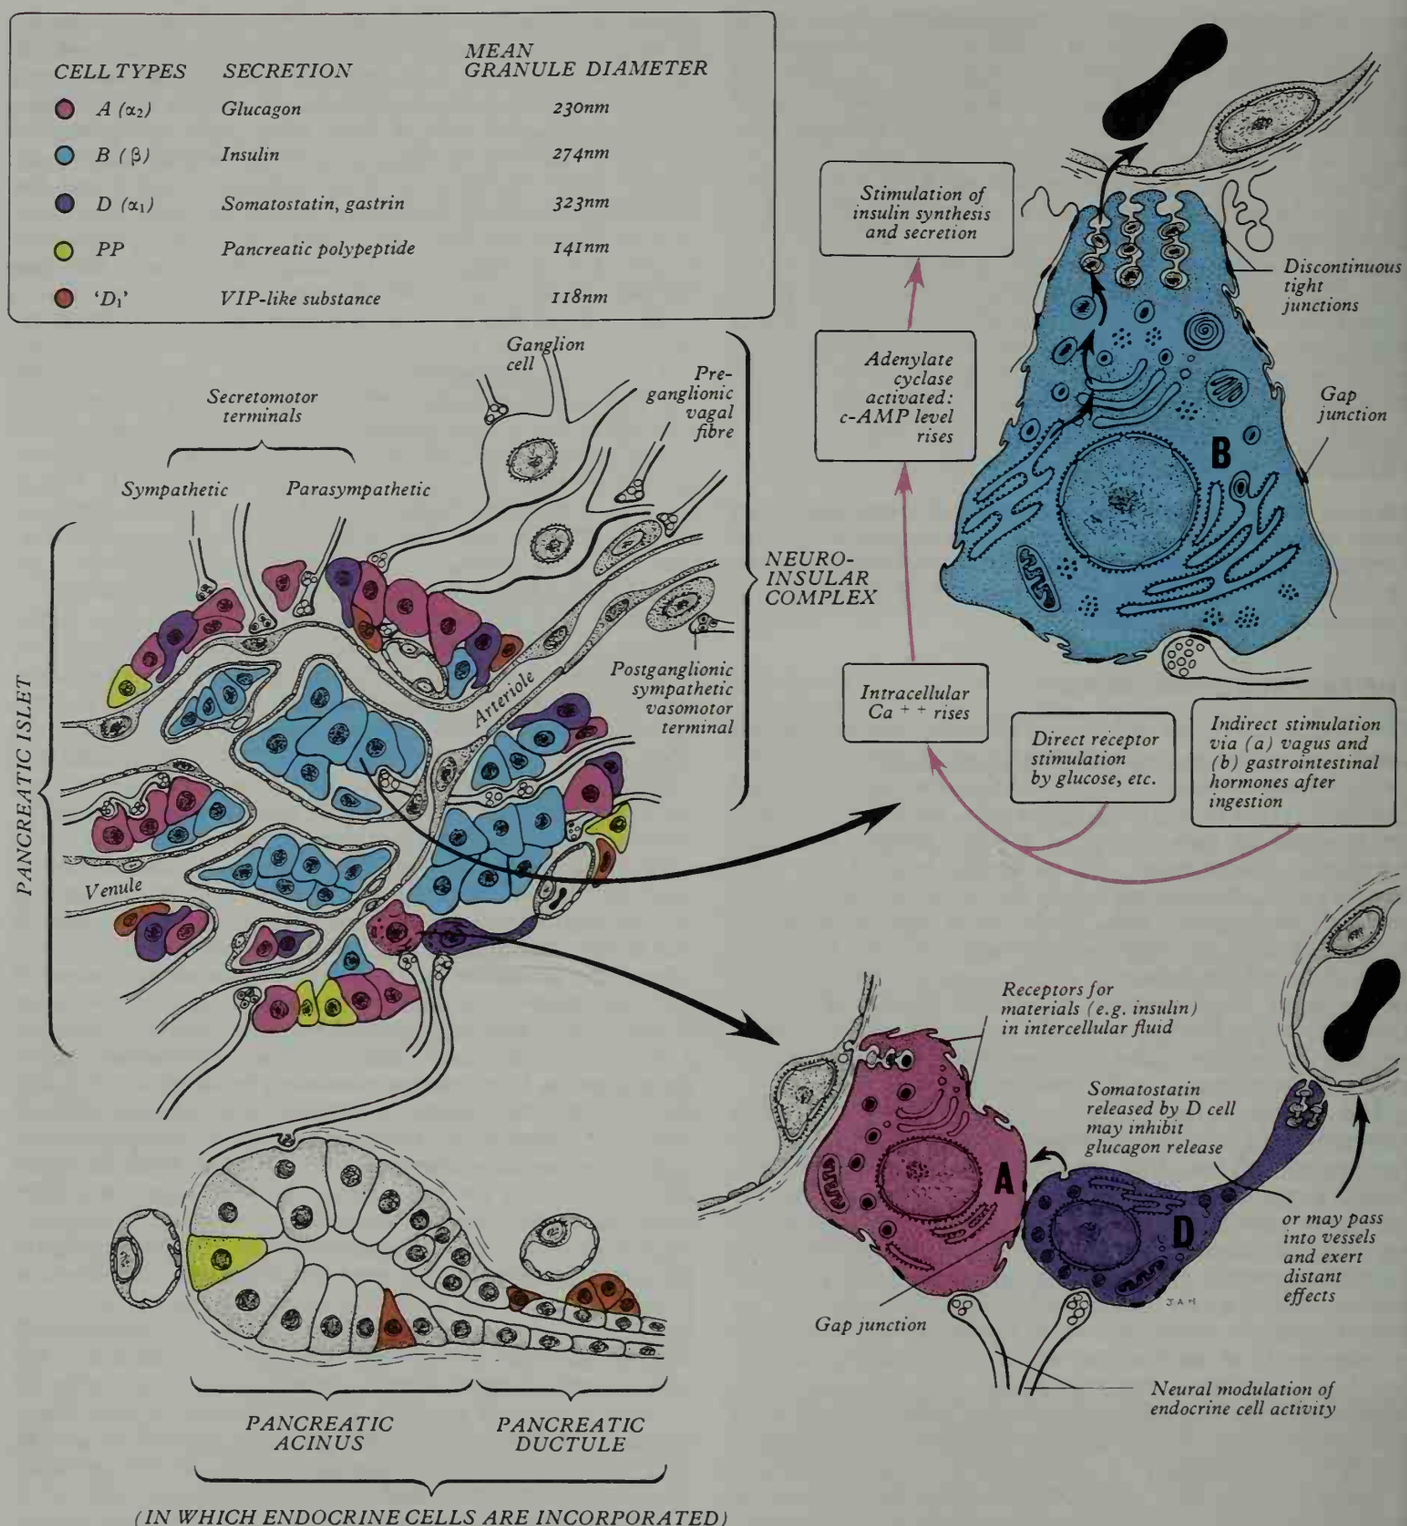
THE EXOCRINE PANCREAS

The exocrine part of the pancreas is a lobulated, branched, acinar gland, surrounded and partially divided into lobules by delicate loose connective tissue (de Reuck and Cameron 1962; Beck and Sinclair 1971). The secretory acinar cells, pyramidal in shape, are arranged in flask-shaped or tubular groups. A narrow intercalated (intralobular) duct is deeply inserted into each secretory mass, the initial part of the duct walls being lined by low cuboidal *centro-acinar cells*, whilst more distally these are replaced by taller cuboidal and eventually columnar cells. The larger ducts are interlobular in position, and are surrounded by areolar tissue which contains nonstriated muscle fibres, and autonomic nerve fibres. Argentaffin cells (p. 1366) are present amongst the undifferentiated columnar cells of the duct walls, and mast cells are numerous in the connective tissue sheaths.

The acinar cells of the exocrine pancreas are typical zymogenic cells, containing a basally situated nucleus, which is surrounded with basophilic cytoplasm, seen ultrastructurally as regular arrays of granular endoplasmic reticulum, interspersed with mitochondria and dense secretory granules. In the apical, supranuclear compartment of the cell, a prominent Golgi complex is present, surrounded by numerous larger secretion granules; the latter are membrane-bound bodies containing the powerful enzymic constituents of the pancreatic secretion. These enzymes are in an inactive form whilst within the granules, and only become activated after their release. Because of the highly ordered nature of their cell contents, acinar cells have been widely used to establish the morphological pathway of secretion synthesis and transport, as an example of typical protein-secreting cells, (see also *Cytology*). In post-mortem specimens the hydrolytic enzymes of the pancreas tend to cause rapid degeneration of cellular detail.

Ganglionic cells and cords of relatively undifferentiated epithelial cells are also present in the exocrine pancreas; the latter may provide stem cells for the replacement of the degenerating exocrine cells, and perhaps, also for islet tissue.

The structure of the exocrine pancreas and the mechanisms by which its activity is controlled are shown diagrammatically in **8**.132 and have been described in detail by Webster *et al.* (1977); Singh and Webster (1978); Case (1979); and Wormsley (1979).



THE ENDOCRINE PANCREAS

This consists of the pancreatic islets (of Langerhans), spheroidal or ellipsoidal clusters of cells randomly embedded in the exocrine part of the pancreas (Laguesse 1906; Lane 1907) together with scattered, often solitary, endocrine cells (Heitz *et al.* 1976).

The islets, which may number more than one million in a normal individual, tend in man to be most numerous in the tail of the pancreas (Findlay and Ashcroft 1975). Each consists of a mass of polyhedral endocrine cells pervaded by a network of fenestrated capillaries (Goldstein and Davies 1968) and with a rich autonomic innervation (Gerich and Lorenzi 1978). Histological staining procedures have been used successfully to distinguish between the major types of secretory cell (Lane 1907; Bensley 1911; Bloom 1931; Kito and Hosoda 1977) and the development of highly specific fluorescent antibody labelling of sections of pancreas (Lacy and Davies 1957), often accompanied by electron microscopic examination of adjacent ultrathin sections (Heitz *et al.* 1976; Baetens *et al.* 1977) has led to confirmation of the identity of their secretory products and to the recognition of other less numerous endocrine cell types (**8**.134).

The most numerous endocrine cells, types A (or alpha) and B (or beta), secrete glucagon (Baum *et al.* 1962) and insulin (Lacy and Davies 1957) respectively. Although there is interspecific variation (Findlay and Ashcroft 1975), in man the A cells tend to be arranged towards the periphery of the islets while the B cells are more central in position (Orci 1976). The cytoplasmic storage granules of the A cells are fixed by alcohol, are generally smaller than those of the B cells, stain brilliant orange or red with the dyes Orange G and Mallory-Azan, and are aldehyde-fuchsin negative. Those of the B cells are alcohol-soluble and, after appropriate fixation, are aldehyde-fuchsin positive. A third type of endocrine cells, the D cell, discovered in human pancreatic islets by Bloom (1931), and generally described as producing gastrin, has recently been shown to contain somatostatin or a closely related peptide (Orci *et al.* 1975). In man the D cells tend to be peripherally located in the islets, as are the A cells. It has been suggested (Orci and Unger 1975) that the islets may consist of two functionally distinct regions: a homocellular medulla containing mainly B cells, where insulin is secreted at a relatively constant rate in response, for example, to the presence of glucose in the surrounding intercellular fluid, and a heterocellular cortex of A, B and D cells, particularly rich in vascular and neural elements, where rapid changes in secretory activity are made in response to various environmental stimuli. In this latter region somatostatin release by the D cells may inhibit the secretory activity of adjacent A or B cells (Orci 1976). Since in many mammalian species including man, D cells are more frequently in contact with A cells than with B cells, it might be expected that the main effect of pancreatic somatostatin would be to inhibit glucagon release. Convincing evidence that this is so has come from the organ culture studies of Barden *et al.* (1977) who found that when antisomatostatin serum was incubated with rat islets there was a ten-fold increase in glucagon release but no significant change in the release of insulin. The mechanism by which somatostatin inhibits glucagon, and possibly also insulin, release is not yet known, but it has been suggested that it may act intracellularly after transmission through gap junctions from adjacent cells (Gerich and Lorenzi 1978). Another suggested hormonal modifier of islet cell activity is gastric inhibitory peptide which appears to potentiate the insulin secretory response to glucose (Dupré *et al.* 1973). The 'neurohormones' of the autonomic nervous system, acetylcholine and noradrenalin, also affect secretion, acetylcholine augmenting insulin and glucagon release, while noradrenalin inhibits glucose-induced insulin release; they may also affect somatostatin and pancreatic polypeptide secretion. At present the relative importance of circulating noradrenalin and adrenalin of adrenal origin, and of neurogenous noradrenalin acting locally on islet cell secretion, remains to be clarified. The control of islet cell activity is shown diagrammatically in **8**.134.

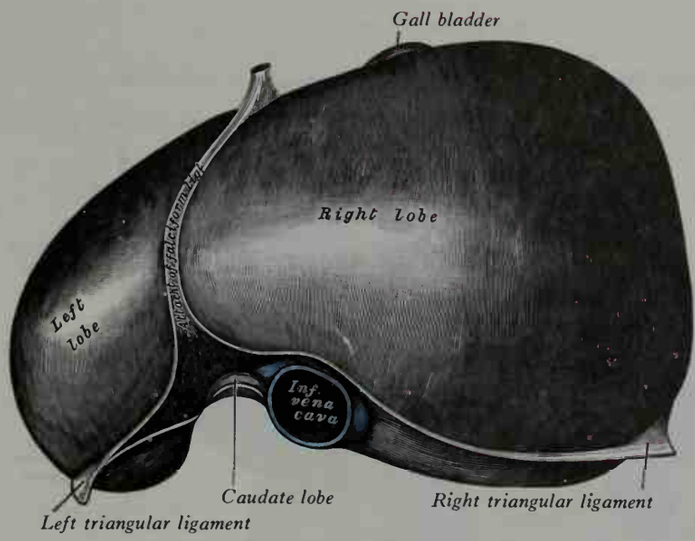
Peptide-secreting cells with smaller cytoplasmic granules than those of the A, B and D cells have been identified recently in the human pancreas. There are at least two types: one, termed the PP cell, has been shown to contain the hormone pancreatic polypeptide, while the other has an ultrastructure similar to that of the D_1 cells of the gastric mucosa (p. 1365). The pancreatic 'D_1' cells differ from the PP cells in that the granules of the former do not react with anti-bovine pancreatic polypeptide serum while those of the latter do (Baetens *et al.* 1977). Although the nature of the secretory product of the gastro-enteric D_1 cells is still uncertain, it has been suggested that it may be related to vaso-

8.134 Diagram of the histology, ultrastructure, and mode of operation of the endocrine pancreas. (VIP = vaso-active intestinal polypeptide.)

active intestinal polypeptide (Buffa *et al.* 1977); that of the pancreatic 'D_1' cells is still uncertain.

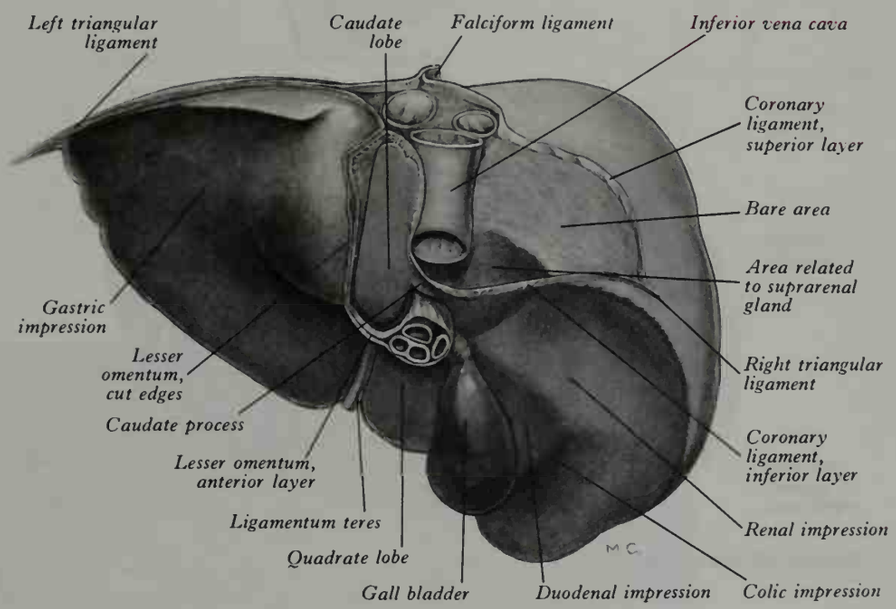
'D_1' and PP cells are not restricted to the islets but are also found scattered throughout the predominantly exocrine compartment of the pancreas (**8**.134).

Islet vessels and nerves



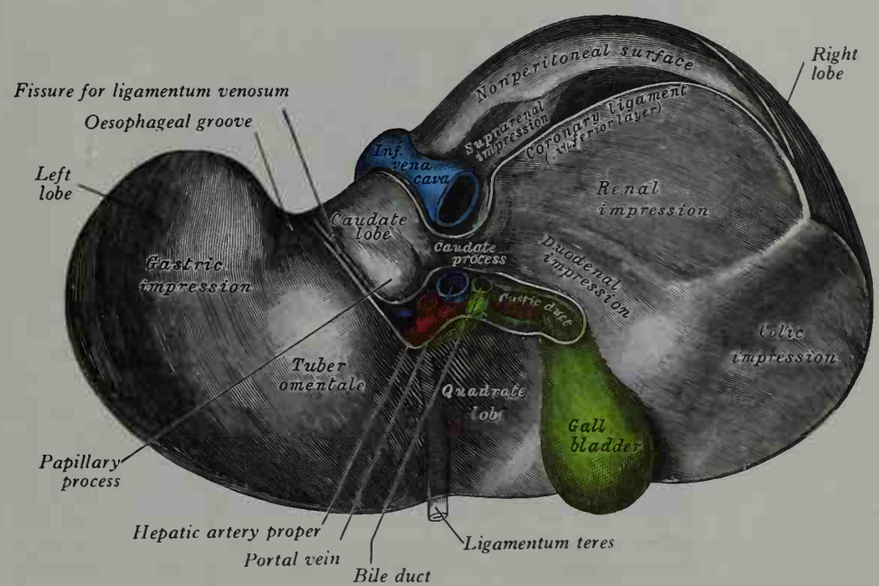
The *arteries* of the pancreas are derived from the splenic artery and the pancreaticoduodenal arteries (pp. 713, 716 and **6**.86). Its *veins* drain into the portal, splenic and superior mesenteric veins. Its *lymph vessels* are described elsewhere (p. 793). The larger blood and lymph vessels travel with ducts and nerves in the interlobular connective tissue and from them branches supply the lobules of the gland. Bunnag *et al.* (1963) have shown that in mice one to three afferent arterioles arise from the arterial branches to supply each islet, before which they may supply acini. Once within an islet they branch into a network of capillaries so rich that it is reminiscent of a renal glomerulus. The islet capillary bed is drained by from one to six venules which join together before entering an adjacent intralobular vein. McCuskey and Chapman (1969) have reported that flow through individual islet capillaries is intermittent, local interruption being brought about by bulging of the endothelial cells into the capillary lumen. The islet capillaries are fenestrated.

The pancreatic *nerve supply* is derived from the coeliac plexus and enters the organ along with branches of the arteries supplying the pancreas. As well as afferent fibres about which little is known, there is an efferent supply consisting of sympathetic postganglionic fibres from the coeliac ganglion and parasympathetic preganglionic fibres from the right vagus nerve. The fibres, which are mainly nonmyelinated (Benscome 1959) are vasomotor (sympathetic) and parenchymal (sympathetic and parasympathetic) in their distribution. Fine branches ramify among the islet cells from peri-insular plexuses (Findlay and Ashcroft 1975). Fibres frequently make synaptic contact with acinar cells before innervating the islets, suggesting a close linkage between the neural control of the exocrine and endocrine components of the pancreas. Many fibres enter the islets in company with arterioles (Coupland 1958).



Parasympathetic ganglia lie in the inter- and intra-lobular connective tissue, and in the latter case are frequently associated with islet cells, together with which they constitute *neuro-insular complexes*. These intimate associations of islet cells and neural elements were first described by van Campenhout (1925) who named them the 'complexes sympathico-insulaires', the term being revised to 'complexes neuro-insulaires' by Simard (1937). They were classified into two groups by Fujita (1959), one consisting of nerve cells and islet cells (Fig. **8**.134) and the other of nerve fibres and islet cells, the latter being described in detail by Kobayashi and Fujita (1969). The islet cells involved in the neuro-insular complexes include both A and B types. The significance and role of the complexes are still speculative; if, however, the islet cells have a neural crest origin, as suggested by Pearse (1969) and Weichert (1970) then the close anatomical association of the islet cells and neural elements is not surprising, nor is the involvement of the autonomic system in the control of islet secretion.

Three types of nerve terminal have been identified in the islets (Smith and Porte 1976): cholinergic (having 30–50 nm diameter agranular vesicles), adrenergic (having 30–50 nm dense-cored vesicles) and an as yet uncharacterized type (having 60–200 nm dense-cored vesicles). No selective association with any particular islet cell type has been found, and sometimes more than one type of terminal is associated with a single cell type (Esterhuizen *et al.* 1968). Orci *et al.* (1973) have shown that some of the chemical synapses between axon terminal and islet cell show areas of narrowing of the synaptic cleft suggesting the presence of an electrical synapse or gap junction. Similar gap junctions have been found between the islet cells (Orci 1974), and the concept of electrical coupling of the nerve supply to a functional network of islet cells has been introduced. Some nerve terminals appear to end remote from the surface of the islet cells (Kobayashi and Fujita 1969); neurotransmitters released from such endings into the intercellular spaces of the islets could, perhaps, diffuse to and affect numerous islet cells.



Applied Anatomy. Cysts of the pancreas may attain a large size, and cause symptoms by pressing on the stomach, diaphragm or bile duct. They generally push their way forwards between the stomach and transverse colon, and may then be felt in the upper part of the abdomen as a definite tumour in the median plane. The tumour is fixed and does not move with respiration. The pancreas may be the site of cancer; this usually affects the head, and therefore speedily involves the bile duct, leading to persistent jaundice; or it may press upon the portal vein, causing ascites, or involve the stomach, causing pyloric obstruction. The descending part of the duodenum is occasionally encircled by the head of the pancreas (annular pancreas), and should the latter then be the seat of malignant disease or chronic inflammation it may cause obstruction of the duodenum. (For a case report of annular pancreas and a resumé of the literature *see* Kasai *et al.* 1974.) Similarly, if the bile duct lies in a canal in the head of the pancreas (p. 1383), chronic inflammatory disease of the pancreas may obstruct the duct and produce jaundice. Accessory nodules of pancreatic tissue may sometimes be present in the wall of the duodenum (most commonly), the jejunum, the ileum or the ileal diverticulum (p. 1345). Those in the duodenum may be associated with the occasional presence of duodenal diverticula. These take the form of small protrusions which involve all the coats of the

duodenum, or only the mucous and submucous layers, and they are usually situated on the wall of the duodenum adjacent to the pancreas and in close relation to the opening of the bile duct.

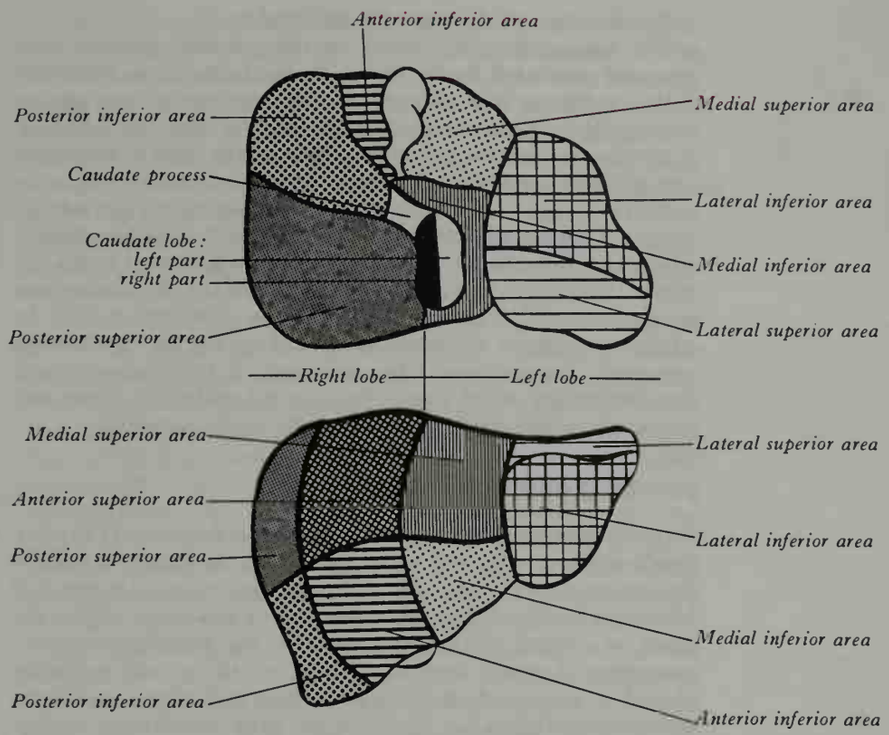
The Liver

The liver (hepar), the largest gland in the body, is situated in the upper and right parts of the abdominal cavity, occupying almost the whole of the right hypochondrium, the greater part of the epigastrium, and extending into the left hypochondrium as far as the left lateral line (Rouiller 1964). In the male it commonly weighs from 1·4 to 1·8 kg., in the female from 1·2 to 1·4 kg. with, however, a range of 1·0–2·5 kg. It is relatively much larger in the fetus than in the adult. It is somewhat wedge-shaped, reddish brown and, although firm and pliant to the touch, it is friable and easily lacerated. For this reason wounds of the liver must not be too tightly sutured. Owing to its great vascularity, wounds of the liver cause considerable haemorrhage. In spite of its relatively great weight, it is widely held that the liver, like the other abdominal organs, is maintained in its position, not by its peritoneal folds (p. 1376) or connective tissue attachments, but by the general intra-abdominal pressure due to the tonus of the abdominal muscles. Continuity of the hepatic veins with the inferior vena cava also provides some support. However, it should be noted that rather dogmatic statements such as the foregoing should be treated with caution. In the absence of systematic studies of the intra-abdominal perihepatic pressure gradients and their variations with posture, respiration, gastrointestinal dilatation and so forth, together with studies of the statics and dynamics of the peritoneal folds, connective tissues, adjacent viscera and vascular pedicles, our knowledge of the mechanisms maintaining the position of the liver (and other abdominal organs) remains quite rudimentary.

BORDERS OF THE LIVER

The superior, anterior and right surfaces are continuous at rounded 'borders', but a sharp *inferior border* (**8**.135), separates the right lateral and anterior surfaces from the inferior surface. Somewhat rounded where it intervenes between the right lateral and inferior surfaces, the inferior border is thin and sharp where it forms the lower margin of the anterior surface and is notched by the *ligamentum teres*, just to the right of the median plane. Lateral to the fundus of the gall bladder, which often corresponds to a second notch 4 to 5 cm to the right of the median plane, this border generally corresponds with the costal margin. To the left of the fundus of the gall bladder, it ascends less obliquely than the right costal margin and, crossing the infrasternal angle, passes behind the left costal margin in the neighbourhood of the tip of the eighth costal cartilage. Thereafter it ascends sharply and merges with the thin left margin of the left lobe. As it crosses the infrasternal angle the inferior border is closely related to the deep surface of the anterior abdominal wall and is readily accessible to examination in the living subject by percussion, though normally it is not palpable; in the median plane the inferior border of the liver lies on the transpyloric plane, about a hand's breadth below the xiphisternal joint (**8**.123). In women and children this border usually lies at a slightly lower level, and it tends to project downwards for a short distance below the right costal margin. As will be apparent below, the other 'borders' are indistinct and arbitrary.

THE HEPATIC LOBES



The liver is divisible into a right lobe and a much smaller left lobe. The original basis for the demarcation between these lobes was entirely a concatenation of superficial features (attachment of falciform fold, fissures for ligamenta teres et venosum), and this description persists in most anatomical texts. However, the classical studies of Hjortsjö (1948, 1951, 1956), upon the segmental branching of the bile ducts, hepatic artery, and portal vein within the liver, have emphasized that the primary anatomical and functional lobation is better defined by the distribution of the right and left hepatic ducts. Although there is

individual variation and naturally some interdigitation between the smaller tributaries of the right and left hepatic ducts, the zone of division between the two lobes is a plane considerably to the right of the customary demarcation noted above (**8**.136C). Inferiorly and posteriorly the division is indicated by a line extending from the fossa for the gall bladder towards the inferior vena cava. Thus the quadrate and caudate lobes (*vide infra*) are part of the *left* lobe, *not* the right, except for the processus caudatus, which is served by the right hepatic duct. The plane between the right and left lobes is not quite sagittal in position, being tilted in both the horizontal and vertical planes.

A considerable number of other workers have confirmed Hjortsjö's classification (e.g. Healey and Schroy 1953, Goldsmith and Woodburne 1957, Stucke 1959) during investigations—by corrosion cast techniques, dissection and radiology—of the further subdivision of the lobes into segments (*vide infra*). In such preparations, particularly those produced by casts of the ducts or vessels, so-called 'fissures' are visible (**8**.136A) at the frontiers between the territories of their right and left branches, and also less clearly between lobar subdivisions (segments). It is important to note that these fissures, even the main interlobar zone described above, do not produce reliable surface indications which could be utilized with confidence in right or left lobectomy.

The *right lobe* of the liver, much greater in volume than the left, contributes to all surfaces of the organ, as described later, including the whole of the right or costal aspect. These somewhat arbitrarily separated surfaces—anterior, superior, inferior and posterior—all pass uninterruptedly on to the *left lobe*, except where shallow grooves partially demarcate the quadrate and caudate 'lobes', which are really parts of the left lobe.

The *quadrate lobe* is placed on the inferior surface, and is somewhat rectangular in outline. It is bounded in front by the inferior border of the liver; on the left by the fissure for the ligamentum teres; behind by the porta hepatis: and on the right by

8.136B The segmentation of the liver, based upon the principal divisions of the hepatic artery and accompanying hepatic ducts. a shallow fossa which lodges the gall bladder.

The *caudate lobe* is situated on the posterior surface. It is bounded on the left by the fissure for the ligamentum venosum, below by the porta hepatis and on the right by the deep groove which lodges the upper portion of the inferior vena cava. Above, it is continuous with the superior surface on the right of the upper end of the fissure for the ligamentum venosum. Below and to the right, the caudate lobe is connected to the mass of the right lobe by a narrow tongue of liver substance, termed the *caudate process*, which lies immediately behind the porta hepatis and forms the roof of the epiploic foramen. Below and to the left the caudate lobe presents a small rounded projection, the *papillary process*. In addition, owing to the depth of the fissure for the ligamentum venosum, the caudate lobe possesses a peritoneal-covered anterior surface, which forms the posterior wall of the fissure and is in contact with the hepatic part of the lesser omentum.

HEPATIC SEGMENTATION

As in the case of other organs with a hilum at which enter or leave single arteries, veins and sometimes ducts, investigations of the branching of these structures in the liver has promoted a system of lobes and further subdivisions (sectors or segments). From the mode of growth of such organs, with the branching and re-branching of vessels and ducts, it is inevitable that territories should be associated, as in the liver, with individual rami of the portal triad of tubes (i.e. fine branches of the portal vein, hepatic artery and hepatic ducts). The size and hence number of such territories, or segments, is dependent upon the size of tube recognized as 'segmental' or, in other words, upon the level within the arborization which is arbitrarily selected. The hepatic artery, portal vein and common bile duct divide and subdivide upon a common pattern, as is implied in the classical observations of Glisson (1654) and confirmed by many subsequent workers. Moreover, no evidence of intrahepatic anastomosis upon a significant scale between the elements of these dendriform systems has been recorded. For example, despite variation in its origin (and the occurrence of accessory vessels), the hepatic artery is a system of end-arteries (Michels 1966), a frequent consequence of the development of any organ from a single vascularized blastema of dichotomizing potentiality. However, the implications of this pattern of growth were not followed up until the late nineteenth century, apart from the recognition of right and left hepatic lobes (consult McIndoe and Counsellor 1927 and Hjortsjö 1948, for earlier literature). The division into two lobes, based upon the primary triadic divisions, and not upon surface features, is generally accepted, although confusing descriptions based on the latter persist in many texts. Inevitably, however, further subdivision has been suggested, if only in the interests of partial hepatectomy; and the classical figure in this field was Hjortsjö (1948, 1951, 1956, 1975), who was the first to propose a complete segmental model of the liver (**8**.136A) basing his concepts of subdivision of the hepatic lobes on dissections, injections, and radiographic technique, particularly applied to the biliary ducts and portal vein. Many subsequent workers have modified or enlarged upon his scheme of segmentation, subdividing some segments, redefining and renaming others. (*See*, for example, Elias and Petty 1952, Healey and Schroy 1953, Couinaud 1954, Goldsmith and Woodburne 1957, Bilbey and Rappaport 1960.) The main extension of Hjortsjö's scheme has been the division of his segments into superior and inferior parts, chiefly by Healey and Schroy 1953 (**8**.136B) and Couinaud 1954. Apart from this, and some minor differences in delineating the major segments, there is general agreement amongst these observers upon a division of the right hepatic lobe into approximately 'anterior', intermediate and 'posterior' segments, and of the left lobe into lateral and medial parts. Most of these reports have been based upon injections and casts, and principally upon corrosion casts of one or more of the biliary, hepatic arterial and portal venous ramifications. It is easy to discern in such casts (**8**.136C) a sagittal zone between the right and left lobes, the *fissura principalis*, which is picturesquely described by Hjortsjö (1956) as being in the same plane as the left tympanic membrane. All other 'fissures', as described with some variation by different investigators, are intersegmental, dividing the right and left lobes into segments. The term '*spatium*' has been suggested for 'fissure', and Hjortsjö recognized a number of these (**8**.136A). The appearance of such 'spaces' in corrosion casts is, of course, due to an absence of all but the smallest visible rami of the portal triad of structures. However, these demarcations do not correspond to any substantial zones of connective tissue in the living organ, which might produce superficial or internal indications for the purposes of subtotal resection (cf. broncho-pulmonary segments). The surface projections of the segmental fissures are shown in **8**.136A and **8**.136B, according to the schemes of Hjortsjö (1948) and of Healey and Schroy (1953), the chief difference being that in the latter scheme superior and inferior regions are shown in each of the major segments (as also recognized in the studies of Elias and Petty 1952, Couinaud 1954, and Platzer and Maurer 1966). Most recently Gupta *et al.* (1978) have put forward a similar scheme (9 segments), comparing previous findings with their own. No attempt will be made here to equate the segments described, with differing names and delimitations, by the investigators quoted, because this would not improve the reliability of this information in practical application. As Gupta *et al.* (1978) have pointed out, the segmental pattern (apart from the minor disagreements of different observers) is in itself variable; in their own series of 41 corrosion casts more than half of these showed marked variation in the volume of one segment or another, and this variability has been noted by others. Although most observers regard the segments as functionally independent and uncomplicated by, for example, intrahepatic arterial anastomosis, occasionally this has been noted. Surgical opinion is divided upon the reliability of hepatic segmentation in hepatic resections. Dawson (1974) and others consider resection of less than a lobe as hazardous, while others, such as Ryncki (1974) have recorded successful segmental resections. Even if such operations are to be attempted, individual variation points to the need for portal venography and cholangiography to define segmental patterns before operation, wherever feasible. Finally, the disposition of the hepatic veins and their tributaries is not a favourable factor. These veins, which have also been studied by corrosion casts (Goldsmith and Woodburne 1957), do not follow the pattern of the hepatic triads; they drain parts of adjoining segments. It is therefore most difficult to plan a resection plane which is optimal in respect of the triadic structures and the hepatic veins.

PERITONEAL CONNEXIONS OF THE LIVER

With the exception of an extensive, triangular area on the posterior surface of the right lobe, the liver is almost completely invested with peritoneum. It is connected to the stomach and duodenum, to the diaphragm and to the anterior abdominal wall by a number of peritoneal folds, and the lines along which they meet the organ are also necessarily devoid of a peritoneal covering. These folds include the falciform ligament, the right and left triangular ligaments, the coronary ligament and the lesser omentum.

The *falciform ligament* (**8**.93) is a sickle-shaped fold, consisting of two closely applied layers of peritoneum, which connects the liver to the diaphragm and the supra-umbilical part of the anterior abdominal wall. Its convex margin is fixed to the inferior surface of the diaphragm and to the posterior surface of the anterior abdominal wall, extending downwards to the umbilicus; as this attachment ascends from the umbilicus it passes slightly to the right of the median plane. The falciform ligament is attached to the notch for the ligamentum teres on the inferior border of the liver and to the anterior and superior surfaces of the liver. Its free edge, which extends from the umbilicus to the notch for the ligamentum teres, contains the latter structure and the small para-umbilical veins, and lies in front of the pyloric region of the stomach. At its upper end the two layers of the falciform ligament separate from each other and expose a small triangular area on the superior surface of the liver which is devoid of peritoneum. The left layer becomes continuous with the anterior layer of the left triangular ligament: the right with the upper layer of the coronary ligament.

The *coronary ligament* (**8**.135) is formed by the reflexion of the peritoneum from the diaphragm to the superior and posterior surfaces of the right lobe. It consists of an upper and a lower layer, continuous at their right extremities with the right triangular ligament of the liver then diverging widely to the left so as to enclose posteriorly a large triangular area of the right lobe which is not covered with peritoneum and is termed the 'bare area'. The upper layer is continuous with the right layer of the falciform ligament, skirts anteriorly the upper end of the groove for the inferior vena cava and then gradually descends from the posterior part of the upper surface to the upper part of the posterior surface. There it is continuous with the anterior layer of the right triangular ligament. The lower layer is continuous with the posterior layer of the right triangular ligament and passes almost horizontally along the lower limit of the posterior surface of the right lobe. In this situation the peritoneum may be reflected on to the upper part of the anterior surface of the right kidney (*hepatorenal ligament*), instead of on to the diaphragm beyond the margin of that organ. At its left extremity the lower layer of the coronary ligament passes in front of the lower end of the groove for the inferior vena cava and becomes continuous with the line of peritoneal reflexion from the right border of the caudate lobe, i.e. the right margin of the upper recess of the omental bursa.

The *left triangular ligament* passes from the upper surface of the left lobe upwards and backwards to the under surface of the diaphragm. It consists of two closely applied layers of peritoneum which become continuous with each other when traced to the left, where the ligament ends in a free margin. Traced to the right the anterior layer becomes continuous with the left layer of the falciform ligament, and the posterior layer with the anterior layer of the lesser omentum at the upper end of the fissure for the ligamentum venosum. The triangular ligament is placed in front of the abdominal part of the oesophagus, the upper end of the lesser omentum and part of the fundus of the stomach. Much variation occurs in this peritoneal fold; it may contain blood vessels of considerable size (Outrequin *et al.* 1967).

The *right triangular ligament* is a short V-shaped fold which connects the lateral part of the posterior aspect of the right lobe to the diaphragm. The apex of the V forms a free right margin for the ligament, around which its two layers become continuous with each other. The ligament really constitutes the right extremity of the coronary ligament.

The *lesser omentum* has already been described (p. 1327) in detail. At the upper end of the fissure for the ligamentum venosum, its anterior layer becomes continuous with the posterior layer of the left triangular ligament, and its posterior layer with the line of reflexion of the peritoneum from the upper end of the right border of the caudate lobe and so, indirectly, with the lower layer of the coronary ligament (**8**.135B).

HEPATIC SURFACES

The superior surface of the liver (**8**.135) includes portions of the right and left lobes. It fits under the vault of the diaphragm, and is covered with peritoneum, except over a small triangular area where the two layers of the upper part of the falciform ligament diverge. Its right and left portions are convex, but its central part presents a shallow *cardiac impression*, which corresponds with the position of the heart on the upper surface of the diaphragm. It is related to the diaphragmatic pleura of the right side and the base of the right lung, to the pericardium and ventricular part of the heart, and, to a much smaller extent, to the diaphragmatic pleura of the left side and the base of the left lung.

It should be noted here that because of the overall convexity of the superior surfaces of the right and left lobes, the superior surface grades insensibly into the so-called anterior surface and also into the peritonealized part of the posterior surface of the right lobe. No definite border or other anatomical feature separates the superior, anterior, right lateral and right posterior *aspects* of the liver, and in many ways it is more appropriate to group these as the *diaphragmatic surface*. In contrast, most of the latter is separated from the *visceral surface* by a well defined, narrow edge or border.

The **anterior surface**, which is triangular in shape, is covered with peritoneum except at the line of attachment of the falciform ligament. A large part of this surface is in contact with the diaphragm, which separates it, on the right side, from the pleura and the sixth to the tenth ribs and their cartilages and, on the left side, from the seventh and eighth costal cartilages. The thin anterior margin of the base of the lung is related to the upper part of this surface, but the relationship is much more extensive on the right than it is on the left side. The median part of the anterior surface of the liver lies behind the xiphoid process of the sternum and the anterior abdominal wall in the infracostal angle (**8**.92).

The profile of the liver may be marked out on the anterior aspect of the trunk as follows (**8**.123): its upper border corresponds to a line drawn through the xiphisternal joint and ascending to the right to a point a little below the right nipple (fourth intercostal space) and ascending less sharply to the left to a point a little below and medial to the left nipple; its right border corresponds to a curved line, convex to the right, drawn from the right end of the upper border to a point 1 cm below the right costal margin at the tip of the tenth costal cartilage; its lower border is drawn by joining the ends of the upper and right borders, this line crossing the median plane at the level of the transpyloric plane and showing a slight concavity opposite the right linea semilunaris.

The right surface is covered with peritoneum and is related to the right portion of the diaphragm, which separates it from the right lung and pleura, and the seventh to eleventh ribs. Over its upper third both lung and pleura intervene between the diaphragm and the ribs; over its middle third only the costodiaphragmatic recess of the pleura is interposed; over its lower third the diaphragm is in actual contact with the costal arches.

The posterior surface is wide and convex on the right, but narrow on the left. A deep concavity marks its median region and corresponds with the forward convexity formed by the vertebral column (**8**.135A). A large part of this surface is devoid of peritoneal covering and is attached to the diaphragm by areolar tissue. This non-peritoneal surface constitutes the 'bare area' of the liver. It is triangular and is limited above and below by the superior and inferior layers of the coronary ligament. Its base, to the left, is the deep groove for the inferior vena cava, while its apex, directed downwards and laterally, corresponds with the right triangular ligament. The *groove for the inferior vena cava* is a deep, linear depression, occasionally a complete tunnel, on the posterior surface of the liver and is devoid of peritoneal covering. It lodges the upper part of the vessel and its floor is pierced by the hepatic veins (p. 763). At its lower end the groove is separated from the porta hepatis in front by the caudate process. Immediately lateral to the lower end of the groove, the 'bare area' adjoins the upper part of the right suprarenal gland (*suprarenal impression*). On the left side of the groove for the inferior vena cava the *caudate lobe* occupies part of the posterior surface of the left lobe. It lies in the superior recess of the omental bursa, and the peritoneum covering its posterior aspect is continued round its left border on to its anterior aspect, which forms the posterior wall of the fissure for the ligamentum venosum (**8**.135). The caudate lobe should therefore be regarded as projecting into the superior recess of the omental bursa from its right border. The posterior surface of the caudate lobe is related to the crura of the diaphragm above the aortic opening and to the right inferior phrenic artery, and is separated by them from the descending thoracic aorta. The *papillary process* often projects downwards in front of the origin of the coeliac artery.

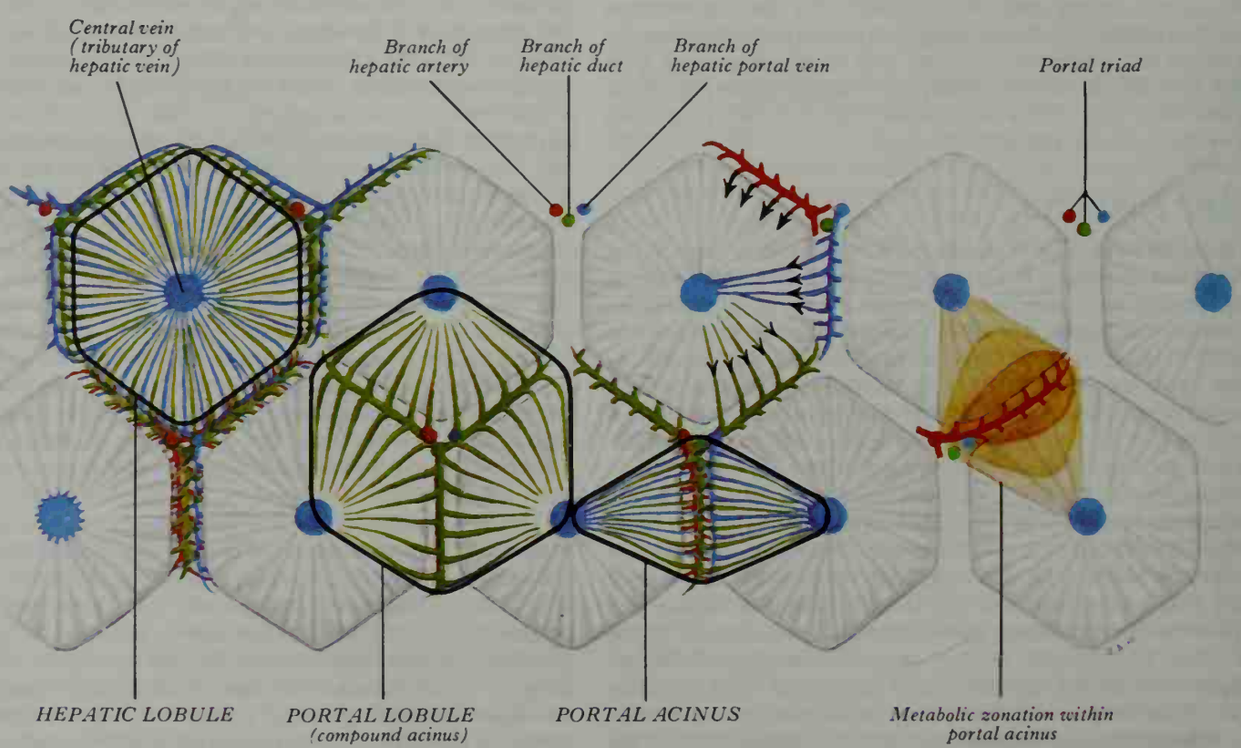
The lips of the *fissure for the ligamentum venosum* (**8**.135) separate the posterior aspect of the caudate from the main part of the left lobe. The fissure itself cuts deeply into the liver in front of the caudate lobe and contains the two layers of the lesser omentum. At its lower end it curves laterally in front of the papillary process, and reaches the left extremity of the porta hepatis. The *ligamentum venosum*, which is the fibrous remnant of the ductus venosus (p. 665), is attached below to the posterior border of the left branch of the portal vein. It ascends in the floor of the fissure and passes laterally at the upper end of the caudate lobe to join the left hepatic vein near its point of entry into the inferior vena cava, or sometimes the vena cava itself.

The posterior aspect of the left lobe is marked by a shallow *oesophageal impression* near the upper end of the fissure for the ligamentum venosum, which is occupied by the abdominal part of the oesophagus. To the left of this impression the left lobe is related to a part of the fundus of the stomach.

The inferior or visceral surface (8.135) is directed downwards, backwards and to the left, and, in the formalin-hardened organ, bears the imprints of the neighbouring viscera. It is invested with visceral peritoneum except at the porta hepatis, the fissure for the ligamentum teres and the fossa for the gall bladder. On the inferior surface of the left lobe, in direct continuity with the oesophageal impression, the *gastric impression* is moulded over the stomach. On the right of this impression there is a rounded *omental tuberosity*. This occupies the concavity of the lesser curvature of the stomach and is in contact with the lesser omentum. The *fissure for the ligamentum teres* is a cleft of variable depth which passes upwards and backwards from the corresponding notch on the inferior border of the liver to the left end of the porta hepatis where it meets the lower end of the fissure for the ligamentum venosum. It forms the left boundary of the quadrate lobe and may be, partially or completely, bridged over by a band of liver substance. Its floor lodges the *ligamentum teres of the liver*, which is the obliterated vestige of the left umbilical vein of the fetus (p. 665). Commencing at the umbilicus it ascends in the free margin of the falciform ligament to the inferior border of the liver, traverses the fissure and ends by joining the left branch of the portal vein at the left extremity of the porta hepatis opposite the attachment of the ligamentum venosum.

The gastric impression may be continued on to the anterior part of the *quadrate lobe*, which is hollowed out and moulded over the pyloric part of the stomach and the beginning of the duodenum, when these organs are dilated. The posterior part of the quadrate lobe is in contact with the right free border of the lesser omentum and its contained structures. When the stomach is empty the quadrate lobe is related to the superior part of the duodenum and a segment of the transverse colon.

The *porta hepatis* is placed on the inferior surface of the liver between the quadrate lobe in front and the caudate process behind. It is a deep fissure which runs transversely between the upper ends of the fissure for the ligamentum teres and the fossa for the gall bladder. Through the porta hepatis the portal vein, the hepatic artery proper and the hepatic plexus of nerves enter the liver, and the right and left hepatic ducts and some lymph vessels emerge. The hepatic ducts are situated anteriorly, the portal vein and its right and left branches posteriorly and the hepatic artery proper and its right and left branches are intermediate in position.



The *caudate process* connects the lower and lateral part of the caudate lobe (of the left lobe) to the right lobe. It is placed behind the porta hepatis and in front of the inferior vena cava and forms the roof of the epiploic foramen. The caudate process is commonly considered a part of the right lobe, whereas the caudate lobe is, of course, part of the territory of the left hepatic duct, i.e. it is part of the *left* lobe (*vide supra*).

The *fossa for the gall bladder* forms the right boundary of the quadrate lobe and extends from the inferior border of the liver to the right extremity of the porta hepatis. It is usually shallow and devoid of peritoneal covering, but the breadth of this bare area is subject to individual variation.

To the right of the fossa for the gall bladder, the inferior surface of the right lobe is marked by three impressions, viz. colic, renal and duodenal. The *colic impression* is related to the right colic flexure and is within the anterior part of the area, immediately adjoining the inferior border of the liver. The *renal impression* is usually well marked; it is situated behind the colic impression and is separated from the neck and the adjoining part of the gall bladder by the duodenal impression. It is related to the upper part of the anterior surface of the right kidney, and in its superomedial part to the lower pole of the right suprarenal gland. When the lower layer of the coronary ligament is reflected from the liver on to the right kidney, the renal and suprarenal impressions extend for a short distance on to the lower part of the 'bare area'. The *duodenal impression* lies to the lateral side of the neck and adjoining part of the gall bladder, and is related to the termination of the superior part and the commencement of the descending part of the duodenum.

The relations of the liver show considerable variation, for which posture and the movements of respiration are only partly responsible. Those which have been enumerated refer to the body in the supine recumbent position.

The branches of the portal vein and the tributaries of the hepatic veins are more numerous before birth; after birth a reduction in their number takes place by fusion of vessels or by degeneration. In the fetus the portal vein joins the umbilical vein in a smooth curve to the right; this direction is maintained after

8.137 A diagram of the histological organization of the liver, showing the principal types of subdivisions which have been proposed. For purposes of clarity, the territories of the classical hepatic lobules are shown as regular hexagons, unlike their real appearance which is highly variable (see text).

birth and there is a sharp angle between the trunk of the portal vein and its left branch, so that the left (physiological) lobe of the liver would appear to be at a circulatory disadvantage and not able to keep pace with the growth of the right lobe. At the left end of the left lobe in the adult there is sometimes a fibrous band (*the fibrous appendix of the liver*), which represents the atrophied remains of the more extensive left lobe in the young child; it contains atrophied remnants of bile ducts, known as the *vasa aberrantia of the liver*. Similar remnants may be present in the edges of the left lobe and near the inferior vena cava. Occasionally the lower border of the right lobe, a little to the right of the gall bladder, may project downwards for a considerable distance as a broad tongue-like process (*Riedel's lobe*).

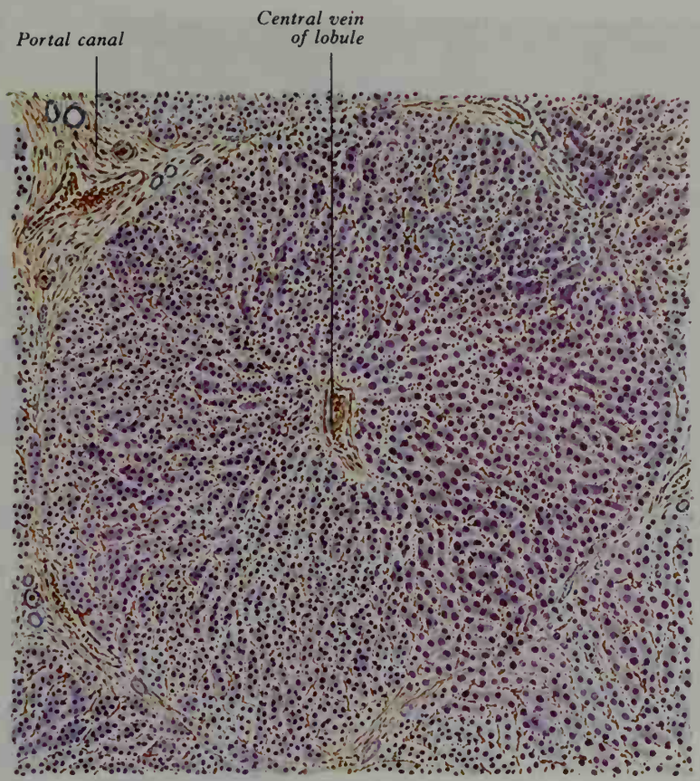
HEPATIC VESSELS AND NERVES

The vessels connected with the liver are the portal vein, the hepatic artery proper and the hepatic veins.

The *portal vein* and *hepatic artery proper* ascend between the layers of the lesser omentum to the porta hepatis, where each divides into two branches; the *bile duct* and *lymph vessels* descend from the porta hepatis between the layers of the same omentum. They are all enveloped in a loose areolar tissue, termed the *perivascular fibrous capsule* (or *hepatobiliary capsule of Glisson*), which surrounds the vessels in their course through the portal canals in the interior of the liver and is continuous with the fibrous capsule of the liver.

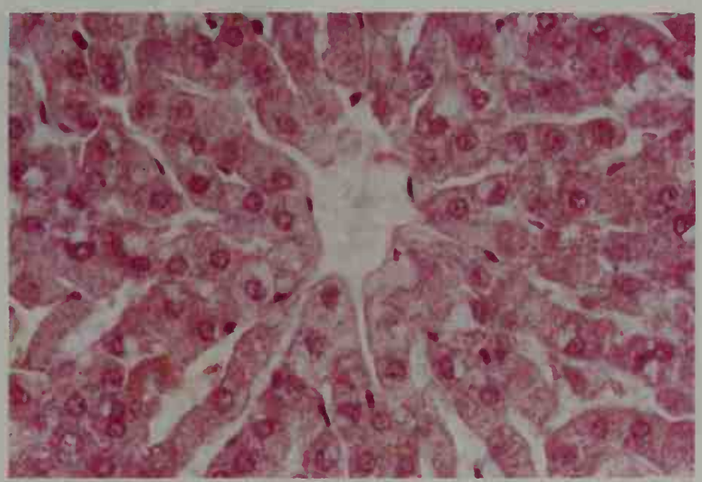
The hepatic artery and its branches pursue a variable course in the porta hepatis. The smaller branches finally become associated with a specific branch of the portal vein and are distributed to the same territory. There are no anastomoses between hepatic arterial territories and hench each branch is an end-artery (Glauser 1953).

The *hepatic veins* (**8**.136C) convey blood from the liver to the inferior vena cava, and are described on p. 763. They have very little fibrous investment, but what there is binds them closely to the walls of the canals through which they run; so that, on section of the liver, they remain widely open and are solitary, and may be easily distinguished from the branches of the portal vein, which are more or less collapsed, and always accompanied by an artery and duct.



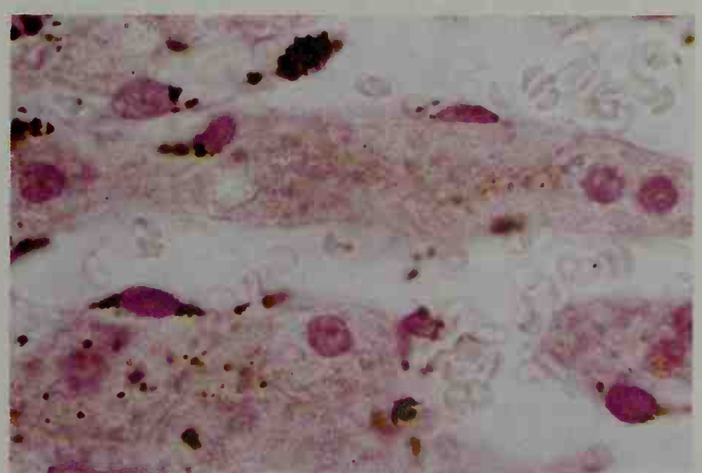
The *lymph vessels* of the liver are described on p. 794. Lymph from the liver has a very rich protein content and obstruction of the venous drainage of the liver results in a considerable increase of lymph in the thoracic duct. The importance of the trans-diaphragmatic lymph drainage of the liver into the internal mammary and diaphragmatic lymph nodes has been emphasized by Nidden *et al.* (1973). They confirm that this drainage reaches the right lymphatic duct, partly via the tracheobronchial group of nodes.

The *nerves* of the liver are derived from the hepatic plexus (p. 1134) and contain both sympathetic and parasympathetic (vagal) fibres. They enter the liver at the porta hepatis and for the most part accompany the blood vessels and bile ducts; very few run amongst the liver cells and the node of termination of these is not known with certainty. Nerve fibres, both myelinated and non-myelinated, also reach the liver parenchyma from nerves in the various peritoneal folds of the organ (Sutherland 1965).

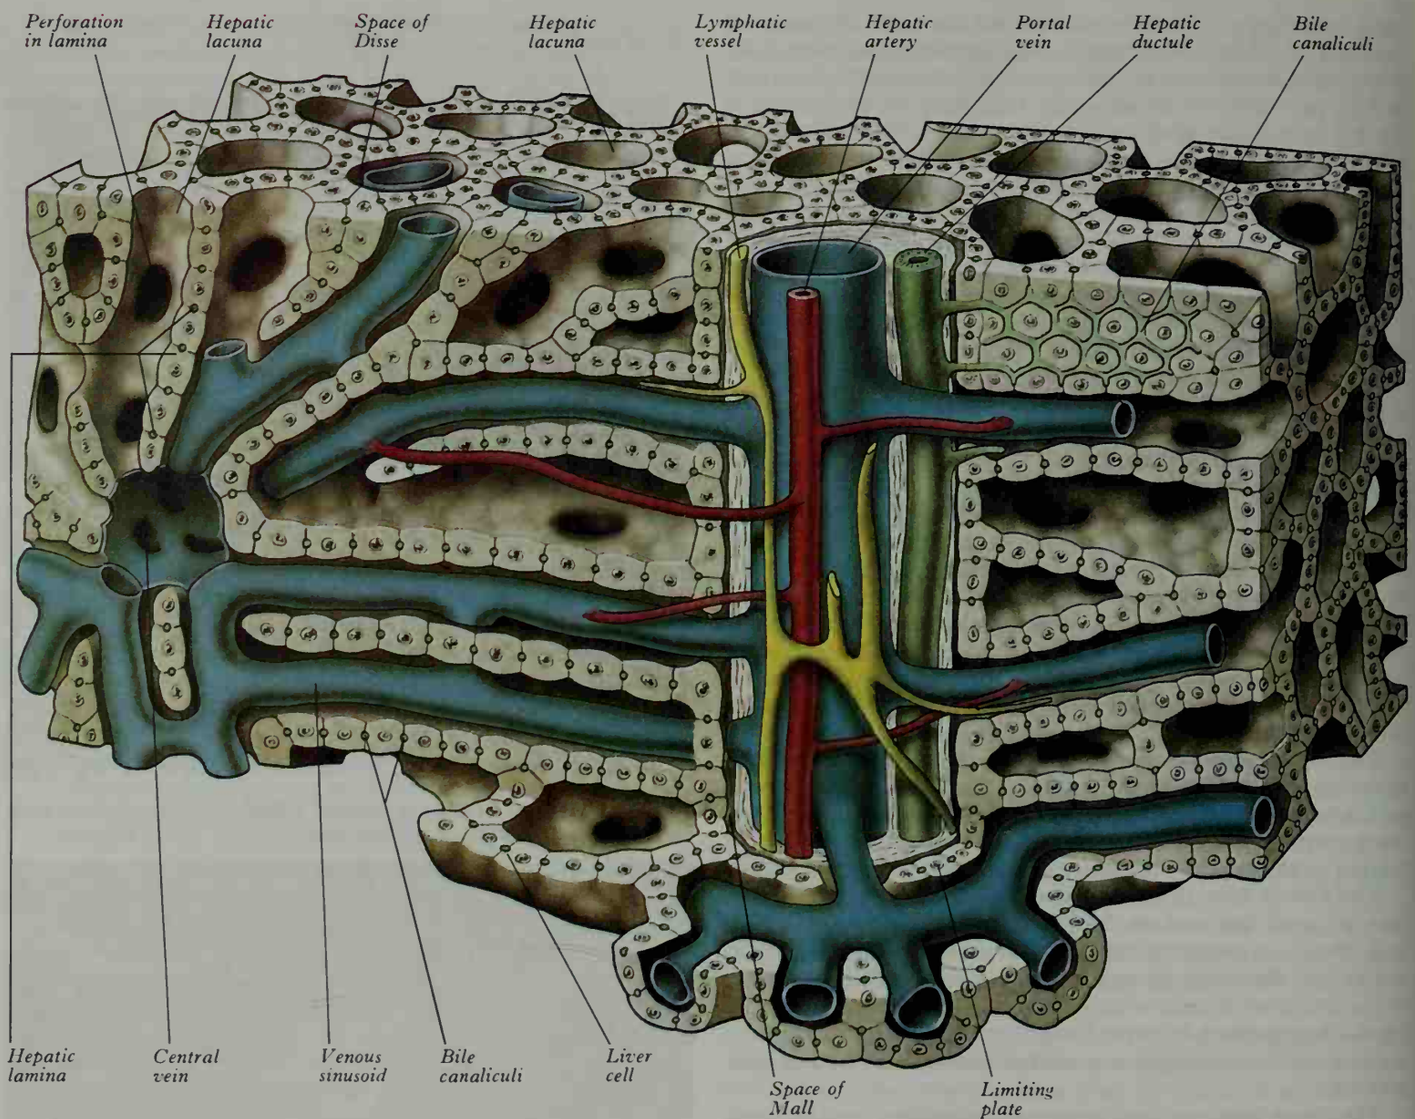


HEPATIC STRUCTURE

In the following remarks, hepatic structure (*see* **8**.137–140) is considered firstly in relation to its lobular architecture, followed by the cytology of the hepatocyte, the microanatomy of the lobules, the vascular channels and the duct system.



The greater part of the liver is invested with peritoneum, which covers a thin capsule of connective tissue (Glisson's capsule). As classically described in the pig and in several other species of mammals, the liver consists of a very large number of polyhedral *hepatic lobules* (which often appear to be hexagonal in histological sections), each being about 1 mm in diameter and having a small *central vein* (a tributary of the hepatic veins) as its central axis, and surrounded at its edges by groups of three tubes, each group being termed a *portal triad* (**8**.137). Each portal triad contains a branch of the portal vein, a branch of the hepatic artery and an



8.138A A section through a hepatic lobule. Human. Stained with haematoxylin and eosin. Magnification about × 70. (After Sobotta.)

8.138B A section through a number of hepatic cords radiating from a central hepatic venule of the rabbit. The hepatocytes appear cuboidal, and the Kupffer cells, which line the sinusoids, have flattened, densely staining nuclei. Haematoxylin and eosin.

8.138C A section similar to that shown in B, but taken from the liver of a rabbit previously injected intravenously with carbon particles. The Kupffer cell nuclei are outlined with phagocytosed particles which demonstrate the limits of the cell cytoplasm.

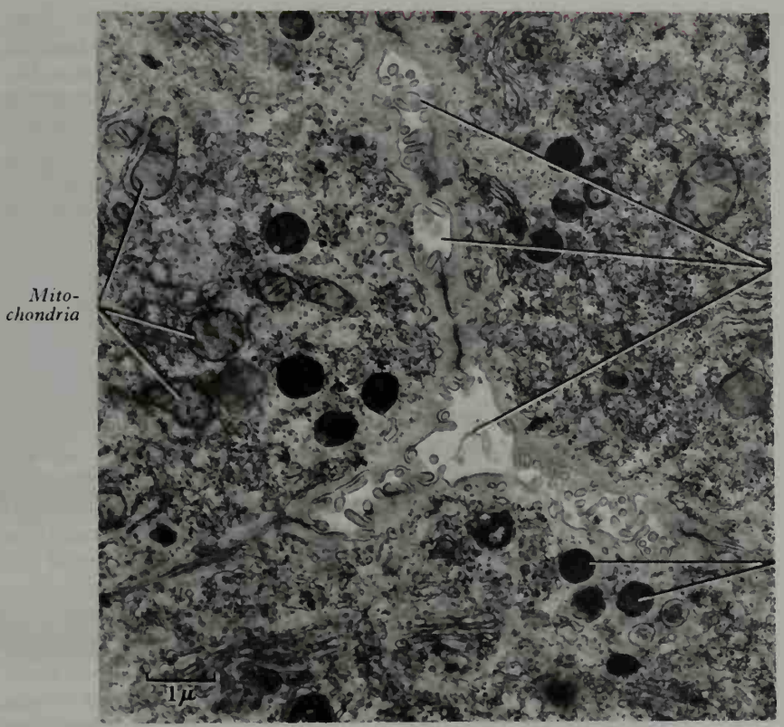
8.139 Diagram of hepatic structure (after Prof. H. Elias, Department of Anatomy, Chicago Medical School).

interlobular bile ductule; all these structures are in a connective tissue sheath, the *portal canal* or *perivascular fibrous capsule*. In the adult pig, each *hepatic lobule* is sharply marked off from neighbouring lobules by connective tissue septa, but in man (and many other mammals) the hepatic lobules are not normally separated by such septa. A '*portal lobule*', on the other hand, consists of the adjoining parts of three hepatic lobules, the bile from which drains into a bile ductule in the portal canal at the meeting place of the three hepatic lobules; in sections therefore, a portal lobule is the polygonal territory centred on a portal triad, its boundary line passing through adjacent central veins. The concept of a third type of unit structure, the *portal acinus*, is useful in considerations of blood flow, patterns of oxygenation, and pathological degeneration. This unit is centred around a preterminal branch of an hepatic arteriole, and includes the parenchyma served by this vessel, bounded by the territories of other portal acini and by two adjacent central veins (**8**.137). Because several phenomena, for example, zones of anoxic damage, glycogen deposition and removal, and toxic trauma are related to the arterial blood flow patterns, they tend to follow the acinar pattern rather than any other. Rappaport (1969) has also proposed multiple units, (*compound portal acini*) for more complex groups of hepatic units. Neither the hepatic nor the portal lobules are to be considered as fixed anatomical entities; under normal conditions the '*hepatic lobular structure*' is evident, but this can be changed to a '*portal lobular structure*' by alteration in the relative blood pressure in the portal and hepatic veins (e.g. by raising the hepatic venous pressure or lowering the portal pressure), the change being reversible. Such alterations in the venous pressure gradients are produced by various pathological conditions.

The bulk of the cells within the liver, constituting about 80%, are the *hepatocytes* or *parenchymal cells*, which are derived from the endoderm of the caudal part of the foregut during embryonic development, and with which they retain their connexion through the bile ductules and hepatic ducts. Each hepatocyte is polyhedral, having five to twelve sides, and is from 12 to 25 μm across. The nucleus is spheroidal and euchromatic, often also being polyploid or present in multiples (2 or more) within each cell (Doljansky 1960). The cytoplasm typically displays copious amounts of both granular and agranular endoplasmic reticulum, high concentrations of mitochondria, lysosomes, and a well-developed Golgi complex—all features indicating a high metabolic activity. Glycogen granules and lipid vacuoles are usually prominent storage substances. Peroxisomes and vacuoles containing enzymes such as urease (uricosomes) in distinctive crystalline forms are characteristic features, reflecting the complex metabolic pathways operating in these cells. Their role in iron metabolism is seen in the common presence of iron storage vacuoles containing crystals of ferritin and of haemosiderin. Where hepatocytes adjoin bile canaliculi, microvilli are present at their surface, and numerous membrane-bound vesicles are clustered near the lumen (**8**.140A).

Hepatocytes carry out a multitude of metabolic activities. They synthesize and release into the blood various plasma proteins including albumins, clotting factors and complement components; they deaminate amino acids by means of the urea cycle pathway, liberating urea into the blood for excretion through the

urinary system; they convert bilirubin, formed by breakdown of haemoglobin, to the bile pigment biliverdin which is secreted into the biliary tract; they synthesize bile salts which are also secreted into the bile as important agents in the emulsification of fats during digestion; they eliminate many endogenous and exogenous substances from the bloodstream, and are thus important in detoxification of the blood; they convert the thyroid hormone tetra-iodothyronin to the more active tri-iodothyronin. Hepatocytes also store carbohydrates as glycogen, and tri-glycerides as lipid droplets, metabolizing these substances when required and releasing glucose and lipid into the bloodstream. Most of the lipid secreted in this way passes out of the perisinusoidal surface of the cell in secretory vesicles, having been conjugated with protein in the endoplasmic reticulum and Golgi apparatus, and forms the 'very low density lipoprotein' moiety of the blood plasma (Claude 1970). Some cholesterol is also secreted into the bile, apparently as an excretory activity. Iron is stored in the cells as ferritin.

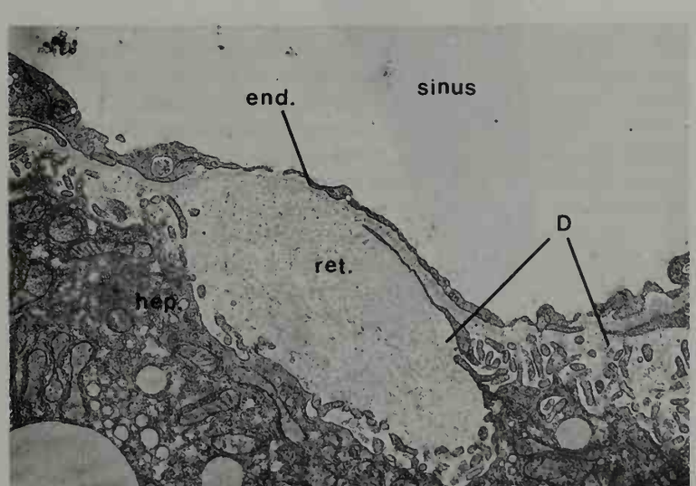


All of these metabolic processes also result in the production of heat by the liver which is therefore important in the maintenance of body temperature.

The large number of chemical activities carried out by the hepatocytes is reflected in their structural complexity, which varies according to metabolic demand. This is seen, for example in the proliferation of the agranular endoplasmic reticulum which occurs during barbiturate detoxification (Jones and Fawcett 1966), and is also observed in the effects of starvation, when glycogen and lipid reserves disappear. Also, because of their involvement in many chemical processes, hepatocytes are particularly vulnerable to anoxia, various poisons and carcinogens which cause characteristic patterns of degeneration within the portal acini.

The arrangement of hepatocytes within the liver has been the subject of some controversy. It has been customary to consider the hepatic lobule as consisting of 'cords' of liver cells radiating from a central vein, each cord consisting of two rows of liver cells, with a bile capillary between them, and radiating venous sinusoids lying between adjacent cords in such a way that the bile capillary is separated from the sinusoids by the thickness of a liver cell. More recent studies, however, indicate that the liver cells are really arranged as plates or sheets (*hepatic laminae*), *one cell thick*, which form a continuous system throughout the liver (**8**.139). These laminae form a 'wall-work' or *muralium* and are irregularly arranged, with interlaminar bridges of liver cells connecting adjacent laminae. Between the laminae lie spaces (*hepatic lacunae*) which contain the venous sinusoids, and the laminae are perforated to allow the passage of anastomoses between the sinusoids. Where the liver cells adjoin portal canals or tributaries of the hepatic vein, they form a sheet, the *limiting plate*, which surrounds the vessels and is perforated by radicles of these vessels as well as by branches of the hepatic artery and bile ductules; a similar limiting plate, consisting of a single layer of liver cells, lies beneath the capsule of the liver.

In histological sections of the liver (**8**.138A), the rows of liver cells seen radiating from the central vein to the periphery of the hepatic lobule really represent sections through the hepatic laminae. These rows of cells, with intervening sinusoids, do not pass regularly and straight like the spokes of a wheel to the periphery of the lobule, but pursue irregular courses, because the hepatic laminae themselves are irregular and branched. Some of the rows of cells (and sinusoids) pass at the periphery of the lobule between adjacent portal canals, while others pursue very indirect courses between the central vein and the portal canals.



The intralobular venous sinusoids are wider than blood capillaries and are lined by thin and highly fenestrated endothelial cells interspersed with *hepatic macrophages* also known as *stellate cells of von Kupffer* (*Kupffer cells*). The hepatic macrophages form a major part of the mononuclear phagocyte system and they are responsible for clearing much of the cellular debris and other particulate material from the circulation and for removing microbial infections, these activities being shared with the spleen and circulating leucocytes (Wisse 1970). The radicles of the portal vein contained in the portal canals give off branches, called *inlet venules*, which pass through holes in the limiting plate

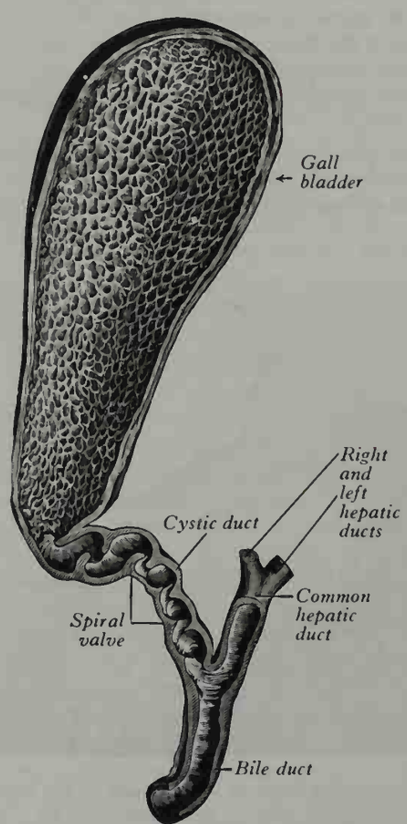
surrounding the portal canal in order to enter the hepatic lobules, where they become continuous with the sinusoids. These convey blood mainly from the interlobular branches of the portal vein (in the portal canals) to the central veins. The sinusoids lie in the hepatic lacunae between the hepatic laminae, and are separated from the liver plates by the *perisinusoidal space of Disse* (**8**.140B), which becomes distended in conditions of anoxia. Reticulin fibres are present here, and irregular microvilli of the phagocytic cells in these walls and of adacent hepatocytes also project into the space of Disse, itself continuous at the periphery of the lobule with a *space of Mall* which surrounds the vessels and bile ductules in the portal canals; and it is in the latter space that the lymph vessels of the liver commence (as in other organs) by blind ends. Very few, extremely small, lymph vessels penetrate into the periphery of the lobule. Adipocytes are also found occasionally in the space of Disse.

The *central veins* from adjacent lobules join to form *interlobular veins* and these in their turn unite to form the *hepatic veins*, which drain the blood from the liver into the inferior vena cava.



8.140B A transmission electron micrograph of the border of a hepatic sinusoid (*sinus*) showing part of an hepatocyte (*hep.*) and the tenuous fenestrated endothelium (*end.*) separated by the space of Disse (*D*) in part of which lies a reticulin bundle (ret.). Magnification × 5,000.

In the hepatic lobules, minute *bile canaliculi* (**8**.140A) form networks of polygonal meshes, each mesh surrounding an individual liver cell except on the surfaces of the cell apposed to the venous sinusoids. Individual bile canaliculi lie between the walls of the liver cells which form their borders. At the periphery of the hepatic lobules the bile canaliculi join to form extremely thin intralobular bile ductules (*terminal ductules* or *canals of Hering*) lined by cuboidal epithelium, penetrating the terminal plates to enter the interlobular hepatic ductules within the portal tracts. The intralobular ductules are distinct from other canals of the biliary tract in their structure and reactions to injury, proliferating greatly, for example, when the flow of bile is interrupted by extrahepatic obstruction (Biava 1964; Jones *et al.* 1975). The hepatic ductules in the portal canals are lined by cuboidal to columnar cells which may contain crystals of cholesterol and droplets of fat.

The relationship between the blood, the hepatocytes and the bile canaliculi is clearly seen in experiments with colloidal tracers, the diffusion barriers to which can be determined by electron microscopy. Horseradish peroxidase, for example, injected into the circulation, diffuses freely from the sinusoids through the gaps between the stellate endothelial cells, into the intercellular spaces between hepatocytes, which are held together largely by communicating junctions (p. 7). Diffusion is, however, halted at the edges of the bile canaliculi by the tight junctions which mark the boundaries of the hepatocytes here. It is inferred that blood-borne materials have free access to the hepatocyte, but that substances can only enter the bile canaliculi through the cytoplasm of the hepatocytes, which are therefore in many respects exocrine glandular cells secreting into a duct system.

The preterminal branches of the hepatic arteries, contained in the portal canals, give off branches which convey arterial blood to the liver sinusoids by a variety of routes. The chief pathway is through the system of fine capillaries which form a plexus around the interlobular hepatic ductules and ducts and drain into various branches of the hepatic portal veins, inlet venules and hepatic sinusoids. Some arterial blood also passes directly into the hepatic sinusoids without entering such capillary networks, but this appears to form only a small proportion of the total flow (Burkel 1970; Healey 1970; Jones and Spring-Mills 1977). The sinusoids therefore contain mixed venous and arterial blood which nourishes the liver cells. The composition, amount and velocity of the blood streaming at any time through any minute area of the liver may change and be adapted to the necessities of the moment by sphincteric arrangements in the inlet venules and in the branches of the hepatic arteries, and by the contractile walls of the sinusoids. Each portal triad (branches of the hepatic arteries, portal vein and bile ducts) supplies its own sharply delimited territory, and normally there are no anastomoses between these territories. On the other hand, the hepatic veins for the main part run independently of the portal veins, hepatic arteries and bile ductules, and cross the boundary lines of the territories of the liver supplied by the latter structures.

During fetal life the liver acts as one of the main haemopoietic organs, both red and white blood corpuscles being developed in the mesenchyme covering the endothelium of the sinusoids (p. 66).

1382 **8**.141 Interior of the gall bladder and bile ducts.

The Biliary Ducts and Gall Bladder

The excretory apparatus of the liver consists of: (1) the *common hepatic duct*, formed by the junction of the *right* and *left hepatic ducts* which leave the liver at the porta hepatis; (2) the *gall bladder* which serves as a reservoir for the bile; (3) the *cystic duct*, or duct of the gall bladder; (4) the *bile duct*, formed by the junction of the common hepatic and cystic ducts.
